IM-05 (3), Lecture Theater 3, august 27, 2024, 10:30 - 12:30

Background: High-resolution energy dispersive x-ray spectroscopy (HR-EDX) in STEM is a technique of choice for conducting chemical analyses of III-nitride materials quantum wells (QWs) used as UV sources [1]. When travelling through a crystalline material, the phenomenon of “cross-talk” – the interaction of the electron beam (EB) with surrounding atomic columns - can significantly affect the quantitative results. Although the phenomenon was widely studied [2], there is still a lack of experimental works showing the possibility to quantify the impact of these effects on chemical analyses. The present contribution aims to show how to correlate HR-EDX mappings with inelastic multislice simulations [3] to determine the aluminum content in such devices.
Methods: Two GaN QWs with respective widths of 1.5 and 10 nm (Figure 1a) are studied, both surrounded by Al0.1Ga0.9N barriers. Both structures are grown by plasma assisted molecular beam epitaxy (MBE), and the samples are prepared with a Ga+ focused ion beam scanning electron microscopy (FIB-SEM) based on the standard lift-out method. STEM-EDX analyses are conducted using a probe-corrected TFS Titan Themis microscope operating at 200 kV and equipped with a Super-X detector system. Spectroscopic high-resolution data are acquired through a multi-frame spectrum-imaging approach, with thousands of frames rapidly acquired at high-resolution and automatically realigned thereafter. EDX quantification analyses are conducted using the ζ factors approach [4], and considers the inhomogeneity of the sample in the x-rays absorption correction process. Finally, beam propagation and EDX intensity maps were simulated using the µSTEM software [3].
Results: Figure 1b highlights the significant difference of EDX Al K emission observed between the two structures studied, when the probe is positioned at the middle of the respective QWs. The simulation of the probe propagation (Figure 1c) reveals that, for the 1.5 nm width layer, the electron wave is quickly delocalized into the adjacent barriers even for thin samples (~30 nm), explaining the disparity in intensity measured between the two structures. Quantification of this signal using the ζ factor method [4] estimates the Al content inside the 1.5 nm width QW around 1 at.%, significantly impacting the structure’s band properties. To understand the effect of such beam broadening on EDX quantification, we compare the experimental results with a simulated HR-EDX profile of Al K obtained from a given theoretical structure (Figure 1d). The chemical properties of this hypothetical structure, considering interfaces chemical gradient and well aluminum content, were adjusted until achieving optimal agreement between experimental and simulated profiles (Figure 1e). If a significant chemical gradient at the interfaces is confirmed, the results reveal that most of the Al K emission detected within the QW can be attributed by the propagation of EB in the surrounding layers.
Conclusion: This study aims to present a clear methodology to detect the effect of beam broadening on HR-EDX quantitative analyses. The demonstration is done on a regular heterostructure and conventionally (FIB) prepared sample, showcasing its potential application on various systems. In this presentation, we will particularly focus on which conditions this comparison between experimental data and simulations can be carried out to quantitatively detect these slight changes in chemical

compositions at high spatial resolution. This work, performed on the Platform for NanoCharacterisation (PFNC) of CEA, was supported by the “Recherche Technologique de Base” Program of the French Ministry of Research.

Structural remodeling of neural circuits through synthetic biological control of neuron-astrocyte interactions

Gyu Hyun Kim[1,2], Mrs. Shin Heun Kim[3], Ms. Sangkyu Lee[3], Ms. Kea Joo Lee[1]
[1]Korea Brain Research Institute, Dong-gu, Republic of Korea, [2]Korea University, Seongbuk-gu, Republic of Korea, [3]Institute for Basic Science, Yuseong-gu, Republic of Korea

LS-04 (2), Lecture Theater 4, august 29, 2024, 14:00 - 16:00

Background incl. aims
In the adult hippocampus, synaptic plasticity is essential for information processing, learning, and memory formation. Astrocytes, the most common type of glial cells, play pivotal roles in synapse formation, maintenance, and elimination. However, our understanding and manipulation of complex interactions between neurons and astrocytes are just the beginning.
Methods
Here, we present a synthetic approach for synapse elimination via engineering of direct neuro-glial interactions which result in the uptake of synaptic components by astrocytes. Trogocytosis is a process in which a cell takes up a portion of another cell's membrane and internalizes it. Induced synthetic trogocytosis, the uptake of ligand-labeled membrane fragments by receptor-expressing cells, has the property of unidirectional molecular transfer. We assessed potential structural changes induced by engineered neuron-astrocyte interactions using 3D correlative light and electron microscopy (CLEM) and array tomograhy.
Results
Our results provided clear evidence for the partial capture and elimination of presynaptic boutons and axons in ligand-expressing CA3 neurons by receptor-expressing astrocytes in the CA1 area. Notably, astrocytes mainly engulfed partial axonal debris or small vesicles at the initial stage of viral expression, while they later swallowed up larger presynaptic materials including mitochondria.
Conclusion
This approach will provide an insight into how the brain adaptively shapes neural circuits upon synapse elimination and offer a versatile means to structurally modulate cell-cell connections.

EBSD analysis of twin boundaries of prismatic calcite in oyster shells

Dr Katarzyna Berent[1], Prof. Kinga Nalepka[2], Prof. Antonio Checa[3,4]
[1]AGH University of Krakow, Academic Centre for Materials and Nanotechnology, Krakow, Poland, [2]AGH University of Krakow, Department of Strength and Fatigue of Materials and Structures, Krakow, Poland, [3]Universidad de Granada, Departamento de Estratigrafía y Paleontología, Granada, Spain, [4]CSIC-Universidad de Granada, Instituto Andaluz de Ciencias de la Tierra, Armilla, Spain

Poster Group 2

Oyster shells are biocomposites consisting of calcium carbonate crystals with a percentage of organic matrix. The organic fraction in these shells plays a crucial role in stress distribution control, leading to a hierarchical structure with high self-organization and low internal energy. This microstructure, with its unique combination of high strength and fracture toughness, holds significant potential for the development of advanced biomimetic materials.
We studied two specimens from the order Ostreida, Pinna nobilis Linnaeus, 1758 (Mollusca, Ostreida, Pinnidae), which comes from the Mediterranean Sea, and Pteria penguin Röding, 1798 (Mollusca, Ostreida, Pterioidea) collected in Lapu Lapu, Cebu, Philippines. The electron backscatter diffraction (EBSD) technique was used to study the crystallographic relations observed between prisms in a columnar calcite prismatic (CCP) layer. EBSD analysis was performed using a FEI Versa 3D FEG scanning electron microscope (SEM) equipped with an Oxford Instruments Symmetry S2 CMOS-based EBSD detector. EBSD data were collected using Aztec 6.1 software from the polished cross-section. The system was operated in low vacuum (LV-SEM) mode at a pressure of 40 Pa and an accelerating voltage of 15 kV.
The obliquely oriented calcite prismatic grains to the predicted load's direction are observed in P. nobilis. EBSD results show that strictly defined low-energy boundaries, i.e. rotation angles, are preferred. The disorientation described by the 60° rotation about the c-axis is mainly observed. Two symmetrically equivalent orientation relationships correspond to it, and one of them is observed in this case. The twin boundary (0 1 -1 0) is present, positioned perpendicular to the growth line, enabling the prisms to curve. The other preferred disorientations are also generated by twin relationships, with mirror planes characterized by higher indices: (1 -5 4 0) for 38° and (4 7 -11 0) for 18°. These new, previously unknown orientation relationships are common in P. nobilis shells. The shell is ornamented with radial ribs that strengthen it while giving it the flexibility needed to tighten its seal against predators. The growth lines become flatter in the area outside the ribs with the shell thickening, which affects the change in the direction of the c-axis, which becomes more parallel to the normal direction (ND). Such a microstructure improves hardness and compressive strength, which reaches an outstanding value of 700 MPa. In the case of P. penguin, EBSD was combined with theoretical boundary energy analysis using the Gautam-Howe method, which revealed that prisms as basic structural units show good mutual fitting and a sequence of twins arising within them is used to relax internal stresses. Consequently, a low-energy structure with an exceptionally high compressive strength of 600 MPa is achieved.

An analytical ion microscope for high-resolution imaging, nanoscale analytics and nanofabrication

Peter Gnauck[1], Torsten Richter[1], Alexander Ost[1]
[1]Raith GmbH, Dortmund, Germany

Poster Group 1

The Liquid Metal Alloy Ion Source (LMAIS) has been described as a high-impact technology offering new insights into the structure and function of nanomaterials [1]. Combining the high brightness of a Liquid Metal Ion Source (LMIS) with the capability of emitting light and heavy ions such as Silicon and Gold or Lithium and Bismuth simultaneously makes the LMAIS the ideal ion source for high-resolution imaging, nanofabrication, and nano-analytics (Fig. 1) [2]. The ion species are emitted simultaneously from a single source and separated in a downstream Wien filter. This mature source technology allows for high-resolution Secondary Electron (SE) imaging with exceptional surface details by using light primary ions as well as adjusting the required sputter yield and resolution for nanofabrication and sample modification by selecting the most suitable ion species from the LMAIS.
With a top-down FIB geometry and capability of fast ion toggling a novel workflow for 3D sample reconstruction with sample tilt becomes possible: heavy ions have an excellent depth resolution for sample delayering. The selection of various beam paths or looping strategies as known from many applications in nanofabrication minimize selective sputtering and redeposition while digging into the sample.
Intermittent imaging with light ions prevents further sputtering and allows 2D sample imaging for mapping the region of interest layer by layer. Obtained ion images are then stacked for 3D sample reconstruction [2].

By adding a specifically designed compact magnetic sector mass spectrometer, the ion microscope becomes a high-resolution analytical instrument [3].
Secondary Ion Mass Spectrometry (SIMS) is a robust and highly sensitive surface analysis method capable of detecting all elements ranging from hydrogen to uranium. It offers trace element identification, differentiation of isotopes, elemental imaging at the nanoscale, shallow depth profiling, and three-dimensional analysis.
By selecting the most suitable ion species from the LMAIS the SIMS system takes advantage of the LMAIS technology by selecting the most suitable primary ion species for the analysis.
The SIMS system is based on:
(i) specifically designed secondary ion extraction and transfer optics for highest extraction efficiency and transmission, resulting in excellent sensitivity.
(ii) a compact floating double focusing magnetic sector mass spectrometer allowing operation in the DC mode at high transmission and hence avoiding secondary ion losses due to duty cycles like in TOF systems.
(iii) a focal plane detection system allowing the detection of all masses in parallel (up to 400 m/z).

This contribution outlines the working principles and features of the focal plane magnetic SIMS detector combined with a LMAIS. By combining LMAIS technology with a stable stage and sensitive SIMS unit, this system offers a pathway for advanced nano-analytics, surpassing conventional methodologies for sample analysis.

Poster Group 2

Aims: Benzofuran and tetrahydrodipyrazolopyridine are heterocyclic compounds with diverse biological activities. Benzofuran derivatives have potent anticancer, antiviral, and antimicrobial properties [1]. Tetrahydrodipyrazolopyridines are used in various pharmaceuticals and exhibit anticancer, antiallergic, and antiherpetic properties [2, 3]. The hybridization of these two molecular frameworks presents an innovative approach to crafting novel compounds with significant biological activity. Lung cancer is one of the most common types of cancer worldwide and is a serious health problem affecting both men and women. Although current lung cancer treatment methods are effective against certain types of the disease, many patients may develop resistance or develop side effects. Therefore, the discovery and development of new molecules that are more effective, have fewer side effects and can prevent the development of resistance is an important need in lung cancer treatment [4].
Methods: In this study, benzofuran-tetrahydrodipyrazolopyridine hybrids were successfully synthesized with high efficiency via a room-temperature condensation reaction. The synthesis involved the benzofuran derivatives with an aldehyde functional group, ethyl acetoacetate, hydrazine, and ammonium acetate. The biological activity of the new molecules synthesized within the scope of the study was obtained by MTT test on A549 lung adenocarcinoma cells.
Results and Conclusions: The resulting hybrids were characterized using proton (1H) and carbon (13C) nuclear magnetic resonance (NMR) spectroscopy, which confirmed their structure and purity. As a result of the Mtt test, the IC50 values for the molecule coded DB-1 were determined as 5.26µm for 24 hours at the lowest concentration, while the 24 hour value for the other molecule coded DB-2 was determined as 15.58µm.

[2]International School of Materials Science and Engineering, Wuhan University of Technology, Wuhan, China

Poster Group 2

Room-temperature liquid metals (LMs) with high conductivity and deformability have received considerable attention in soft and stretchable electronics [1]. In recent years, there has been extraordinary progress in the fabrication of LM-based elastic circuits such as embedding LM particles in an elastomer, mixing LMPs with a solid conductive filler composite, doping LMPs in a polymer matrix, etc. [2]. The formation and separation of liquid bridges between LM particles correspond directly to the connection and disconnection processes of these components, respectively. Hence, unveiling the kinetics of liquid bridge formation and evolution is crucial for achieving controllable design of stretchable LM-based conductors in the assembly of electronic components, thus propelling the development of electronics with enhanced flexibility and adaptability.
Herein, we employed in-situ transmission electron microscopy (TEM) techniques to systematically investigate the wetting behavior between Gallium (Ga), a typical liquid metal, and various substrates, as well as the influence of surface Ga oxide layer thickness on the evolution of Ga liquid bridge formation. As a demonstration, Figure 1 illustrates the dynamic evolution process of Ga liquid bridges on Mo substrates. Our findings indicate that the presence of a thin oxide layer promotes the fluidity of gallium, thereby facilitating the formation of liquid bridges, with their evolution being influenced by interfacial wettability dynamics. Moreover, a delicate equilibrium between viscoelasticity and surface tension emerges with a slight increase in the thickness of the surface oxide layer, resulting in the formation of super-stretched liquid bridges. In contrast, an excessive thickness of the oxide layer constrains the formation of liquid bridges due to its high viscoelasticity.

Organisms develop within the physical context of their external environment. Molecular signals and physical properties or constraints provide external conditions with which the developing organism interacts and to which it responds. This dynamic reciprocal interaction results in and is required for morphogenesis and self-organization. Thus, a mechanistic understanding of emergent tissue-scale phenomena, such as tissue shape and patterning, require spatial quantification methods that can link single-cell properties and interactions to tissue-scale measurements. To address this need for a multiscale spatial analysis method, we developed scMultiplex, a bioimage analysis method that combines spinning disk confocal fluorescence microscopy, machine learning, parallelized image processing, and optimized imaging and staining protocols to quantify whole tissue shape, cell composition, and molecular expression in 3D. We use mouse small intestinal organoid development as a model multicellular system that self-organizes from a single cell into a complex 1,000+ cell structure. Specifically, the full single-cell composition of the fixed organoid is imaged and segmented in 3D, with molecular expression, cell type markers, and cell states identified with immunostaining. Cells are spatially linked across iterative rounds of staining and imaging to achieve multiplexing of ~10-20 protein markers. Organoid tissue shape features are also extracted from a reconstructed surface mesh using a machine learning approach. We thus apply scMultiplex to thousands of organoids to link cell type composition and spatial arrangement to tissue shape emergence and uncover mechanisms of intestinal morphogenesis. This approach can be applied to diverse multicellular systems to address fundamental questions in developmental and systems biology on emergence of higher-level organization from single-cell behavior.

Achieving methanol photo-oxidation to hydrogen and formaldehyde over lead-free halide perovskite

Mr Zhiyang Zhong[1,2], Prof Shik Chi Edman Tsang[2], Prof Angus Kirkland[1,3]
[1]Department of Materials, University of Oxford, Oxford, UK, [2]Department of Chemistry, University of Oxford, Oxford, UK, [3]Rosalind Franklin Institute, Harwell Campus, Didcot, UK

Poster Group 2

Background
Hydrogen can be a source of clean energy, but its production heavily relies on fossil fuels [1]. Methanol can be a good storage vessel for hydrogen, as each molecule contains four hydrogen atoms. Industrially, methanol can be decomposed into H_2, CO and/or CO_2, but high temperature and pressure are required [2]. Alternatively, at milder conditions such as room temperature photo-oxidation, it can be split into hydrogen and formaldehyde, but a suitable catalyst is required. In this research project, I have been studying $Cs_2AgBiBr_6$ (CABB) as a type of lead-free halide perovskite photocatalyst, which has been found to possess the ability to dehydrogenate methanol to acquire H_2. Multiple electron microscopy techniques have been used to examine the structures of CABB before and after reactions. As CABB degrades in methanol easily, the aims of this project are to keep the structure of CABB stable in the reactions, and to enhance hydrogen production rates.
Methods
Synthesis of bulk CABB: CsBr, AgBr and $BiBr_3$ were mixed with HBr, heated to 110°C, and kept for 2 hours. After cooling, CABB was collected by using centrifuge and dried in vacuum oven.
Synthesis of CABB nanocubes [3]: Cesium acetate, bismuth acetate and silver acetate were dissolved in oleylamine, oleic acid and 1-octadecene. The mixture was heated under vacuum, and then filled with argon at a higher temperature, where bromotrimethylsilane was rapidly injected. Next, the mixture was quenched in water bath, centrifuged and dried.
Synthesis of CABB nanosheets [4]: Cs_2CO_3 was dissolved in oleic acid by heating in vacuum followed by argon to prepare Cs-oleate. Separately, $BiBr_3$, $AgNO_3$, octadecene, HBr, oleic acid, oleylamine were mixed and heated in vacuum. The mixture was cooled to room temperature, and Cs-oleate solution was injected into the mixture. After that, the mixture was then heated in argon. Finally it was quenched in water bath, centrifuged and dried.
Photocatalytic tests: For reactions in liquid methanol, CABB was put into liquid methanol with or without bromide additives, and irradiated with 300W Xe lamp. For reactions in gaseous methanol, CABB was placed in the reactor but not in direct contact with liquid methanol, and irradiated with 300W Xe lamp.
Characterisations: Quantification of hydrogen was performed on Agilent 7890B Gas Chromatograph. Powder X-Ray (XRD) data were collected by Bruker D8 Advance Eco, using Cu Kα1,2 as source. Transmission electron microscope (TEM) images were obtained on a JEOL JEM-2100 at 200kV. Scanning transmission electron microscope (STEM) images were obtained using JEOL ARM-200F operated at 200kV.
Results
Without additional support, all three forms of CABB (bulk, nanocubes, nanosheets) degrade quickly in methanol. Adding bromide additives allows bulk CABB to remain stable during the photoreaction, and it showed an overall H_2 production rate of 167 µmol h-1 g-1. However, for nanosize CABB the protection given by bromide additives turned out to be inadequate, and CABB still degraded during

the photoreaction. The H_2 generation rates were 76 µmol h-1 g-1 for CABB nanocubes, and 74 µmol h-1 g-1 for nanosheets. STEM images clearly showed their change in structures after reaction. Reaction with methanol vapour is another approach to keep CABB stable in the photoreaction, without the need of bromide additives. XRD results demonstrated that the structure of bulk CABB was retained during the reaction. An overall H_2 generation rate of 524 µmol h-1 g-1 was achieved. Nanosize CABB will be tested and characterised using this method soon.

Conclusion

Both bromide additive method and methanol vapour method could prevent the structural degradation of halide perovskite CABB, and the results showed that photo-oxidation of methanol using CABB as photocatalyst is feasible. However, both methods has been proved to be useful on bulk CABB only, while for CABB nanocubes and nanosheets more research is needed.

In-situ TEM ion irradiation studies of layered MAX phase materials

Mrs Eman Al Ruqeishi[1], Max Rigby-Bell[2], Graeme Greaves[3], Alexander Eggeman[1], Sarah Haigh[1]
[1]University of Manchester, Manchester, United Kingdom, [2]UK Atomic Energy Authority, Abingdon, United Kingdom, [3]University of Huddersfield, Huddersfield, United Kingdom

PS-12, Lecture Theater 2, august 29, 2024, 10:30 - 12:30

Materials in the core of a nuclear reactor are exposed to severe environments, particularly in future Generation IV nuclear systems, which perform in environments with high temperatures and high fluxes of fast neutrons, causing hundreds of displacements per atom (dpa) as well as substantial helium (He) doping by nuclear transmutation. MAX phases have attracted attention for their potential in nuclear materials due to their demonstration of high stabilities [1]. This study investigates the impact of sequential irradiation with light and heavy ion irradiation of MAX phases, specifically comparing the irradiation induced changes in Ti_3SiC_2 and Ti_3AlC_2. Cross sections of both MAX phases were prepared using focused ion beam milling. These were irradiated inside the MIAMI transmission electron microscopy (TEM), in situ TEM irradiation facility [2], first with 75 keV He+ ions at a dose of 2.6 x 10^{16} ions/cm² up to 3 dpa, and then with 600 keV Ar^2+ ions with a total fluence of 9.2 x 10^{16} ions/cm² up to 50 dpa, at both room temperature and 350°C. TEM imaging and diffraction are used during in-situ ion irradiation for direct observation of the microstructural and unit cell evolution. In-situ TEM observations indicate that both materials retained their crystal structures for the full irradiation dose. There was no observation of significant amorphization, phase transformations, He bubbles, or decomposition. The helium irradiation-induced damage, manifested as point defects, increases with damage level (dpa), resulting in anisotropic changes in lattice parameters in both structures up to ~ 9% and at both room temperature and irradiated temperatures. Interestingly, a significant recovery towards the as-synthesized unit cell parameters was observed post-irradiation within a few days of ambient storage at room temperature. Subsequent irradiation then followed similar irradiation damage profiles as the original pristine MAX phase with lattice parameter changes up to ~ 8% without significant amorphization, followed by another room temperature structural recovery when the irradiation is stopped. This observation of exceptional irradiation stability combined with room temperature recovery provides new evidence of the potential of MAX phases in protective coatings for nuclear applications and for radiation sensing and detection.

Nanoscale tribology of hair fibres over large displacements

Dr James Bowen[1]
[1]The Open University, Milton Keynes, UK

IM-09, Lecture Theater 5, august 29, 2024, 14:00 - 16:00

Background incl. aims
Hair is a protein-based, filament-like biomaterial that grows from follicles beneath the surface of the skin. The evolution, structure and function of human hair is of great interest to anatomists and anthropologists, and the use of hair for social and cultural functions is well established. There have been many scientific studies regarding hair structure, the physicochemical properties of the hair cuticle surface, and hair damage mechanisms. Atomic force microscopy has played a crucial role for studies of friction and conditioners applied to single hair fibres.
Methods
This work reports the development of a method for measuring the tribological properties of two orthogonally crossed cylinders over a 2 mm displacement with nanoscale precision in loads and displacement. Specifically, a human hair fibre was used as the lower cylinder, while the upper cylinder was a 0.5 mm section of 75 µm diameter tungsten wire. Measurements were performed at a sliding velocity of 20 µm/s, the compressive normal load between the cylinders was 600 nN, and data were recorded every 2 nm.
Results
Topography and lateral load were recorded throughout the bidirectional measurement, with differential friction observed upon comparison of the ‘with cuticle’ and ‘against cuticle’ sliding directions (Fig. 1). To assess the influence of sliding velocity on the frictional behaviour a sequence of increasing velocities in the range 0.01-1.0 mm/s was programmed; the total displacement of this measurement covered 5 mm.
Conclusion
The mean friction coefficient did not vary significantly with sliding velocity, although occasional high lateral loads were observed at velocities in excess of 0.1 mm/s.

Manufacture and calibration of high stiffness AFM cantilevers

Dr James Bowen[1], Dr David Cheneler, Dr James Vicary
[1]The Open University, Milton Keynes, UK

Poster Group 2

Background incl. aims
Atomic force microscopy (AFM) employs microfabricated cantilevers as sensing elements, which are used to measure surface topography and interaction forces. The flexible free end of a cantilever often presents either a pyramidal tip or a colloid probe particle. Force-displacement measurements have been applied to a wide variety of scientific and engineering disciplines, and across many industrial sectors. For many studies, the use of colloid probes or chemical functionalisation permits the selective study of a particular material/material interaction, often under non-ambient environments. Force-displacement measurements can provide information regarding sample mechanical properties, during tip/sample approach and contact, as well as adhesive properties, during the tip/sample separation. The spring constant is a measure of the cantilever stiffness, i.e. the resistance to bending. The spring constant of a rectangular cantilever can be estimated using Euler-Bernoulli beam theory. Once calibrated, the spring constant is used to convert normal (i.e. vertical) deflections into normal forces using Hooke's law.
Methods
The range of AFM cantilevers commercially manufactured means that spring constants in the approximate range 0.001 to 100 N/m are available. Deflections in the range 0.1-100 nm are typically measurable on the PSD, and hence forces can be measured in the picoNewton to microNewton range. Accurate control of the beam thickness during fabrication is particularly difficult to achieve, due to the nature of the etching process employed. The width and length of the beam are generally much more reliable and repeatable. Given the sensitivity of the spring constant to the beam thickness, typically proportional to the (thickness) cubed, accurate calibration is a necessity for accurate force-displacement measurements.
Results
We are currently calibrating 40 different designs of rectangular AFM cantilever, designed using Timoshenko beam theory, manufactured from Si. The various designs incorporate a range of widths, lengths, and thicknesses. These cantilevers are expected to exhibit spring constants in the range 100 to 10,000 N/m. This would afford researchers the opportunity to perform adhesion, indentation, and tribological testing with normal loads approaching 1 mN, whilst retaining the displacement resolution of the AFM.
Conclusion
We present the latest results of this project, including measured cantilever resonant frequencies and calculated spring constants, which are compared to analytic expressions and finite element models.

Solvent-induced softening of polymethyl methacrylate surfaces

Dr James Bowen[1], Dr Simon Collinson
[1]The Open University, Milton Keynes, UK

Poster Group 2

Background incl. aims
Exposing plastics to solvents is known to alter their surface and sub-surface properties, depending on the extent and duration of exposure. Amorphous plastics are prone to penetration and diffusion by low molecular mass solvents, leading to physical deformation including swelling, cracking, and dissolution. Unwanted or unexpected solid/liquid interactions can irretrievably compromise the visual characteristics of an object were it to be cleaned using an inappropriate method. This is of particular importance to the heritage and conservation sector, who use solvent-based cleaning systems to preserve the appearance of culturally-important artworks over many decades. There is increasing interest in the applicability of nanocharacterisation techniques to inform remedial conservation strategies for plastic artworks, supporting the preservation of the original intent of the artists and designers.
Methods
Polymethyl methacrylate (PMMA) is an important plastic in modern art and design collections, having been used since the mid-20th Century for creating artworks but also aircraft cockpit hoods, automotive and architectural lighting, and even windows on deep-sea submersibles. According to Hildebrand solubility theory, PMMA does not dissolve in aliphatic alcohols such as ethanol.
Results
We report that nanomechanical mapping of PMMA surfaces exposed to liquid ethanol experienced a decrease in elastic modulus according to an approximately exponential relationship. Further, interrogated regions of the surface were observed to have their mechanical properties altered because of the compressive load applied during the measurement process (Fig. 1).
Conclusion
These findings, which are of use to heritage and conservation scientists, also suggest opportunities for developing novel micro- and nanofabrication strategies, whereby a surface which has been temporarily and reversibly softened can be manipulated topographically, for example using nanolithography, nanoscratching, or nanoindentation.

Background and Aim
Metallic NPs are widely used as a catalyst, in heterogeneous catalysis, with high reactivity and selectivity [1]. Ni/NiO nanoparticles (NPs) have attracted significant research attention as catalysts due to their low cost and wide applications that includes, CO oxidation, oxygen evolution, photocatalysis and water-gas shift reaction [2, 3]. Many catalytic reactions require the oxidation and reduction of metal/metal oxides where the dynamic interaction between catalyst and gas proceeds via intermediate products and adsorbed species to form a solid-gas interface. Atomic changes at this interface are linked directly to the catalytic processes [4]. This involves morphology changes, oxide formation, surface facets modification, as well as surface reconstruction. These dynamic structural changes play an important role in the catalytic activity of the NPs. Therefore, tracking these structural changes at the atomic scale under the reaction conditions is vital for the identification of intermediate structures and ultimately understanding the reaction mechanisms. Open-cell Environmental TEM/STEM (E(S)TEM) has the capability for in-situ studies of gas-solid reactions by allowing gases in the sample area without the need of special sample holders [5]. In this work we employed aberration-corrected E(S)TEM to investigate the evolution of NiO NP surfaces during reduction in vacuum and H2 environments and subsequent oxidation of Ni metal pristine surfaces in O2, H2O and CO2 + H2O vapour environments.
Method
Two types of Ni samples were investigated: thin films grown by Molecular Beam Epitaxy (MBE) and NPs synthetized by chemical methods. The MBE Ni films, 2 nm in thickness, were directly grown onto SiN membranes of heating MEMS chips (DENSsolutions) and afterwards exposed to air. Similarly, Ni NPs dispersed in ethanol were prepared for in-situ experiments by drop cast deposition of 5µl solution of NPs onto the chips membranes. DENSsolutions Wildfire MEMS heating system was used to form metallic NPs by annealing in vacuum and 1Pa H2 atmosphere. A set of samples were heated gradually (10°C per minute) from RT to 500°C to track the particles formation/evolution. To minimise beam exposure, TEM images and diffraction patterns were only acquired at every 100°C interval. For another set of samples, live movies were acquired during the reduction under 1Pa H2. In both cases, once obtained pristine metallic surfaces, the oxidation process under O2, H2O and CO2 + H2O vapor environments was followed by video recording (5fps) using OneView Camera.
Results
MBE thin films after exposure to air showed a partial natural oxidation. Time series HRTEM imaging and selected area electron diffraction showed NPs formation and full reduction to Ni metal at 300°C following by an increase of crystallinity at higher temperatures in both vacuum and 1 Pa H2

environments. Chemically grown Ni NPs showed a thin NiO shell (Figure 1a), fully reduced at 400°C under 1Pa H2 (Figure 1b). Video recording revealed NP migration and coalescence followed by facets formations and surface reconstruction to eventually gain clean metallic surfaces. Furthermore, introducing oxidising environment (1Pa O2 gas at 400°C) lead to an initial epitaxial oxide growth followed after1.8s by the growth of polycrystalline NiO grains. After 1hr of exposure to O2 the reaction ends with fully formed NiO Kirkendall voids structures (Figure1 c,d). In addition, subsurface atomic oxide layers dynamics were captured and oxidation rates along two main crystallographic direction [111], [200] were measured of (14.6 ±1.8 planes/s) and (11.2 ±1.2 planes/s) respectively with a combined total of 1.7±0.1 nm/s. This higher value than the rate reported in literature (0.5nm/s) [6] could be due to the continuum exposure to the electron beam that accelerate the reaction. Moreover, a comparison of oxidation of Ni NPs under water vapour vs water vapour plus CO2 shows that in both cases nanoparticles tend to coalesce and form irregular 2D clusters of few NiO NPs, however only in the case of CO2 and water vapour gas condition faceted surfaces are formed.

Conclusion

In this study, open-cell environmental TEM was used to investigate Ni/NiO thin films and nanoparticles reduction and oxidation under different environmental conditions (vacuum, H2, O2, H2O and H2O +CO2) from room temperature to 500°C.

The NPs formation and reduction were followed by time series HRTEM imaging and selected area electron diffraction with intermittent beam exposure to reduce beam driven effects until the formation of single crystal Ni nanoparticles with pristine metallic surfaces.

In addition, the dynamic behaviour of such surfaces formation and evolution was successfully followed by live video recording to determine the reduction and oxidation mechanism, rates, facets formation and interaction.

Crystalline analysis by W-SEM using a newly developed EBSD detector

Dr. Yohei Kojima[1], Yuta Matsumoto[1], Daniel Goran[2], John Gilbert[2], Naoki Kikuchi[1]
[1]JEOL, Ltd., 3-1-2, Musashino, Akishima, Japan, [2]Bruker Nano GmbH, Am Studio 2D, Germany

Poster Group 1

Background incl. aims
Understanding crystalline properties of material is essential for controlling its physical characteristics. EBSD method in SEM (SEM-EBSD) is a well-established technique for investigating the phase orientation and identification of single or polycrystalline materials. It is commonly used to determine crystalline properties in micro and nanotextures [1]. The development of SEM-EBSD significantly contributes to the analysis of microstructure, crystallography and physical properties in various fields, including materials science and mineralogy, such as metals, ceramics, and minerals. Thus, the SEM-EBSD method is widely recognized as a requisite tool in these fields now.
To obtain high-quality EBSD measurement results, large probe currents ranging from several 10 to 100 nA are generally required. Therefore, the SEM equipped with a Schottky-type field emission gun (FE-SEM) has been basically employed for EBSD measurements due to its ability to maintain high resolution even when large probe currents are applied. On the other hand, the crystal grains to be measured by EBSD are usually a few to several 10 of micrometers in size, which falls within the measurable range of the SEM with Tungsten thermal filament (W-SEM). However, there are few cases where W-SEM is installed together with the EBSD detector in laboratory, because the spatial resolution of Tungsten filament gun when using a large probe current is significantly inferior to that of field-emission guns [2].
Recently, CMOS has increasingly replaced CCD as the image sensor in EBSD detectors. This shift has made it possible to obtain fast and clear EBSD patterns with less probe current, resulting in more practical EBSD measurement by W-SEM. Here, we present a new EBSD detector from Bruker (e-Flash XS) in combination with JEOL's entry-level W-SEM. Although the body of e-Flash XS is significantly smaller than the conventional EBSD detectors, its CMOS image sensor provides high-definition EBSD patterns even at a small beam current, enabling fast analysis. The EDS detector is also included in this system, called ED-XS, which allows an elemental analysis during the EBSD measurement simultaneously. This report presents an overview of the e-Flash XS with ED-XS system and one of its applications.
Methods
The ED-XS system including an EDS (XFlash 630; Bruker Nano GmbH) and an EBSD detector (e-Flash XS; Bruker Nano GmbH) is installed on the entry model W-SEM, JSM-IT200 (JEOL, Ltd.). Details are described in the following "Results" section. Cross section of zirconia ceramic made with Cross Section Polisher (IP-19520CCP; JEOL, Ltd.) was used as a specimen. The crystal structure of cubic zirconia (ZrO_2, Fm-3m, No. 225) was used for EBSD pattern analysis. The acquisition parameters were an acceleration voltage of 20 kV, a probe current of 15 nA, a working distance (WD) of 7 mm, and a chamber vacuum of 10 Pa.
Results
Graphic (a) displays an external view of the complete ED-XS system with JSM-IT200. Simultaneous acquisition of EDS and EBSD is possible because the detectors are located in the same direction. The phosphor screen inside the sample chamber can be manually attached and detached. A specimen to be measured is mounted on a pin-type stub and placed in a designated holder with

the specimen surface tilted at 70 degrees. This holder allows high-resolution EBSD measurements with a short WD of less than 15 mm (minimum 6 mm) without tilting the stage.

The pattern quality map of the zirconia ceramic obtained by e-Flash XS is shown in graphic (b) at a magnification of 5,000. Although this ceramic is the non-conductive material, EBSD measurements can still be performed without a conductive coating using the low-vacuum feature. The pattern quality map reflects the shape of the grains and their boundaries based on the clarity value of the Kikuchi pattern image. Then, the crystal grain size of the zirconia ceramic measured in this study was found to be approximately 2-3 µm for the largest ones and several 100 nms for the smallest ones. Additionally, inverse pole figure (IPF) map indicates that the orientation of the individual grains are random, while kernel average misorientation (KAM) map demonstrates that there is little local plastic deformation in the ceramic. Moreover, simultaneous EDS elemental map revealed that Zr and O were mainly present thoughout the measurement area, with small amounts of Y and Hf also detected. No segregation of other elements was observed, indicating the absence of foreign materials.

Conclusion

In this report, we present a new EBSD detector e-Flash XS and ED-XS integrated system designed for the compact model of W-SEM. As described, this small detector can measure the properties of crystal grains as small as several 100 nm, even under low-vacuum conditions using W-SEM. Electron channeling contrast images are generally used for measuring crystal grains. However, it is important to note that the contrast of these images can be affected by changes in the acceleration voltage or angle of incidence of the electron beam. On the other hand, crystal grain measurement via EBSD can be performed independently for acceleration voltage and angle of incidence. In addition, it is possible to analyze distortion and deformation resulting from differences in crystallographic orientation. This system is optimal for all SEM users, especially W-SEM users, to enhance their crystallographic analysis.

Poster Group 2

2D materials have attracted scientific research for decades, since they posses distinct physico-chemical properties compared to their 3D counterparts due to quantum confinement. These atomically thin structures such as graphene, hBN, etc. are typically based on so-called van der Waals systems. These 3D counterparts are defined by strong bonds oriented in-plane and solely weak bonding interaction between the layers.

However, 2D materials can also be created from a parent material with strong bonding interactions in all three directions. For these, it is significantly more complicated to cleave them into individual layers. After cleavage into atomically thin layer, the non-van der Waals 2D materials could offer a playground to explore the changes in properties induced by dimensionality restriction. Recently, a new member of these non-van der Waals 2D materials has been introduced: hematene, the 2D form of α-Fe_2O_3 [1].

The dimensional confinement of hematene structure is expected to introduce intrinsic strain to the lattice. This distortion of interatomic positions affects electronic configuration and therefore the magnetic, electronic and optical behavior of the system [2]. Here, we employ transmission electron microscopy and selected area electron diffraction to investigate the atomic structure and distortions of the lattice in thin hematene sheets with the aim to quantify the intrinsic strain to facilitate the physical description of the material.

With the increasing popularity of cryo-electron tomography (cryo-ET) in recent years, the quest to establish a method for growing primary neurons directly on electron microscopy grids (EM grids) has been ongoing. Here we describe a straightforward way to establish a mature neuronal network on EM grids, which includes formation of synaptic contacts. These synapses were thin enough to allow for direct visualization of small filaments such as SNARE proteins tethering the synaptic vesicle (SV) to the active zone plasma membrane on a Titan Krios without prior focused ion-beam milling.

Microstructure and thermal stability of ultrafine-grained CuZn5 processed by HPT

Yuting Dai[1,2], M.Sc. Marcel Sos[2], Prof. Christian Kübel[1,2]
[1]Institute of Nanotechnology, Karlsruhe Institute of Technology, Karlsruhe, Germany, [2]Department of Materials and Earth Sciences, Technical University Darmstadt, Darmstadt, Germany

Poster Group 2

Background and aims:
High-pressure torsion (HPT) is widely known as an effective method for severe plastic deformation (SPD). This intense shear strain, combined with high pressure, not only results in notable grain refinement but also introduces a substantial density of dislocations, thereby enhancing mechanical strength [1].
Concurrently, ensuring the stability of ultrafine-grained (UFG) microstructures is crucial for their reliable performance in practical applications. Grain growth can compromise the enhanced strength of UFG materials, highlighting the importance of investigating microstructural stability for their commercial feasibility [2].
This concern is particularly notable in certain pure metals with low stacking fault energy such as fcc metals. In order to avoid grain growth, the grain boundary (GB) migration has to be limited. This can be done through the segregation of solute elements, which depends on the GB character. In this work, we use copper (Cu) as bulk material and add different amounts of Zn to examine the impact of varying Zn content on microstructural changes and thermal stability of GBs after HPT processing at room temperature.

Methods:
CuZn5 solid solutions were processed using HPT with a pressure of 4.5 GPa. The thermal behaviors of these materials were studied using differential scanning calorimetry (DSC). Scanning transmission electron microscopy (TEM) in combination with energy dispersive X-ray spectroscopy (EDX) was used to investigate the microstructure and composition of Cu-5at.%Zn (CuZn5), with a focus on GB segregation before and after annealing at different temperatures. Additionally, 4D-STEM (ACOM) was utilized to extract information on grain size distribution, grain orientation, and grain boundary types.

Results:
Annealing of CuZn5 up to 300°C by DSC shows a single exothermic peak at about 275°C. it should be mentioned that no grain growth or changes in the grain orientations occurred up to 200°C. High-angle annular dark-field (HAADF)-STEM imaging helps to understand the effect of Zn on the microstructure and GBs. From the 4D-STEM orientation mapping, the GBs can be classified into low-angle GBs, special coincidence site lattice (CSL) boundaries as well as high-angle general GBs. Together with STEM-EDX, it was found out that low energy boundaries such as Σ3 twin boundary is not enriched by Zn. On the other hand, Zn general GBs are segregated with Zn. This observation agrees well with the theory that solute segregation depends strongly on the GB energy. While special Σ-boundaries have low energy, they are less affected by solute segregation.
Conclusion:
CuZn5 maintains a single-phase structure even after annealing, suggesting that the improved thermal stability of the alloys compared to pure Cu is attributed to the presence of solute content. This is due

to the solute-drag effect [3], hindering the diffusion of GBs and contributing to the enhanced thermal stability of the alloys

PS-04 (3), Plenary, august 27, 2024, 10:30 - 12:30

Background incl. aims
All solid-state batteries (ASSBs) using metal anode (e.g. lithium and sodium) are projected to possess high energy and power density and avoid the fire risk of liquid electrolyte counterparts. However, few commercial ASSBs working at room temperature are reported due to sluggish kinetics and severe solid-solid interfacial problems. Among various interfacial problems, the dendritic growth potentially leading to cell failure cannot be yet avoided through the high elastic modulus of solid electrolytes (SEs) as initially expected for ASSBs. Apart from the mechanical property of grain boundaries (GBs), their electronic properties are also expected to be responsible for lithium filamentary dendrite growth and penetration in the SEs. Although this intergranular growth mechanism in inorganic SE based lithium ASSBs is well studied, there is still much to be learned for sodium ASSBs. Especially, anisotropic Na+ ion transport presented in grain bulk of the well-known Na superionic conductor (NaSICON) (e.g. Na3Zr2Si2PO14) even with 3D transport path, not to speak of Na-β''-alumina with layered crystal structure and 2D transport path. Its contribution to the overall Na+ ion transport and the sodium filament growth, for instance, at GBs is still unclear.
Methods & Results
Due to the outstanding stability to Na metal, we used polycrystalline Na-β''-alumina SE (Ionotec. Ltd, UK) as a model material to investigate the microstructural impact on the sodium filament growth. A transmission electron microscopy (TEM) suitable Cu | Na-β''-alumina | Au(Pt) multilayer system was prepared with a focused ion beam (FIB) (FEI Strata 400S) equipment. The electric bias was applied on this system through a scanning tunneling microscopy (STM) nanotip (ZEPtools Technology Company) as schematically illustrated in Figure 1a - b. Na+ ion transport can be prompted by the biasing from the Na-β''-alumina towards the Au/Pt layer and cathodic deposition of sodium occurred at the interface between Na-β''-alumina and the Au/Pt layer in a transmission electron microscope (ThermoFischer Scientific Themis Z). Time-series scanning transmission electron microscopy (STEM) imaging (Figure 1c – f) was used to record the morphological changes e.g. filament growth at the interface between the SE and electrode as well as at the GB. In addition, to build a direct correlation between the filament growth and microstructure, automated crystal orientation mapping (ACOM) by precession electron diffraction-assisted 4D STEM (Figure 1g) was conducted across the polycrystalline Na-β''-alumina specimen. It revealed randomly oriented crystals distributed in the polycrystalline Na-β''-alumina mostly connected by random HAGBs, but hardly any coincidence site lattice boundaries have been observed. Furthermore, since the Na+ ion transport can be different in the grains due to the distinctive orientation of the Na+ ion conduction planes and the external electric field, the GB behavior can also be different as the schematic illustration in Figure 1h for corresponding types. In this case, the filament growth occurred at the GB, which can block the ion transport due to the anisotropic character as shown in Figure 1g.

In addition, significant electron beam effects have been excluded by blank beam reference experiments and sodium filament formation has further been confirmed by post-mortem secondary ion mass spectrometry (SIMS) studies. Moreover, the observed microstructure has been used to simulate the anisotropic Na+ ion transport in the Na-β''-alumina. This helps to understand sodium filament formation and how a critical filament network might form leading to the failure of the battery.

Conclusion

In our study, the relationship between the microstructure and sodium filament growth as well as Na+ ion transport was explored through a crystal orientation analysis. Moreover, sodium filament growth occurred at random HAGBs. The anisotropic ion transport can contribute to the Na+ ion transport blockage of GBs. This blockage at GBs seems to facilitate formation of sodium filaments. Therefore, the microstructure including GB types and orientation should be taken into account for optimizing oxide based SE performance both in terms of sodium filament formation as well as overall ionic conductivity.

Cryo-EM and ED are driving structural studies at the University of Warsaw

Dr Tomasz Góral[1], Dr Szymon Sutuła[1], Prof Krzysztof Woźniak[1,2,3]
[1]Cryomicroscopy and Electron Diffraction Core Facility,Centre of New Technologies, University of Warsaw, Warsaw, Poland, [2]Biological and Chemical Sciences Research Centre, University of Warsaw, Warsaw, Poland, [3]Department of Chemistry, University of Warsaw, Warsaw, Poland

Poster Group 2

Background incl. aims
In 2019 the University of Warsaw purchased and installed one of the first cryo-EM microscopes in the country - the 200kV Glacios equipped with a Falcon3EC camera and a phase plate solution. In the next few years the Cryomicroscopy and Electron Diffraction Core Facility has been established and started providing many local structural biologists and chemists with a direct access to this groundbreaking and Noble-winning cryo-EM technology. To date, there have been only two cryo-EM Core Facilities operating in Poland which provide services in all cryo-EM modalities.
Methods
This poster shows the current possibilities of our Core Facility and a range of services which are offered to our users. We follow the open-access policy and welcome users from both national and international academic institutions as well as industry.
Results
Our recent developments include benchmarking the Single Particle Analysis (SPA) reconstruction of GroEL with GroTAC peptide at the 2.45Å resolution level with local resolution reaching 2.2Å (PDB: 8S32) and the 2.27Å reconstruction of the AbiK bacterial polymerase (PDB:7R06). The results are further enhanced with the upgrade of the microscope to the micro-ED functionality allowing for a rapid structure determination of small molecules and/or proteins based on electron diffraction data. On top of that, we have recently completed a process of building up a €0.5M-worth IT infrastructure support for the cryo-EM data storage (up to 1.6PB dedicated storage space) and expanding on the data processing capabilities (utilising our 200 GPU-based computer cluster) which will be a unique set-up of its kind not only in Poland but also in Central Europe.
Conclusion
We highlight the importance of smaller cryo-EM Core Facilities such as ours to serve as a first point of contact for users, in particular for those who are new to the cryo-EM field and would like to explore different possibilities of getting high quality data prior to applying for the measurement time on high-end 300kV microscopes. We also show that being able to offer all cryo-EM modalities in one instrument (SPA, cryo-ET and micro-ED) significantly boosts a research potential and opens up new possibilities across many Life Science applications.

Poster Group 2

Background incl. aims
In recent years, ferroelectric field-effect transistors (FeFETs) have become valuable alternatives to the flash technology for nonvolatile memory applications. Not only do they incorporate ultra-fast and energy-efficient switching as well as radiation hardness, but they also provide high thermal stability of their logic states. [1, 2]
The low-VT and high-VT states have been intensively studied and characterized, e.g., as described in [1], yet the understanding of the exact electrostatic field in the polarized ferroelectric (FE) gate stack is still subject of discussion. While various TCAD simulations aim to analyze these from a theoretical perspective [3], utilizing scanning transmission electron microscopy (STEM) can deliver more direct insights. Recent work [4] has shown the observation of the FE polarization in STEM utilizing the differential phase contrast (DPC) method. In addition, STEM-DPC analysis of FE devices would provide the opportunity to conduct failure analysis, not only of structural defects in single devices, but also of imperfections in the crystallographic phase and the resulting electrostatic field itself.

Methods
DPC is a STEM imaging method which can visualize local electrostatic and magnetic fields in specimens at high resolution. The fields are detected as a shift of the transmitted bright-field disk on a segmented annular or a pixelated detector resulting from the interaction of the local fields with the incident electron beam. Since the FE polarization in FE materials creates electrostatic fields, the DPC method is suitable for the investigation of local polarization effects in the thin FE layers of FeFETs.
In this study, HfO_2-based FeFET arrays were programmed in a striped pattern, as described in [2]. The FeFETs consisted of 10 nm FE HfO_2, a 1 nm SiO_2 interfacial layer, TiN and a top electrode made from polycrystalline Si. For investigation with the DPC method, TEM specimens of the programmed array were prepared by in-situ lift-out utilizing the focused ion beam (FIB). A convergent electron beam was employed to achieve high spatial resolution and thus investigate the FE polarization states in the FE material.

Results
The local charge carrier density was calculated from the DPC data and analyzed for the investigated FeFETs, respectively. The FeFETs programmed in low-VT and high-VT states showed opposing gradients of the charge carrier density in the FE layer. The direction of the electrostatic fields indicated by those gradients was found to be in accordance with the theoretical direction of the electrostatic fields due to the FE polarization of the material.

Conclusion

In future investigations, the use of DPC can provide deeper insights into the properties of FeFETs. Combining DPC with other techniques, such as precession electron diffraction (PED), could yield additional information about these devices. Employing PED would help reduce diffraction-related artifacts in DPC data. Furthermore, PED can identify grains of both FE and non-FE phases within the material. In addition, observing the in-situ switching behavior of FE devices would contribute significantly to understanding the electric behavior of FeFETs during operation.

Novel, low-cost hardware for ‘STEM in SEM’ imaging

Mr Andrew Sturt[1], Dr Gareth Hughes[1], Dr Ian Griffiths[2], Dr Phani Karamched[1], Dr Neil Young[1]
[1]Department of Materials, University of Oxford, , United Kingdom, [2]JEOL (UK) Ltd, Welwyn Garden City, United Kingdom

Poster Group 1

Background
Scanning transmission mode imaging can offer better contrast and resolution than secondary electron imaging in nano, soft and biological materials[1]. The concept of ‘STEM in SEM’ is to replicate the improved image quality of scanning transmission electron microscopy (STEM) in lower-cost scanning electron microscopes (SEM). In the hardware discussed in this work, a conversion plate allows the transmitted electrons to produce a signal using the Everhart-Thornley Detector (ETD). This enables bright field STEM imaging to be added to most SEMs through using only an additional sample holder.

Although this is not a new concept [2], little work has been published on the optimisation of the design and operational parameters. A higher efficiency allows a lower probe current to be used. In the SEM, the spot size is limited by the probe current and the brightness of the source. Due to this the improved efficiency in ‘STEM in SEM’ results in improved resolution.

The schematic (a) shows the basic concept of the ‘STEM in SEM’ holder. A standard TEM grid is clamped between plates at the top of the holder. The electron beam passes through the sample and reaches a conversion plate. Here transmitted electrons generate secondary electrons within the plate which may be detected by the ETD. Furthermore, an aperture may be inserted between the sample and the conversion plate to control the acceptance angle of the detector.

Methods
The optimisation process consisted of a series of experiments analysing the effect of each parameter in isolation.

The efficiency of the conversion of transmitted electrons to secondary electrons was simulated using CASINO, a Monte Carlo method simulation program [3] . The modelling indicated an improved conversion yield when an oxide forming metal coats the surface. The model was validated by comparing the ETD signal produced when a range of coated glass substrates were scanned with a focussed electron beam. The increase in secondary electron yield due to a sputtered aluminium surface coating was verified experimentally. As secondary electrons only escape from within a few nanometres of the surface, only a coating of high-yield material is needed. This was implemented at a low cost by sputtering a gold-aluminium bilayer coating onto glass substrate.

Significant geometrical optimisations in both the angle of the conversion plate and the working distance were found. The image brightness was measured whilst varying the conversion plate angle. It was found that the efficiency of the plate has a significant peak at the optimised angle. It is thought that this is for two reasons. Firstly, as the angle increases, the transmitted electrons travel a greater distance within the material at a depth at which secondary electrons can escape. Secondly, the alignment of the emitted electrons to the ETD improves the detection efficiency.

One of the challenges with 'STEM in SEM' is the convolution of the desired transmitted signal with undesirable secondary electrons from the sample. The difference in detection efficiency of the ETD at different working distances was used to combat this. The ETD has poor detection efficiencies close to the polepiece. When using a sample working distance of 3mm and a converter plate working distance of 18mm, the signal was dominated by the transmission mode. The noise was further reduced by a reduction of the ETD cage bias from the 250-400V typically used to 50V. This limited the detected electrons to those emitted aligned closely to the detector.

The overall performance of the 'STEM in SEM 'converter was evaluated by imaging drop cast 40nm and 20nm nominal size silver nanoparticles on a holey carbon TEM grid. Ostwald ripening of the nanoparticles produced a broad distribution of particle sizes for resolution testing. The samples were imaged at 30kV using a tungsten filament SEM. The other microscope parameters were adjusted to suit the two imaging methods.

Results
The figure shows silver nanoparticles on a holey carbon film observed whilst using a tungsten filament SEM in (b) secondary electron mode at 30kX magnification and (c) using the STEM converter at 75kX magnification. The contrast was improved using the optimised 'STEM in SEM' converter when compared to secondary electron imaging. An improvement in contrast to noise ratio was seen in the STEM images. The improved contrast enables faster and easier imaging of the nanoparticles in the STEM mode. The smallest particles seen in secondary electron mode were 75nm in diameter. With the STEM converter, this was improved to 25nm.

Conclusion
The optimised 'STEM in SEM' converter presented here is a low-cost method to enable transmission mode imaging in the SEM. It has been shown this can be utilised to improve the image quality when imaging nanoparticles. Although, this does not represent new functionality compared to dedicated silicon STEM detectors, it is a much more accessible method of adding STEM capabilities to an SEM.

Structural phase transition induced microstructure changes in V2O3 based hybrid magnetic heterostructures

Prof. Unnar Arnalds[1]
[1]University of Iceland, Reykjavik, Iceland

Poster Group 2

Vanadiumsesquioxide (V_2O_3) stands out in the realm of transition metal oxides for its distinctive and multifaceted phase transitions, offering a rich ground for exploration in the context of structural, electrical and magnetic properties [1, 2]. At room temperature, V_2O_3 is in a rhombohedral phase, exhibiting metallic properties and upon cooling to below ~150 K it undergoes a structural phase transition to an insulating monoclinic phase. Through the transition the material also changes from a paramagnetic state to a low temperature antiferromagnetic state and has been observed to induce an exchange bias into overlying magnetic layers [3].

In this work we present an investigation on the interplay between the microstructure of V_2O_3 thin films, deposited using reactive dc magnetron sputtering, and their structural properties during the phase transition. Specifically, we examine the changes in the microstructure during the phase coexistence region of the V_2O_3 layer and how these changes correlate with alterations in the magnetic properties of overlying magnetic layers in V_2O_3/Ni heterostructures [4].

Using scanning transmission electron microscopy (STEM) using high-angle annular dark-field (HAADF-STEM) imaging, energy dispersive x-ray analysis (STEM-EDX) and electron energy loss spectroscopy (EELS) we investigate the stoichiometric composition of the films and confirm their crystalline quality at the sub-nm lateral scale and observe an atomically flat interface between the Al_2O_3 substrate and the V_2O_3 layer, as well as a sharp interface between V_2O_3 and the overlying magnetic Ni layer.

The simultaneous presence of two phases in V_2O_3 during its structural phase transition was identified with temperature dependent high resolution x-ray diffraction measurements performed at the BM28 (XMaS) beamline at the European Synchrotron Radiation Facility (ESRF) in Grenoble, France. The measurements reveal an increase in surface roughness during the transition which is attributed to the coexistence of the two phases in different regions of the film. During the phase coexistence region we observe a concomitant increase in the coercivity of the magnetic layer correlated with the increased roughness of the V_2O_3 surface.

In situ closed-cell microscopy study of Ti3C2Tz MXene

Phd Student Changjie Huang[1], Asst. Prof. Leiqiang Qin[2], Prof. Johanna Rosen[2], Prof. Per O.Å Persson[1], Assoc. Prof. Justinas Palisaitis[1]
[1]Thin Film Physics Division, Department of Physics, Chemistry and Biology (IFM), Linköping University, Linköping, Sweden, [2]Material Design Division, Department of Physics, Chemistry and Biology (IFM), Linköping, Sweden

Poster Group 2

Background incl. aims
MXenes are referred to as 2D transition metal carbides, nitrides, or carbonitrides and first reported in 2011. They are described by the general Mn+1XnTz (n=1,2 or 3) formula, where M is a transition metal, X stands for C or/and N and Tz represents the surface terminating species [1]. Owning to their structural and chemical diversity, MXenes enable the wide variety of properties, which makes them competitive in a wide range of applications including catalysis, energy storage, supercapacitors, sensors, spintronics, thermoelectrics and beyond [2].
Despite the immense progress in the field of MXene, a number of unresolved challenges remains, including a fundamental understanding of post synthesis stability and processing of MXenes at application relevant environments. In particularly, the detailed knowledge of the degradation mechanisms, in the environment(s) containing presence of water, is highly debated in the literature.
Previously, transmission electron microscopy (TEM) studies provided atomic level insights into the Ti3C2Tz structure and surfaces [3]. In situ TEM was applied to study Ti3C2Tz surface termination alternations [4]. Post synthesis in situ gas heating treatments of Ti3C2Tz was successfully demonstrated via environmental TEM studies [5].
The introduction of environmental closed-cell holders brings unique opportunities for the study of MXenes under real-world conditions closer to practical processing and/or application environments inside TEM.
In this study, we employed in situ closed-cell TEM to study the role of water on thermal stability of Ti3C2Tz MXene sheets during annealing in Ar or N2 atmospheres.

Methods
Ti3C2Tz MXene sheets were synthesized by the previously reported MILD method in which selective extraction of Al from Ti3AlC2 MAX phase and delamination of the layers were achieved using hydrochloric acid and lithium fluoride.
In situ experiments were performed in the Linköping double Cs corrected FEI Titan3 60-300, using a closed-cell gas heating system (Protochips, Atmosphere). During pretreatment, holder was pumped and purge with Ar to remove residual gasses from the holder tip. This was followed by continues Ar flow while annealing at 300°C for 60 min. In situ heating of Ti3C2Tz was accomplished by increasing the temperature from 600 °C to 1000 °C in steps of 100 °C and holding for 15 min at each step while continuously flowing Ar (inert) or N2 (no affinity for Ti3C2Tz) gasses at 760 torr.
After each heating step the temperature was lowered to 300 °C for acquisition of images and spectra. The structural and chemical evolution of Ti3C2Tz was tracked using high angle annular dark field STEM (HAADF-STEM) imaging and electron energy loss spectroscopy (EELS). A residual gas analyser (RGA) was used to monitor the status of the experimental and residual gases in the system.

Results

To explore the effect of water on thermal stability at atmospheric pressures, Ti3C2Tz was annealed to high temperatures while been kept at flowing Ar (99,9999% purity) or N2 (99,9999% purity) gasses at 760 torr.
The graph shows a series of HAADF-STEM images recorded during in situ heating of Ti3C2Tz during exposure to flowing N2 at 760 Torr. The morphology of Ti3C2Tz sheets remained largely unaffected up to 800 °C as observed by imaging and tracking Ti-L2,3 fine edge structure evolution. At 900 °C the morphology of the Ti3C2Tz changed entirely as it decomposed to titanium oxide nano particles. At 1000 °C the titanium oxide particles coarsened while the amorphous SiN window undergone the crystallization.
Independent of the applied atmosphere (Ar or N2), the decomposition of Ti3C2Tz resulted in the formation to titanium oxide nanoparticles at high temperatures. Water pressure decrease, achieved via extensive baking of the system, from ~3x10-7 torr to ~6x10-9 torr delayed titanium oxide particle formation and coarsening by more than 100 °C. The lower water level also suppressed SiN window crystallization at 1000 °C. Thus, the oxidation is suggested to occur from the residual water present in the system while the thermal activation offset for oxidation could be directly linked to the water pressure level.

Conclusions
The study uncovered the effect of water on thermal behaviour of Ti3C2Tz during annealing at Ar or N2 atmospheres. Residual water has the detrimental effect on the offset of the observed oxidation phenomena. Consequently, obtained results increase understanding of factors and conditions responsible for Ti3C2Tz environmental stability. As important, study highlights the importance of water level control for MXene gas reaction experiments using in situ closed-cell TEM and beyond.

Exploring Cell-Material Interactions at Focal Adhesion Points

Dr Krzysztof Berniak[1], Dr Daniel P. Ura[1], Prof. Adam Piórkowski[2], Prof. Urszula Stachewicz[1]
[1]Faculty of Metals Engineering and Industrial Computer Science, AGH University of Krakow, Kraków, Polska, [2]Department of Biocybernetics and Biomedical Engineering, AGH University of Krakow, Kraków, Polska

Poster Group 1

Background
In tissue engineering, electrospun fibers are pivotal scaffolds, shaping cell interactions through their mechanical strength and surface characteristics. Focal adhesion sites, multi-protein complexes, regulating cell adhesion dynamics, form mechanical links between intracellular actin bundles and the substrate. Widely used in bioengineering, PMMA fibers play a crucial role as an integral component of bone implants, serving as an adhesive platform for various cell types (1). The aim of the research is to investigate the distribution and structure of proteins paxillin and vinculin in focal adhesion (FA) sites using advanced microscopy techniques, particularly AiryScan confocal super-resolution microscopy and the Density-Based Spatial Clustering of Applications with Noise (DBSCAN) cluster algorithm. Moreover, this research is performed on cells bind to polymer fibers commonly used in tissue scaffolds and compared to standard glass slides. Therefore, our results contribute to designing scaffold and understanding the interactions between cells and materials applied in/for tissue regeneration.
Methods
PMMA fibers were electrospuned using the EC-DIG apparatus with climate control. Studies involved human osteoblast-like cell line MG-63 on PMMA electrospun fibers. Cells were cultured under standard conditions, fixed, and permeabilized after 3 days. Actin filaments were visualized with Alexa Fluor 488 Phalloidin, and nuclear DNA was stained with DAPI. Focal adhesion proteins (vinculin and paxillin) were labeled with immunofluorescence. Confocal microscopy, specifically Zeiss LSM 900 with the high-resolution concept Airyscan, captured multicolor 3D microscopy images of cells connecting to PMMA fibers. Image analysis was performed by using ImageJ.
Results
AiryScan microscopy offered detailed insight into cell adhesion onto PMMA fibers, confirming the binding process. Additionally, DBSCAN cluster analysis revealed substrate-specific correlations in osteoblast behavior, providing a quantitative understanding of cell-PMMA interactions. Effective adhesion correlated with well-organized, larger focal adhesions characterized by increased protein accumulation. Interestingly, a shift in paxillin and vinculin signals was observed during cell attachment to both glass and polymer fibers. Focal adhesions on polymer fibers appeared smaller and elliptical but exhibited higher protein density compared to glass (2). These attributes, influenced by paxillin and vinculin, likely signify cell adhesion strength. This innovative cluster analysis uncovers variations in adhesion clusters, offering valuable insights for scaffold design refinement, diverse substrate adhesion evaluation, and enhanced cellular interactions in biomedical applications.
Conclusion
We introduce a new method for analyzing protein distribution in cell adhesion to polymer fibers, crucial for tissue engineering scaffolds. Our study reveals significant differences in adhesion complex distribution compared to glass, with a focus on vinculin and paxillin. By quantitatively comparing osteoblast adhesion on glass and polymer scaffolds, we provide the first detailed analysis in a model

incorporating polymer fibers, paving the way for understanding cell-material interactions in medical biomaterial research.

The effect of fixation-induced cell blebbing: how to minimize a loss of proteins from cells?

Prof. Pavel Hozak[1]
[1]Institute of Molecular Gentics ASCR, Prague, Czech Republic

LS-05, Lecture Theater 5, august 26, 2024, 14:00 - 15:00

In the course of the preparation of biological samples for various microscopy techniques, the first and the most essential step is a fixation. The efficiency of the fixation procedure is estimated by two main factors: the preservation of the cellular constituents and the suitability for further treatments like immunolabelling. However, till now the detailed mechanisms of the cell fixation are not fully understood and we rely mostly on empirical experiences. We concentrated on studying the fixation-induced cell blebbing, and searched for the way to minimize this deteriorating effect. By means of different microscopy methods, we quantitatively assessed the loss of cytoplasmic content during the rupture of blebs. With holography microscopy time-lapse experiments, we found that the key points are the formation and rupture of blebs, and we discuss the possible mechanism of blebs appearance. Importantly, it was shown that up to 30% of soluble proteins can be lost from cytoplasm after the blebs rupture. Based on these data, we tested a wide range of fixation mixtures applied during different time intervals to minimize the loss of cytoplasmic proteins. Taking into account different quantitative parameters, we determined the optimal procedures to fix the cells. Finally, we provide some recommendations on the fixation protocols which are suitable for future experiments.

PS-08 (2), Lecture Theater 2, august 27, 2024, 14:00 - 16:00

Background incl. aims
In order to unveil the magneto-resistive fingerprint of Skyrmions, it is necessary to measure the material's magnetic field dependence of the Hall resistance while acquiring Lorentz TEM (L-TEM) images at the same time [1, 2]. We demonstrate a measurement platform allowing for in-situ magnetic transport measurements in a TEM [3] by utilizing a DENSsolutions biasing holder and a Hall sensor for quantification of the objective lens' magnetic field. We aim to correlate the Hall effect in skyrmionic materials with the magnetic field dependent occurrence of topologically protected magnetic phases such as the helical phase and Skyrmions [4].

Methods
In-situ L-TEM investigations were conducted using a FEI Themis-Z double-corrected microscope (300 kV, X-FEG) equipped with a fast Ceta-M camera. A DENSsolutions Lightning holder with spring contacts connected to electrical feedthroughs was used to measure the Hall voltage.
In Lorentz mode, the objective lens of the microscope was used to apply an external magnetic field perpendicular to the sample plane. The magnetic field of the objective lens was calibrated with an Asensor Technology analog Hall sensor fitted into the in-situ biasing holder, see Fig. 1 (a). A Co8Zn9Mn3 TEM lamella was cut using a Thermofisher G4 Hydra Plasma FIB. Subsequently, the lamella was positioned on a commercial chip and soldered to the underlying substrate by Pt deposition in the FIB. The DENSsolutions nano-chip was then further modified for the Hall measurements: In order to realise a four-point measurement geometry, insulating SiOx patches were deposited on top of the inner tracks. By writing W tracks over the SiOx, the conductive paths were bridged (cf. Fig. 1 (b)).

Results & Conclusions
The demonstrated in-situ setup allows for the simultaneous acquisition of L-TEM images and the measurement of the Hall voltage as function of the out-of-plane magnetic field, which we can control precisely by tuning the objective lens excitation. Fig. 1 (c) shows the Skyrmion phase in Co8Zn9Mn3 at 142 mT. Although the lamella is hosting Skyrmions, no signature of topological solitons is observable in the Hall voltage. The observed Skyrmions do not exhibit any distinctive characteristics in the magnetic transport measurements.

The development of multimodal imaging with functional silica nanoparticle

Dr. Tomohiro Haruta[1], Prof. Michihiro Nakamura[2]
[1]JEOL Ltd., Akishima, Japan, [2]Graduate school of medicine,Yamaguchi university, Ube, Japan

Poster Group 1

Background incl. aims
Organic silica nanoparticles (SiNPs) can be customized in various ways, such as the introduction of fluorescent dyes, addition of metal particles, and surface modification with some chemicals. It was shown that SiNPs containing fluorescent dyes with iron cores could be used for in vivo multimodal MRI and light microscopy imaging. We investigated the SiNPs with fluorescent dye is able to use as the tag for correlative light-electron microscopy, and developed novel SiNPs with heavy metals for correlative light-electron microscopy (CLEM), multicolor CLEM, and multimodal imaging with micro CT.

Methods
(1)We introduced SiNPs containing fluorescent dyes into Paramecium and performed CLEM observations.
(2)We made SiNPs contain green fluorecence dye with gold nano particles (green Au SiNPs) and SiNPs contain red fluorecense dye with iron nano particles (Red Fe SiNPs), deveoloped multicolor CLEM combined with the EDS mapping. After each of the produced particles was introduced into cultured cells, the cells were mixed and co-cultured, and fluorescence observation, electron microscope observation, and EDS mapping were performed.
(3)We performed multimodal imaging using light microscopy, µCT, and electron microscopy using the spleens of the mice intravenously injected with SiNPs contain fluorecence dye with gold nano particles .

Results
(1) The fluorescence of SiNPs introduced into Paramecium was maintained even after sample preparation for electron microscopy, and the fluorescence could be observed in ultra-thin sections. This result indicates that fluorescent dyes incorporated into SiNPs are resistant to chemical treatments for electron microscopy (Pre-fixation with glutaraldehyde, post-fixation with osmium tetroxide, dehydration with ethanol, embedding with epoxy resin, ultra-thin sectioning). In this Paramecium sample, we were able to observe SiNPs within the phagosomes by TEM in regions where fluorescence was observed by light microscopy. However, it was difficult to identify the region where the particles were introduced from the low-magnification electron microscope image, because the SiNPs have a weak contrast in the electron microscope image. Therefore, we carried gold particles on the surface of SiNPs containing fluorescent dyes to enhance the contrast in electron microscopic images. This particle had a very high contrast in electron microscope observation, and it was possible to identify its location even in very low-magnification observation with an electron microscope.
(2) As a result of EDS mapping, although iron could not be detected, particles with gold added and particles without gold added can be distinguish and this localization correlates with the fluorescence image.
(3) We succeeded in CLEM observation by introducing SiNPs at 1 µg/ml, and by introducing SiNPs at 5 µg/ml or more, it became possible to visualize SiNPs in tissues using µCT.

Conclusion
We succeed to perform multicolor CLEM by combining heavy metal-loaded fluorescent organic silica nanoparticles and EDS mapping. By increasing the introduction amount of SiNPs carrying gold particles, it is possible to visualize with µCT, and multimodal imaging of optical microscopy-µCT-electron microscopy becomes possible. It suggests that it is possible to overcome the barriers between devices by synthesizing new SiNPs that match the principle of the device to be measured.

Hybrid electrospun scaffolds for enhanced collagen formation in regeneration processes: electron and confocal microscopy analysis

Dr Joanna Karbowniczek[1], Dr Krzysztof Berniak[1], Prof. Urszula Stachewicz[1]
[1]Faculty of Metals Engineering and Industrial Computer Science, AGH University of Krakow, Krakow, Poland

Poster Group 1

Background
Extracellular matrix (ECM) of bone tissue is a natural composite containing organic and inorganic components, that can be biomimicked using electrospun fibers. Addition of ceramic filler into the polymer fibers can enhance the mechanical properties as well as improve bioactivity. However, to obtain the best hybrid scaffold the uniform distribution of particles and reduction of aggregations are necessary [1]. Here, the careful design of composite fibers can trigger cellular adhesion, proliferation and tissue regeneration via enhance collagen formation in the in vitro cell culture [2]. Therefore, the goal of this work is to optimize and verified production of hybrid electrospun fibers for effective bone tissue scaffolds including visualization using advance electron and confocal microscopy analysis.
Methods
Blend and co-axial electrospinning were employed to manufacture bone scaffolds of poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) with incorporated titanium dioxide nanoparticles (TiO_2) using TechNOVA electrospinning device [3]. Morphology of obtained fibers was evaluated by scanning electron microscopy (SEM) with secondary electron detector (Merlin, Zeiss). Distribution and aggregation of TiO_2 within polymer fibers were studied by SEM imaging with back scattered detector (BSE), energy dispersive X-Ray spectroscopy (EDS, detector Brucker). Additionally similar analysis was also performed at the cross-sections prepared by focused ion beam (FIB, Crossbeam 350, Zeiss). In vitro cell culture study was performed with osteoblast cells up to 14 days. Cell proliferation and morphology in response to various scaffolds was verified after 1, 3 and 7 days of incubation. The collagen formation was confirmed by immunofluorescence staining and visualized by confocal laser scanning microscopy (CLSM, LSM 900, Zeiss).
Results
Over 20% increase in fiber diameter was observed when PHBV was enriched with TiO_2 nanoparticles, reaching 3.84 µm for sample prepared by co-axial process. Blend fibers had smooth surface with visible large particles aggregations, locally exceeding 5 μm^2, in majority covered by polymer. On the other hand, the fibers prepared using co-axial nozzle had core-shell morphology, with polymer fibers homogenously decorated with ceramic particles with significantly smaller aggregations up to 0.3 μm^2. In response to core-shell fibers cells exhibited significantly higher proliferation after 7 days with excellent spreading within the scaffold structure. Additionally, they produced vast network of collagen fibers as the important stage of ECM formation, which was not observed in such extent for any other tested scaffold.
Conclusion
Current study shows the importance of electrospinning strategy for single-step production of bioactive scaffolds supporting bone regeneration. For cellular guidance it is essential not only to provide composite morphology but also to ensure proper particles distribution and availability, which was achieved by co-axial electrospinning. The presence of ceramic nanoparticles, effectively integrated onto the surface of polymer fibers, enhances cells adhesion, ingrowth and promotes the formation of ECM, which are necessary in tissue regeneration processes.

Self-assembly of amphiphilic dendrimers investigated by standard, cryo and liquid TEM

Dr Tom ROUSSEL[1], Pr Ling PENG[1], Pr Suzanne GIORGIO[1]
[1]CINAM - CNRS- Aix Marseille University, Marseille, France

Poster Group 1

The self-assembly of amphiphilic molecules represents a captivating avenue for the creation of innovative materials in drug delivery. In our investigation, we explore the assembling properties of amphiphilic poly(amidoamine) dendrimers, focusing on two distinct dendrimers: one terminated with tertiary amine groups N(CH3)2 denoted as dendrimer A, and another terminated with primary amine groups NH2 denoted as dendrimer B. Our study highlight the influence of surface chemical modifications on their size and packing dynamics, unveiling pathways towards finely tuned molecular architectures.
Complementary techniques of standard, Cryo and Liquid TEM are used to characterize the molecular assemblies.
Concerning dendrimer A, all the TEM technics are consistent with the formation of small nanomicelles ranging in size from 15 to 25 nm, as depicted in figures 1a and b. However, liquid TEM provides additional insights into the arrangement of dendrimers within these micelles. In the expanded view of a single micelle (fig. 1c), regularly spaced dark spots inside the micelle can be observed. The average distance between them is about 5 nm, which is comparable to the diameter of the volume containing the hydrophilic heads with tertiary amines. This supplementary information enriches our knowledge of the intricate assembly of dendrimer A within the micellar structure.
On the other hand, as seen in figures 2a and b, dendrimers B terminated with primary amine assemble in larger particles around 100 nm. Details on the assembly is clearly seen in the liquid TEM images (fig. 2b,c). The magnified image of a particle in fig. 2c corresponds to the aggregation of several micelles with size around (15- 25 nm) into a large particle of around 100 nm.
The Israelachvili assembly model's prediction1 aligns closely with the behavior of dendrimer A, illustrating its propensity to assemble into nanomicelle. However, the assembly process for dendrimer B unfolds uniquely, showcasing distinctions that necessitate a closer examination only made possible through liquid TEM. This sophisticated imaging technique unveils intricate structural nuances that had remained elusive until now, marking a significant advancement in our understanding of dendrimer assembly.
Conclusion : Our study reveals that dendrimer A exhibits consistent formation of small nanomicelles (fig. 3a) of around 20 nm, supported by various TEM techniques. Meanwhile, dendrimer B displays distinct assembly behavior (fig. 3b), forming larger particles around 100 nm. The intricate details of dendrimer A's micelle and the distinctive assembly process of dendrimer B emphasize the critical role of advanced imaging techniques such as liquid TEM in unraveling complex structural properties. This advancement significantly contributes to our comprehension of dendrimer assembly dynamics.

The dynamic development of microscopic techniques offers new opportunities for the comprehensive study of biological processes. However, the application of methods covering a wide resolution range requires the right questions to be asked and the definition of a precise target, without which it is difficult to obtain relevant results. In the following, I would like to demonstrate the application of microscopic modalities with different resolution capabilities in the field of neuroscience by highlighting examples from my own work.
Our research focuses on microglial cells which are the main immune cells of the brain. These cells are essential for the normal functioning of the brain and play an important role in maintaining brain homeostasis, proper development and function of neurons, the formation of their synaptic connections and the regulation of inflammatory processes. They also play a role in the control of cerebral blood flow. Carrying out these complex tasks requires continuous communication between the microglia and the other cells of the brain. However, our current understanding of the cell-cell interactions of microglia with neurons, other glial cells and blood vessel cells is rather incomplete.
We uses different microscopic methods, ranging from micrometre magnification to nanometre resolution, to reveal the connectivity of microglial cells. Starting from the lower resolution, we first investigated the location and heterogeneity of glial cells (microglia, astrocytes, oligodendrocytes) and neurons in the cerebral cortex using slide scanner microscope. With this method, we can obtain information on the distribution and quantity of the cells under investigation in a small but fast way for many samples. We then used a higher-resolution confocal laser scanning microscope to take a closer look at how many different cells a microglial cell interacts with at a given time point and how many different cells it interacts with. Then, to achieve nanometre resolution, we used scanning electron microscopy serial section tomography to verify that the putative contact sites visualised by diffraction-limited confocal microscopy are real direct contacts, where the plasma membranes of microglia and other cells are brought within nanometre proximity of each other. Furthermore, these images can be used to reveal the intracellular ultrastructure characteristic of the different contacts.
In order to study the dynamics and function of these connections, we use two-photon microscopy in vivo, in a departure from the mainly anatomical microscopy techniques used so far.Our studies will allow us to determine the lifetime, stability and signalling pathway involved in the connection of each contact.
By combining these different microscopic techniques, we can gain a complete view of both the anatomical structure and the functional role of microglial cells in their interactions with other cells. Our studies will be carried out in mouse, human adult and elderly samples, which will help us to understand the subcellular processes underlying ageing and related neurodegenerative neurodegenerative diseases such as Alzheimer's disease.

Poster Group 1

In the field of material science, the ability to determine structures at high spatial resolution is paramount for understanding their properties. While traditional X-ray and electron diffraction techniques have been successful in determining crystalline structures, the need for new techniques is evident. Conventional methods fall short in providing detailed structural information for disordered structures, such as those found in nanostructured and amorphous materials, making our research on the disordered nature of anode materials all the more significant.

The pair distribution function (PDF) method based on X-ray and neutron diffraction is widely employed for providing quantitative information in amorphous materials [1]. Nonetheless, understanding medium-range structural order in amorphous materials is non-trivial, where the position of atoms cannot be assigned by any equation based on translation vectors. Electron Diffraction (ED) related PDF (ePDF) in Transmission Electron Microscope has the advantage of investigating ordering locally. However, ePDF-based analyses may be affected by dynamical effects, altering the scattering intensities.

This work aims to expand the developed methodology to battery materials research by employing electron diffraction data to obtain PDF coupled with low-loss electron energy loss spectroscopy [2]. This will enable us to delve into the role of volume expansion during lithiation in silicon-carbon-based anode materials, which is a crucial aspect of the electrode's functioning.

The nature of diffuse scattering in fcc metal alloys – investigation by 3D-ED and 4D-STEM

Hannah Cole[1], Mr James Miller[1], Mr James Hogg[1], Mr Petr Vacek[1], Mr Owain Houghton[1], Prof Howard Stone[1], Prof Paul Midgley[1]
[1]Department of Materials Science & Metallurgy, University of Cambridge, Cambridge,, United Kingdom

PS-02 (2), Lecture Theater 5, august 28, 2024, 14:00 - 16:00

Background and aims:
Previous investigations of some fcc metal alloys have shown the presence of diffuse 'spots' between Bragg reflections at <111> and <112> zone axes. These have been attributed to various effects including thermal diffuse scattering, surface steps, stacking faults or nano twins, short range chemical ordering and even relrod spiking from HOLZ [1,2]. Such diffuse scattering may arises from the presence of local crystalline order/disorder in the alloy. Where it occurs, 3D 'shape' and strength of the diffuse scattering can reveal the origin of the disorder. For example, a linear defect in real space would give rise to a 'plane' of diffuse scattering while a planar defect would produce a diffuse 'rod' [3]. We hypotheses that the 1/3 {422} and 1/2 {311} diffuse 'spots' seen previously are in fact where the Ewald sphere intersects with a <111>* reciprocal lattice 'rod'. Here we use a combination of 3D-ED and scanning electron diffraction (SED), a variant of 4D-STEM, to reveal the nature of the diffuse scattering.

Method:
Two fcc alloys were investigated. The first was a single crystal Ni-base superalloy (CMSX-4) which has a γ matrix (A1 structure) and γ' precipitates ($L1_2$ structure). This specimen was taken from a <001> tensile sample and electropolished as a 3 mm disc. The second sample was an age-hardened AuPt24Pd alloy which was homogenised and then cooled at 5 K/min. This second alloy undergoes phase separation into two regions of chemical segregation: one rich in Au and Pd, and another rich in Pt. The alloy specimen was a TEM foil that was prepared by FIB lift out.

A FEI Tecnai Osiris 80-200 TEM was used to acquire selected area diffraction patterns and HR-TEM images of the specimens. A Thermo Fisher Spectra 300 TEM was used for the 3D-ED, SED and complementary STEM-EDX experiments.

3D-ED was performed using the continuous rotation electron diffraction (cRED) method. Here, the sample is rotated continuously so that a 'movie' with many hundreds of frames is acquired across a tilt range, in this case +/- 60 °. By extracting these movie frames, and considering each as a central section through 3D reciprocal space, a full diffraction 'tomogram' can be reconstructed. This technique has been used primarily for structural determination using the 3D distribution of Bragg reflections. However, here we consider the 3D distribution of diffuse intensity between the Bragg reflections.

The 3D reconstruction was achieved using a combination of python scripts (using the open-source packages hyperspy and pyXem) and the program PETS2 [4]; the 3D

visualisation was performed in either Vesta or Avizo. Strain maps (using SED) and associated elemental maps (EDX) were determined using hyperspy and pyXem.

Results:
Figure 1(a) shows a zero order Laue zone (ZOLZ) section (Fourier slice) taken from the reconstructed 3D reciprocal space of the Ni-base superalloy sample. The zone axis orientation is <110> and the weak Bragg reflections are from the ordered γ' precipitates. In this section, we can see clear evidence of lines of diffuse scattering in the <111>* direction, which is likely to originate from the γ phase. Moreover, these lines of diffuse scattering do not appear along the <111>* rows that pass through the origin as indicated by the dashed arrows in figure 1(a). Figure 1(b) shows a ZOLZ slice from the <111> zone axis. The diffuse scattering is now present as faint, relatively broad 'spots' of diffuse scattering at the 1/3 {422} position. Similar results were obtained using conventional selected area diffraction and SED. Figure 1(c) shows a FOLZ slice from another <110> axis, 60 degrees from that in (a). This illustrates how information can be obtained with this method that is not readily accessible through conventional 2D diffraction. Again diffuse 'lines' are seen in figure 1(c) between Bragg reflections. It is notable that these lines are shifted with respect to those in figure 1(a) as they were obtained from a higher section in reciprocal space.

Similar diffraction results, shown in Figure 1(d), are seen for the AuPt24Pd alloy. The strain and EDX maps (not shown here) indicate clear phase separation at the 10-20 nm scale in the <110> and <100> directions but these orientations rule out that this is the origin of the <111>* diffuse scattering seen in the diffraction patterns.

The results described above are only consistent with the 3D model of diffuse scattering illustrated in figure 1(e) in which rods of diffuse intensity run parallel to <111>*.

Given the nature of the diffuse scattering seen in these alloys it is likely that it is related to a change of local atomic structure in the {111} planes. The lack of diffuse scattering through the origin indicates that any atomic displacement related to the local structure in the {111} planes is transverse in nature – an analogy would be the 'streaking' seen in <110> patterns from fcc crystals arising from stacking faults with shear vectors 1/6 <112> in the {111} planes. However, here, given the rather broad nature of the diffuse scattering it is speculated that its origin may be highly localised chemical order within the {111} planes, leading to small atomic displacements in the plane because of the change in inter-atomic bonding between atom species. Such small, localised shears in the {111} plane would be expected to give rise to the <111>* diffuse rods seen.

Conclusions:
3D-ED has be used to determine the 3D structure of diffuse scattering in fcc metallic alloys. Through the analysis of Laue zone sections, taken from the 3D reconstruction (tomogram) of the diffraction tilt series, it has been shown that the diffuse scattering can be described using a series of <111>* diffuse rods whose origin is likely to be small transverse displacements (shears) in the {111} planes brought about by changes in local atomic structure [5].

Microstructural assessment of mechanically alloyed low activation 9-Cr oxide-dispersion strengthened steels

Dr. Michael Thomas Duerrschnabel[1], Dr. Carsten Bonnekoh[1], Ute Jäntsch[1], Siegfried Baumgärtner[1], Henning Zoz[2], Dr. Michael Rieth[1]
[1]Karlsruhe Institute of Technology (KIT), Institute of Applied Materials, Hermann von Helmholtz Platz 1, Eggenstein-Leopoldshafen, Germany, [2]Zoz Group, Maltozstraße, Wenden, Germany

Poster Group 2

Background incl. aims
In the foreseeable future, it will become more and more necessary to boost energy efficiency to tackle challenges imposed by climate change. Therefore, higher process temperatures are fundamental. Oxide dispersion strengthened (ODS) steels can meet these requirements since they were developed as structural materials in extreme environments such as for example gas turbines, aerospace applications, and nuclear fusion reactors [1]. The latter application limits the use of acceptable elements to those exhibiting low activation [2].
ODS steels represent a class of advanced structural materials that possess compared to conventional type steels superior high-temperature strength and stability. The origin of these exceptional performance lies in their micro and nanostructure, which is characterized by a fine dispersion of nanoscale oxide particles in the steel matrix. These oxide nanoparticles hamper the motion of dislocations and grain boundaries by pinning. Typical oxide nanoparticles consist of Y_2O_3, Y-Ti oxides, Al_2O_3 or similar stable oxides [3].
Electron microscopy is used to characterize grain sizes as well as the size, number densities, structure and chemistry of oxide nanoparticles [3]. Additionally, unwanted nanoscale process remnants need to be monitored.
The aim was to study the mechanical performance as well as microstructure of the ODS steel to reduce the time required for mechanical alloying. When scaling to industrial-scale quantities this helps to reduce production costs.

Methods
Several kilograms of ODS material (Fe-9Cr-1W-0.2Ti+Y_2O_3) was processed by mechanical alloying of the powder under Ar atmosphere in a Simoloyer CM20 and after 5 h, 15 h, and 25 h milling time material was extracted. Afterwards, the material was HIPed at 1150°C and 100 MPa. Each material was tested for hardness and yield strength. Finally, the samples were analyzed by scanning and transmission electron microscopy using a Zeiss Merlin and a Thermofisher Talos F200X. Mainly, electron-backscatter diffraction (EBSD), energy-dispersive X-ray analysis (EDX) and electron energy-loss spectroscopy (EELS) were used.

Results
EBSD maps were employed to determine the grain sizes across different milling times using OIM Analysis. It was found that there is no significant variation in the grain sizes with milling time. In numbers, the average grain size evolved just slightly between 4.6 µm (5 h) and 4.8 µm (25 h) if evaluation with respect to number fraction was chosen.
Thus, TEM experiments were carried out to investigate the nanostructure of the materials and to look for trends depending on the milling time. STEM-EDX elemental mapping revealed that a trend that ODS particles split into two types at short milling times: Y-rich and Ti-rich, whereas at longer

milling times (> 15 h) Y-Ti oxides are observed. Average ODS particle sizes and particle number densities extracted from STEM-EDX elemental mappings are between 25 nm and 50 nm and in the order of 10^{20} particles per m^3 for all samples. The ODS particle size increases from 25 nm at 15 h to 50 nm at 25 h milling time whereas the number densities seem not to depend on the milling time. However, it was also found for all analyzed samples that the distribution of ODS particles is not homogeneous in all grains. In some sample regions, fine ODS particles are present inside grains whereas coarser particles are observed at grain boundaries. A meticulous analysis by EDX and EELS of single ODS particles at higher magnification revealed that some can have a complex chemical structure.
Additionally, the presence of Al-containing nanoparticles was noted, likely stemming from unintentional introduction during the production process. Moreover, nanometer-sized Ar bubbles, attributed to milling in an Ar atmosphere, were observed adhering to ODS particles. These bubbles exhibited an increasing number density with milling time, while maintaining a consistent average size.
Further analysis revealed a few micrometer-sized $M_{23}C_6$-type precipitates in some areas on the sample that can be attributed to excess carbon.
Tensile tests were conducted within the temperature range of 500°C and 800°C. The obtained yield strengths were about 350 MPa and 160 MPa for 500°C and 800°C, respectively. Hardness measurements exhibited no discernible correlation with milling time.

Conclusion
Electron microscopy revealed that a milling time between 5 h and 25 h does not change the microstructure significantly. ODS particle distribution varied, with finer particles within grains and coarser ones at boundaries. TEM revealed Y-rich and Ti-rich particles initially, transitioning to Y-Ti oxides with longer milling. ODS particle number densities showed no significant change with milling time. Some ODS particles had complex chemical structures. However, unintentionally introduced elements like Al or process-related elements like Ar must be closely monitored to ensure material quality and performance of the ODS steel.
Mechanical performance of the ODS material exceeds that of ODS-free material by roughly a factor of 3 at all temperatures.
Thus, the milling time could be reduced in a future industrial ODS steel production process.

Cholesteatoma removal efficiency evaluated by Variable Pressure Scanning Electron Microscopy

Prof Michela Relucenti[1], Prof Edoardo Covelli[2], Prof Orlando Donfrancesco[1], Prof Giuseppe Familiari[1], Prof Maurizio Barbara[2]
[1]Department of Anatomical, Histological, Forensic and Orthopedic Sciences, Section of Human Anatomy, Sapienza University of Rome, Rome, Italy, Rome, Italy, [2]Department of Neuroscience, Mental Health and Sensory Organs (NEMOS), Sapienza University of Rome, Rome, Italy, Rome, Italy

Poster Group 1

Background incl. aims
Cholesteatomas are well-defined non-cancerous cystic lesion that results from the aberrant development of the keratinizing squamous epithelium within the middle ear. They can erode into the CNS and cause severe complications thus surgical removal is needed and is usually performed by manual dissection 1 however, with the possibility of recurrence. To improve the effectiveness of this technique the combined use of Mesna 5% (sodium 2-mercaptoethanesulfonate) has been introduced, this method is called Chemically Assisted Dissection (CADISS®). Our work aimed to evaluate the effectiveness of this combined surgical procedure during middle ear cholesteatoma removal, in terms of the absence of residual pathological tissue.
Methods
6 incus bones involved in cholesteatoma and removed during surgery were randomly divided into 2 groups: a) 3 subjected to CADISS-assisted dissection; b) 3 subjected to manual dissection. Samples were fixed in glutaraldehyde 2.5% in PBS (0.1M, pH 7.4) immediately upon recovery for at least 24 hours. Samples were then washed in PBS and underwent OsO4 post-fixation for 1 h. After washing samples were impregnated with tannic acid 1% for 30 min, then washed, dried on absorbent paper, and directly observed at Hitachi SU 3500 at 30 Pa and 10 kV operating conditions. Images were analyzed by the software Hitachi Map 3D advanced 8.2 (Digital Surf, France) to provide quantitative measurements of cholesteatoma tissue debris on the incus bone surface 2.
Results
Our results show that CADISS-assisted dissection provides a better outcome in terms of clean surface area concerning manual dissection. Data from software-aided BSE image analysis revealed that the clean area/ total surface area ratio is higher in the CADISS method samples (19.7±3.61) than in the manual dissection group referred to as the control group (4.57±1.66), the difference is statistically significant as revealed by t-Test results ($t= 20.91$ $P<0.001$).
The ability of Variable pressure SEM is that observation of samples in their native hydrated state is possible. The absence of dehydration steps in sample preparation allowed the observation of the samples as they came from the operatory room, without any artifact due to the preparation procedure. It is mandatory to use a procedure that does not modify sample surfaces if a comparison between two different surface cleaning procedures has to be performed.
Conclusion
The use of VP-SEM allowed sample observation without dehydration procedures, decreasing the risk of losing the pathological tissue while ossicle processing and allowing the comparison of the surgical technique's effectiveness. Our study also shows how still is important a morphological approach in establishing new surgical technique validity and how the application of innovative image analysis software can transform Scanning electron microscopy from a qualitative imaging modality into a quantitative technique.

3D Electron Diffraction Study on the Local Structure of a doped Metal-organic Framework TCNQ@ZIF-4

Dr. Jianbo Song[1], Dr. Zhehao Huang[1]
[1]Department of Materials and Environmental Chemistry, Stockholm University, Stockholm, Sweden

Poster Group 2

Background incl. aims
Zeolitic Imidazolate Frameworks (ZIFs) become a more and more important sub-family of Metal-organic Frameworks (MOFs). ZIF-4 is one of the prototypical structures among ZIFs, which possesses the basic components of $M(im)^2$ (M = Co^{2+}/Zn^{2+} and im = imidazolate). Exclusive investigations have been applied on ZIF-4 such as mechanical properties[1] and thermal behaviors[2], however its conductivity is still missing.
Methods
7,7,8,8-tetracyanoquinododimethane (TCNQ) forms stable radical anions upon reduction, which can serve as an electron acceptor during the charge mobility.[3] Meanwhile, the transition metals, especially Co^{2+} are expected to donate electrons (i.e. to form Co^{3+}). The incorporation of TCNQ in the pores of ZIF-4 is expected to build up the pathway between the electron donor and acceptor to realize the mechanism of hoping transport[4]. A facial solvothermal method[5] was adopted to dope TCNQ@ZIF-4.
Results and Conclusion
Electron diffraction is revealing that the TCNQ has been successfully incorporated in the pores of frameworks. Further fine structures around the pore area urgently need to be resolved.

Poster Group 1

Rare-earth transition metal perovskite oxides illustrate strong correlations between atomic structure and functional properties (1). When deposited as thin films, this enables manipulation of their electronic properties, for instance by tuning their composition or strain state. To understand these correlations, Cs-corrected scanning transmission electron microscopy (Cs-STEM) has become an important tool to measure the deposited lattices, not only to resolve and identify atomic columns, but also to locate their positions with a few picometer precision.
In this study, we focus on rare-earth vanadate films of composition $LaVO_3$ that are grown, at different temperatures, by pulsed laser deposition (PLD) on (110) $DyScO_3$ substrates. The epitaxial strain resulting from the lattice mismatch between the $DyScO_3$ substrate and $LaVO_3$ film is supposed to be around +0.5% (film under tension). However, in a series of thin films, a change in $LaVO_3$ unit cell volume is observed that depends on the deposition temperature. A double-corrected FEI/Thermo Fisher Scientific Titan Themis 60-300 is used to study the different samples in STEM mode, operated at 300 kV with beam currents down to 50 pA. STEM images are recorded as 90° rotation series, which are then processed using rigid and non-rigid alignment to maximize measurement precision (2). Both the film and the substrate adopt a Pbmn orthorhombic lattice. Depending on the TEM lamellae orientation, different characteristic orthorhombic distortions of the sample can be probed. Data treatment using the open-source python library Atomap (3) coupled with an in-house library allows measurements of the various distortions, i.e., oxygen octahedral rotations and A-site cation antipolar displacements.
Here, we investigate in depth how the different PLD growth parameters affect the $LaVO_3$ film structure. As suggested by X-ray diffraction measurements, key factors include growth temperature and O_2 partial pressure. With the Cs-STEM measurements, we are able to monitor their effects in real space. In particular, we have recently identified a novel structural organization in the $LaVO_3$ film called the “switching plane,” where the orthorhombic long axis direction switches 90° due to a competition between opposing energetic influences on the film’s orientation (4). We study the influence of growth temperature (and unit cell volume), and O_2 partial pressure on the switching plane formation and location, as characterized by spatially mapping the magnitude and direction of the orthorhombic distortions across the film thickness. Our latest results suggest that induced strain state and/or thermal energy play major roles in defining the presence of this novel structural formation.

Restructuring of silver catalysts after oxidation reactions – looking beneath the surface

Dr Tina Bergh[1], Youri van Valen[1], Jia Yang[1], Ole H. Bjørkedal[2], Ann Kristin Lagmannsveen[3], Hilde J. Venvik[1]

Poster Group 2

Introduction

The silver catalysed partial oxidation of methanol is one of the most used industrial processes to produce formaldehyde globally [1]. The industrial catalysts take the form of unsupported silver particles, but it is not possible to run under differential conditions with a particle bed setup at a lab scale. Therefore, we instead use an annular reactor that enables operating at low oxygen and methanol conversions, isothermal conditions and suppressing unwanted gas phase reactions [2]. We study the methanol to formaldehyde reaction and its sub-reactions including oxidation of CO and H_2, with and without water in the feed. At elevated temperatures, oxygen dissolves into the silver, the silver restructures, and pinholes form [3]. Electron microscopy techniques enable us to get a complete view of the restructuring that extends beneath the silver surface. We aim to understand the structural changes as a function of the gas mixture and couple this to the kinetic studies.

Methods

Silver cylinders (Ø 10 mm, 10-20 mm length) were machined from rods (Goodfellow) and placed inside a narrow quartz tube reactor that extended upstream to ensure low path length and linear flow. Fresh silver catalysts were exposed continuously as they were heated up and held for 12, 36 and 84 h at furnace setpoints in the range of 620-650 °C. Gas chromatography enabled quantification of all products except for H_2O. Microstructural characterisation of the catalysts was done after subsequent cooling. For comparison, also fresh silver catalysts and catalysts heated in inert gas and air were characterised. Scanning electron microscopy (SEM) enabled studying large areas of the catalyst surfaces. Focused ion beam (FIB)-SEM tomography, slice-and-view, provided three-dimensional views of the silver grains and enclosed cavities beneath the surface. Further, we prepared cross-sectional lamellae using FIB, collected scanning precession electron diffraction (SPED) data in the transmission electron microscope and did orientation mapping using pyxem [4].

Results

The kinetic studies show that the conversion of CO is enhanced by H_2, while it is completely inhibited if H_2O is added to the feed. Moreover, the methanol conversion and selectivity towards formaldehyde increases with time if H_2O is added. The microstructural characterisation reveals that the fresh silver is decorated by surface scratches and has a nanocrystalline grain structure in the near-surface region. Drastic changes are seen after exposure to the various reaction atmospheres at elevated temperatures. All heated catalysts display larger grains with twins. Faceted pinholes and sub-surface cavities (Ø$\lesssim$10 µm) appear after oxidation of H_2 and syngas (CO and H_2), also with H_2O in the feed. For several catalysts, smaller rounded cavities down to a few nanometres in diameter can also be seen. Most of the heated silver catalysts show surface faceting and preferential exposure of {111} surface planes. An exception is the catalyst after methanol oxidation, which displays rounded surface features and no distinct faceting.

Conclusions
Kinetic data obtained from an annular reactor setup with cylindrical silver catalysts show how the catalyst activity changes with time in various gas mixtures. Microstructural characterisation using primarily FIB-SEM and SPED discloses the silver catalyst restructuring that has occurred after the different oxidation reactions. Distinct changes were documented in terms of grain structure, surface faceting and (sub)-surface pores. By combining the results from the characterisation and the kinetic studies, we explain how the reaction mixture and resulting restructuring affect the catalyst activity.

Deep learning powered light optical microscopy for steel reseach

Dr. Sarka Mikmekova[1], Dr. Martin Zouhar[1], Jan Čermák[1], Ondřej Ambrož[1], Patrik Jozefovič[1], Dr. Jiří Materna[2]
[1]Institute of Scientific Instruments of the CAS, Brno, Czech Republic, [2]Machine learning college, Brno, Czech Republic

Poster Group 2

Background incl. aims
Steel is by far the world's most important, multi-functional, and most adaptable material. The excellent mechanical properties of advanced steels are determined by their microstructure. The microstructure of advanced steels is a combination of different phases or constituents with complex substructures and its characterization is extremely challenging. The light optical microscopy (LOM) is a traditional, crucial, and dominantly utilized technique for investigation of steel microstructure up to now. The LOM has certain advantages over electron microscopes: extremely low-cost, low maintenance costs, fast and easy training of the staff, and easy accessibility. The biggest disadvantage of the LOM is limited spatial resolution. It makes this technique unsuitable for characterization of modern steels. This research aims to utilize advanced deep learning (DL) techniques to enhance the contrast and increase the amount of information in the LOM images of advanced steels.
Methods
Software-based transformation of low-quality images into their high(er)-quality equivalents is a challenging task. It is fundamentally impossible to create high-resolution images with more information than was stored in the original data without hallucinating the details. In this research, we propose that a proportion of the high-resolution information is already stored in the low-resolution images, however, it is hidden from human perception in the image blurriness, deformations and noise. A machine learning (ML) model can generalize about the general properties of the steel materials from their high-resolution images and therefore it can help to unlock more information from the LOM images beyond simple denoising and sharpening. This hypothesis was validated using a pilot proof of concept study concerning transforming LOM images into “pseudo” scanning electron microscopy (SEM) images using deep learning techniques trained on an image dataset of four types of steels. We tested different models and trained each of them to distill all important information from low-resolution images, to combine it with general knowledge of the investigated materials- to be generalized about by the model during training- and to generate high-resolution images. We started with a so-called U-Net neural network architecture [1] but eventually switched to a model based on Generative Adversarial Networks (GANs) [2]. This allowed us to achieve high precision and consistency in the generation process.
Results
Fig. 1 shows results of our pilot experiments. The first row displays as measured pre-processed data; the second row are transformed LOM images. As the labels indicate, the first column represents the U-net results, the rest are GAN results. We have marked some occurrences of several phases which may include: bainite (“B”), ferrite (“F”), pearlite (“P”) and secondary phases (“SP”), each example indicated by an arrow).
Conclusion
Even though the GAN transformation performs better than the standalone U-Net transformation, there is still room for further improvement. In future research, we intend to explore the efficacy of

employing diffusion models and vision transformers in the realm of image transformation. Specifically, our focus will be on enhancing the quality of images obtained through light optical microscopy to approximate the high-fidelity imagery characteristic of scanning electron microscopy.

High quality graphene TEM supports for high-resolution transmission electron microscopy

Jenthe Verstraelen[1], Dr. Adrian Pedrazo Tardajos[1], Dr. Nathalie Claes[1], Dr. Tine Derez[1], Prof. Dr. Sara Bals[1]
[1]EMAT, university of Antwerp, Antwerp, Belgium

Poster Group 2

Background incl. aims
Transmission electron microscopy (TEM) plays a critical role in the investigation of the atomic structure, morphology and chemical composition of nanomaterials. The field has significantly evolved during the last decade through the implementation of improved aberration correctors, novel detectors, more stable stages/holders and the implementation of many new low dose techniques. However, further progress in spatial resolution, contrast and potentially beam damage can still be achieved from improvements in sample preparation, particularly from the optimization of the TEM sample support.
The ideal sample support would be as thin and clean as possible in order to avoid interference with the sample signal, resulting in a background noise and a reduction of the contrast in the final (S)TEM image. Conventional grids consist of a fine metal mesh covered with an amorphous carbon layer (~20 nm), usually perforated with holes. For thin samples, this 20 nm is too thick to provide contrast, therefore a continuous support layer of 2 nm – 5 nm amorphous carbon is often used.
Graphene-based TEM grids have recently appeared as a promising alternative to the regular carbon coated TEM grids. Graphene, a monolayer of tightly bound carbon atoms, possesses exceptional properties. The monoatomic thickness of graphene minimizes the background signal, significantly improving signal to noise ratio which is crucial for high resolution imaging. Additionally, graphene's excellent electrical and thermal conductivity makes it an ideal candidate for dissipating excess heat and charge from the sample, mitigating electron beam induced damage.
However, to fully capitalize on the advantages of these new TEM grids, the graphene substrates need to be of exceptional quality. Therefore, we identify the current state of the art of the available graphene TEM substrates and discuss the existing problems with these grids and how these can be overcome.

Methods
Utilizing TEM and STEM, we evaluate key quality metrics of the currently available graphene TEM grids and discuss their relative importance. Based on these parameters, we compare the commercial grids with in-house made grids and discern their advantage in several advanced experiments.

Results
Unfortunately, depending on the transfer method and subsequent cleaning method, the graphene quality strongly fluctuates. Graphene grids are often plagued by cracks, folds, metal nanoparticles and polymer residues. Such impurities add background noise, introduce undesired obstructions in TEM images and degrade the conductive properties of the graphene. On the contrary, our in-house graphene grids alleviate some off these drawbacks, enabling previously unattainable experiments such as the visualization of surface ligands.

Conclusion

Current graphene TEM grids often lack the necessary quality for advanced experiments. Our in-house produced graphene TEM grids demonstrate significantly higher quality, enabling a set of previously unfeasible experiments.

Application of secondary electron hyperspectral imaging to the analysis of pharmaceutical materials

Stuart Micklethwaite[1], Rastra Basnet[1], Joseph Ma[1], Daniel Hopper[1], James Nohl[2], Nicholas Farr[2], Cornelia Rodenburg[2], Dr Nicole Hondow[1]

Poster Group 1

Background
The importance of pharmaceuticals to the health and wellbeing of society is clear, and it is of upmost importance to have reliable characterisation techniques applicable to the pharmaceutical manufacturing process. Pharmaceutical materials are often complex mixtures, containing multiple organic and possibly inorganic components. The stability and longevity of tablets can be increased through the addition of a coating, and this is evident in many commercially available pain relief medications. The effectiveness of the coating is linked to its surface coverage, and nanoscale characterisation is useful to determine this.
Secondary electron hyperspectral imaging (SEHI) is a recently developed novel electron microscopy technique that provides enhanced surface characterisation. Spectra sensitive to composition, chemical bonding and structure can be formed by collection of the secondary electrons that are emitted from a material following irradiation by an electron beam in the SEM. A variety of materials have been examined by SEHI, not limited to perovskites [1], polymer blends [2] and biomaterials [3], and various carbon materials [4]; however, the technique has not previously been applied to pharmaceutical materials.

Methods
SEM images and SEHI were collected using an FEI Helios G4 CX, a dual beam scanning electron microscope. The hyperspectral images were collected using a monochromated 1 kV accelerating voltage, a typical vacuum pressure of 10^-6 mbar, and a range of probe currents. Complimentary EDX spectroscopy has been undertaken using an Oxford Instruments 150 mm^2 EDX detector. An example commercially available pain relief tablet, Nurofen Plus, has been examined, in addition to reference materials ibuprofen, anatase and rutile. Samples have been prepared by both embedding in Field's metal and by FIB-prepared lamellae.

Results
Sample preparation is a particular challenge in this work, with the non-conductive pharmaceutical samples charging and causing anomalous features in the produced secondary electron spectra. Various sample preparation methods have been compared, each with advantages and disadvantages, with guidance from previous work with sample preparation of powder materials utilised [5]. The chosen commercially available pain relief tablet has a coating containing an inorganic pigment (TiO_2) which has led to the analysis of the different structures, anatase and rutile. The applicability of SEHI to the damage and integrity of the coatings has been examined, to assess this technique for the nanoscale characterisation of formulated pharmaceutical products.

Conclusions

In conclusion, this work will present the first analysis of pharmaceutical materials by secondary electron hyperspectral imaging. The advantages and challenges associated with this technique when applied to these materials will be detailed.

Poster Group 1

Background
Arsenic (As) is a naturally occurring metalloid found in soil and groundwater. As it can enter the food chain, As poses a serious environmental and health risk. In humans, the severity of symptoms of As poisoning depends on the dose and duration of exposure. Chronic exposure to low concentrations of As leads to dysfunction in virtually all body systems, including the impairment of the normal function of endocrine organs. Ovarian estrogens are the most important regulators of female fertility. Acting through specific receptors, estrogens regulate the growth and development of follicles, oocytes and granulosa cells in the ovaries as well as the function of ovulation. The aim of this study was therefore to determine the distribution of estrogen receptor α (ERα) in the ovaries of mice after administration of As(III)-oxide, which is considered to be the most toxic form of inorganic As.
Methods
Female mice from the Naval Medical Research Institute (NMRI, Bethesda, USA) aged approx. 6 months at the end of the experiment were used. Since birth, animals from the experimental group (n=6) drank water in which As(III)-oxide was dissolved at 10.6 mg/l, while the mice in the control group (n=6) drank tap water. For immunohistochemical localization of ERα in the ovaries of the mice, the sections were incubated with rabbit monoclonal anti-human ERα primary antibody (IR084, Dako, Agilent Technologies, Denmark), 1 h at room temperature and then visualized using EnVision FLEX, High pH (Link) system (K8000, Dako, Agilent Technologies, Denmark) for 30 min at room temperature. For negative control, primary anti-ERα antibody was omitted. After hematoxylin counterstaining, slides were analyzed with a Leica DMLB microscope (Leica Microsystems, Wetzlar, Germany).
Results
The control group is characterized by the preserved structure of the ovarian surface epithelium, under which there were numerous follicles in various stages of development as well as numerous corpora lutea and stromal cells. The results showed that the expression of the estrogen receptor was more pronounced in the experimental group than in the control group. A particularly positive response was observed in the corpora lutea, the secondary follicles, and the granulosa cells of the antral follicles, while immunostaining was absent in the stromal cells.
Conclusion
The present results show that chronic arsenic exposure affects the pattern and intensity of ERα-immunoexpression, suggesting involvement in the impairment of estrogen signaling with possible disruption of reproductive function.

Pathogenic variants of the J-domain protein and Hsp70 cochaperone DNAJC12 cause parkinsonism, which seems associated with a defective interaction of DNAJC12 with tyrosine hydroxylase (TH), the rate limiting enzyme in dopamine synthesis. Here, we report the characterization of TH:DNAJC12 complex formation, showing that DNAJC12 binding stabilizes TH and delays its time-dependent aggregation in an Hsp70-independent manner, while maintaining TH activity and regulatory inhibition by dopamine. Interestingly, although DNAJC12 alone is less efficient than other DNAJs to activate Hsc70, the TH:DNAJC12 complex efficiently stimulates its ATPase activity. Cryoelectron microscopy reveals two DNAJC12 monomers bound per TH tetramer, each embracing one of the two regulatory domain dimers, leaving all active sites available for substrate and dopamine interaction. Biochemical data confirm the key role of the DNAJC12 last eight residues in TH binding, explaining the molecular disease mechanism of C-terminal truncated DNAJC12 variants.

LS-09, Lecture Theater 4, august 27, 2024, 14:00 - 16:00

Background
For more than 30 years, since the discovery of WNTs, WNT/β-catenin and planar cell polarity signaling has formed the basis for what we understand to be the primary output of the interaction between the protein ligands of the WNT family and their receptors known as FZDs (ten isoforms: FZD1-10). FZD7 is one of the best characterized receptors within the family and plays a critical role in many biological processes including migration of mesendoderm cells during development and renewal of intestinal stem cells in adults. Moreover, FZD7 has been highlighted for its involvement in tumor development predominantly in the gastrointestinal tract. This research aims to provide a better understanding of FZDs in general with a highlight on FZD7 by combining structural, computational, and pharmacological tools.

Methods
In this study, we apply a combination of conventional cryo-electron microscopy (cryo-EM) single particle analysis, MD simulations, and phylogenetic analysis to draw FZD family-wide conclusions on structural aspects and mechanisms of FZD activation. These data are complemented with pharmacological experiments employing genetically encoded biosensors to functionally validate our structural findings. This comprehensive approach provides us with insights into the function of FZD7 specifically, as well as FZDs in a broader context.

Results
We report the structure of inactive FZD7, without any stabilizing mutations, determined by cryo-EM. This allowed us to provide a direct comparison with the G protein bound FZD7 and to confirm previously identified residues involved in G protein binding mechanism.
We characterized a fluctuating water pocket in the core of the receptor important for FZD7 dynamics and used a phylogenetic analysis to define conserved residue defining the water pocket base that remains hermetic upon G protein binding unlike what is observed in Class A GPCRs. Molecular dynamics simulations were then used to investigate the temporal distribution of those water molecules and their importance for potential conformational changes in FZD7. Additionally, we discovered lipids that interact with the receptor core and a conserved cholesterol binding site. This site plays a pivotal role in the association of FZD7 with a transducer protein, Dishevelled (DVL), and in the initiation of downstream signaling and the formation of signalosomes.

Conclusion
We provided a high-resolution structure of FZD7 and defined functionally relevant features of FZDs dynamic and signaling.

Poster Group 2

4D-STEM has thrived thanks to the emergence of fast pixelated detectors in the last few years. The latter enables recording the rich information of the diffraction patterns in STEM [1]. This also makes it possible to map magnetic and electric properties at microscopic scales using methods like Center-of-Mass (CoM) and electron ptychography. Compared to conventional imaging techniques in STEM, electron ptychography enables imaging of the materials beyond the aberration-limited resolution with an optimal use of electron dose. The resolution achieved by this technique was demonstrated to be as small as 20 pm [2], and the ability to recover the diffraction pattern outside the detector plane allows for super-resolution imaging [3]. Quantitative ptychography, where the potential change over an atom can be directly related to the present chemical species combined with the effect of bonding, will have many applications, but has yet to be demonstrated in literature. Since, to the best of our knowledge, no publication directly compares experimental ptychographic reconstructed phase/potential maps or profiles with simulated data, quantitative ptychography appears still challenging.

In this presentation, 4D-STEM diffraction maps of WSe2 were simulated using abTEM[5]. Then the datasets were reconstructed using electron ptychography on the simulated diffraction maps using different reconstruction algorithms, namely ePIE and difference map (DM), implemented in the PtyPy[4]. The reconstructed diffraction pattern as well as the object function were compared using the ground truth of the input to the simulation, to better understand the strengths and weaknesses of both algorithms. The influence of padding was evaluated on the reconstructed data. Finally, this study allows comparison with reconstructions on experimentally obtained 4D-STEM maps on WSe2 or other 2D materials, intending to develop a method of quantifying the electrostatic potential.

The simulations for the 4D-STEM dataset were done on monolayer WSe2 with focused and defocused probes working at 80 kV with abTEM. The convergence semi-angle is 20 mrad. The diffraction patterns were sampled at 0.41 mrad/pixel and then cropped to a size of 256x256 or 512x512. This results in a collection angle of 51.7 mrad and 103.4 mrad at the edge. The dataset of diffraction patterns of size 256x256 was then fed to the ptychography reconstruction using ePIE and DM in the python package PtyPy: One with added padded zeros around the diffraction pattern up to doubled collecting angle and one without. An extra reconstruction using padded diffraction patterns up to 1024x1024 was done to see if it affected the recovered diffraction pattern. An analysis of a random diffraction pattern generated from the reconstructed probe and the reconstructed object function is shown in Fig. 1. While the reconstructions without padding show a good agreement with the original diffraction pattern, the reconstructions with padding fit the original pattern even better. However, for padded reconstruction, ePIE failed to recover the signals while DM smoothly transits and continues to fit outside the detector region. Further analysis of the power spectrum of the object

function exhibits a similar tendency that can be observed: until about 1.65 Å-1, padded ePIE reconstruction (orange dashed profile) matches the input simulation well, while DM matches up to a cutoff at 1.75 Å-1. The same analysis with extra padding up to 1024x1024 shows no significant signal improvement, implying that the effect of padding has a limited reach.

This work presented a possible method to quantitatively analyze the electrostatic potential of the monolayer WSe2. Padding in the reconstruction can improve the resolution, however, is limited. Moreover, the comparison between low-pass-filtered ground truth and reconstructions with a simulated finite-sized detector shows quantitative agreement. Care must therefore be taken in experiments since this finite-size constraint is always present.

Poster Group 1

Chaperonins, also known as Hsp60s, are a family of chaperones whose structure consists of two juxtaposed oligomeric rings with a cavity in their interior, where the folding process takes place. CCT (Chaperonin Containing TCP-1) is the most complex of all chaperonins, and it participates in the folding of over 10% of newly synthesized proteins (1). There are many evidences that prove that CCT plays a crucial role in the development of different diseases. The first of these diseases is cancer, where CCT has shown to be upregulated, promoting tumor growth and mobility. Furthermore, CCT inhibition has been linked to tumor regression (2,3). On the other hand, CCT has been observed to be inhibited during neurodegenerative diseases such as Huntington disease, in accordance with the fact that CCT can inhibit the aggregation of polyQ proteins in vitro and in vivo (4,5). Although CCT has proven to play a critical role in the development of many diseases, there has been no relevant effort in the discovery of small molecules capable of modulating the activity of this proteins with a potential therapeutic effect, probably due to the structural complexity of the chaperonin. That is why in this work we screened the compounds included in the Prestwick chemical library using Differential Scanning Fluorimetry, from which three stabilizers and five destabilizers were identified. We then performed functional assays in order to characterize the effect that these small molecules have over CCT. ATPase assays have allowed us to identify two molecules that inhibit both activities of CCT, and another molecule that enhances them. Folding and binding assays are being currently carried out. We have optimized the vitrification conditions for CCT in the presence of small molecules diluted in DMSO, a solvent that prevents the proper distribution of the chaperonin in the cryo-electron microscopy grids. This has allowed us to carry out several preliminary 3D refinements: a ~5 Å resolution volume of CCT incubated with the inhibiting molecule Drug 2; a ~4 Å volume of CCT incubated with the activating molecule Drug 5; and a ~3.2 Å resolution volume (at the equatorial domains) of CCT incubated with HSF1A-biotin, a labelled derivative of an endogenous inhibitor of the chaperonin. Several protocols are now being used in order to identify extra densities which could be attributed to each of these small molecules bound to CCT. This structural information provides precise insight on the inhibiting mechanism of this small molecule, and supports its use as an inhibitor of the CCT chaperonin. These results may set the basis for the development of new drugs targeting CCT.

Using super-resolution imaging to understand protein organization within Z-discs of striated muscle.

Prof Michelle Peckham[1], Dr Alistair Curd[1], Dr Ruth Hughes[1], Dr Heather Martin[1], Dr Anna Tang[1], Dr Francine Parker[1], Dr Christian Tiede[1], Dr Darren Tomlinson[1]
[1]Faculty of Biological Sciences, University of Leeds, Leeds, UK

LS-03 (1), Lecture Theater 4, august 26, 2024, 15:00 - 16:00

The Z-disc is a complex structure found at the ends of muscle sarcomeres in striated muscle. It is approximately 100nm in width and comprises over 30 different proteins, which play key structural and signaling roles. However, we have little understanding into how these proteins are organized. Electron microscopy approaches have so far been unable to resolve the positions of most of these proteins. Light microscopy approaches are hampered by low resolution, failure of antibodies to penetrate the dense Z-disc structure (Parker et al., 2023), and the large size and flexibility of antibodies is not well suited to super-resolution fluorescence microscopy approaches. Affimers, are small (~10kDa, 3-4 nm in size) non-antibody binding proteins, developed at Leeds, that overcome the challenges of imaging the organization of proteins within the Z-disc (Cordell et al., 2022; Tiede et al., 2017). Their small size means that they penetrate the Z-disc better than antibodies and that they only introduce a small linkage error, as fluorescent dye molecules conjugated to Affimers are close to the epitope of interest.
Here, we have used Affimers to begin to determine protein organization within the Z-disc, using dSTORM. We isolated Affimers against at >10 different Z-disc protein epitopes, targeting titin, α-actinin-2 (ACTN2), ZASP (LIM domain-binding protein 3), myotilin, capping protein, and others. To achieve this, we expressed and purified domains using E.coli from each of these proteins, using a 'BAP' tag (biotinylation site) to ensure that the proteins are biotinylated as they are expressed, and a HIS tag for purification. Purified proteins were used in a phage display library to isolate binders, which were then subcloned, an unique C-terminal cysteine added for subsequent conjugation of the purified Affimers to fluorophores via a maleimide linkage, and the Affimers expressed and purified from E.coli (Tiede et al., 2017). Purified, dye labelled (e.g. Alexa 647 for dSTORM and iPALM) Affimers were used to label myofibrils isolated from mouse or pig hearts and imaged using an Abbelight dSTORM microscope. Alternatively, Affimers were fused to mEos3, expressed and purified and used in labelling. The resulting image datasets (xyz localisation) were analysed using PERPL to gain a better understanding of their organisation with Z-discs (Curd et al., 2015). We have now successfully tested these Affimers in STED, dSTORM and in iPALM, and the results reveal that Affimers penetrate the Z-disc much better than antibodies, and the overall organisation of specific Z-disc proteins with high (~15nm or better), X,Y and Z resolution.

PS-01 (2), Lecture Theater 3, august 28, 2024, 14:00 - 16:00

The properties of two-dimensional (2D) materials generally depend on their architecture, e.g. the number of layers in a stack, the interlayer distance or the layer functionalization. Focusing on the most studied MXene compound to date, i.e. Ti3C2Tx 2D layers (where T-groups usually correspond to O, OH, F and/or Cl surface terminations inherited from the synthesis process), it has been shown that physical properties have a significant dependence on the number of layers in few-layer stacks. Beyond their thickness, MXene properties are also very sensitive to the interlayer distance which can be increased by intercalation of ions and/or molecules, or reduced by removing the interlayer intercalated water. In order to evidence the thickness/properties interplay in this rich family of 2D materials, one thus needs to precisely determine the architecture of a given MXene few-layer stack during TEM experiments. In this context, we show that valence EELS (VEELS) which corresponds to the excitation of the materials valence electrons, combined to density functional theory (DFT) simulations, provides a direct way to quantify (i) the number of layers in Ti3C2Tx few layer stacks for thicknesses up to ~10 layers, and (ii) the average inter-layer distance. [1]
Figure 1 shows a comparison between experimental VEEL spectra recorded on different Ti3C2Tx multilayers and the spectra simulated for different numbers of layers. To push the comparison quantitatively the mean squared error between experiments and simulations has been plotted, allowing to determine the exact number of layers in the thinnest samples. In addition, the position of the main peak, corresponding to the bulk plasmon, is closely correlated with the distance between sheets in the stack. Its shift can thus be used to estimate interlayer distance variations in a MXene multilayer with nanometer scale resolution
Finally, the thickness of a sample can also be obtained through diffraction measurements and intensity profiles STEM-HAADF analysis. Therefore in order to validate the thickness measurements obtained by the VEELS method, position averaged CBED (PACBED) patterns and STEM-HAADF images were recorded on the very same areas of the Ti3C2Tx MXenes. Different families of reflections exhibit different behavior of their pendellösung allowing to determine the sample thickness by comparison between experimental and simulated intensity ratios (Figure 2). PACBED and STEM-HAADF analysis confirm the outcomes of the VEEL spectra analysis.

Analysis of fire gilding on medieval jewellery using focused ion beam

Jan Manak[1], Jan Duchon[1], Estelle Ottenwelter[2]
[1]Institute of Physics of the Czech Academy of Sciences, Prague, Czech Republic, [2]Institute of Archaeology of the Czech Academy of Sciences, Prague, Czech Republic

Poster Group 2

Fire gilding was a frequently used decorative method in the manufacture of medieval jewellery. Standard metallographic preparation of gilded samples often results in deformation of soft gilded layer resulting in an altered microstructure. For that reason, focused ion beam (FIB) milling is particularly well adapted since it allows to obtain damage free cross-section cuts to analyse fragile gilded layer as demonstrated by previous studies on hollow spherical pendants known as gombiky from the 10th century [1]. To compare the skills of the craftsmen in fire gilding in terms of thickness and porosity on other gombiky, more specimens from the same archaeological context were investigated. A characterisation of the gilding layer was also performed to determine the sublayer structure observed in previous studies [1] and to distinguish different metallic phases present in the gilding layer.
Microstructure was examined by scanning electron microscopy (SEM). Energy dispersive spectroscopy (EDS) and electron backscatter diffraction (EBSD) were used to determine chemical composition and crystallographic structure of gilded layers. Samples were then further investigated in more detail by transmission electron microscopy (TEM). Automated crystal orientation mapping (ACOM) was used for thorough examination of the sublayers.
The analysis revealed that gilded layer consists of several Au-Hg-Cu-Ag phases and Cu-Ag precipitates. Amorphous silicon residual from final polishing of gombiky after fire gilding process is also present in the microstructure of gilded layer. Furthermore, it is shown that there is a sublayer gold structure formed on interface between gilded layer and copper substrate. This sublayer is also visible around voids in gilded layer which are created by evaporation of mercury during fire gilding process.
The precise characterisation of gilding layers revealed different quality of the layers; therefore, confirming different level of skill and knowledge of craftsmen in fire gilding. The two-layer structure of the fire gilding layer was observed in all cases. Further information concerning the metallic phases present in the gilding were evidenced.

Denoising 4D STEM datasets with PCA

Leonid Potapov[1], Mingjian Wu[2]
[1]temDM, Dresden, Germany, [2]IMN&CENEM, Friedrich-Alexander Universität, Erlangen-Nürnberg, Germany

Poster Group 1

Background incl. aims
4D Scanning Transmission Electron Microscopy (4D STEM) provides crucial insights into materials structures by utilizing Differential Phase Contrast (DPC), ptychography, orientation and strain mapping. However, 4D STEM datasets often suffer from noise, hindering accurate analysis. It would be desired to denoise 4D STEM data by Principal Component Analysis (PCA) as it was successfully applied for EELS and EDX STEM datasets [1]. Additionally, PCA allows for accurate separation of the constituting compounds by clustering in the latent PCA factor space.

Methods
The sample used for this demonstration is organic solar cell blend DRCN5T:PC71BM solvent vapour annealed in chloroform. The 4D STEM dataset was obtained in micro-probe STEM (convergence angle ~1 mrad) with a Titan Themis microscope operating at 300kV. The data was collected using a OneView IS detector operating at frame rate of 400 fps (2.5 ms frame time) and probe current of about 5 pA.

We developed a Python-based PCA routine and integrated it into the temDM in-house developed 'Spectrum Imager' tool. This tool, originally designed for visualizing and denoising EELS and EDX spectrum-images [2], is presently adapted for 4D STEM datasets processing, including re-centring, clipping, viewing with virtual circular/ring apertures et cet. [3].

Results
When scanning the focussed beam across a sample, a shift of the diffraction pattern inevitably occurs, known as the pivot effect. While this effect can be minimized through accurate instrument tuning, it cannot be eliminated completely. We found that even a slight pivot effect dramatically influences PCA results, overriding any structural variations. In the considered example, the pivot shift within the scanned field of view was less than 2 pixels. Nevertheless, the data variation in the PCA factor space predominantly reflected the pivot variation rather than the structural changes in the sample (Fig.2, upper).

The diffraction shift was measured with the sub-pixel precision in each individual diffraction pattern using the centre-of-mass method. It important to note that simply centring the patterns is not an option as this would preclude any DPC measurements. Instead, we assumed that the pivot shift changes linearly along both x- and y- directions and calculated this by the least-square fit. The diffraction patterns were then shifted with the cubic-spline interpolation to account for the linear pivot. After the consequent PCA, the principal components clearly revealed the structural changes in the sample (Fig.2, lower).

Conclusion

4D STEM datasets can be successfully denoised by PCA, however it requires precise data pre-processing, particularly addressing the pivot shift. The sub-pixel interpolation is mandatory for the accurate subtraction of the pivot shift.

Figure caption
Impact of pivot correction on PCA results. The clusters are selected as hypercylinders in the latent PCA factor space. Without correction, instrumental pivot shift dominates in the PCA factor space. After correction, clustering in the factor space clearly reveals the structural compounds.

Poster Group 2

Background including aims.
Misfit layered compounds (MLCs) have garnered considerable attention due to their fascinating chemistry and properties [1]. MLCs consist of two different layered oxides or chalcogenides that are stacked alternately along their c direction. The MLC stack is composed of metal chalcogenide (MX) which possesses a distorted rock salt structure and a transition metal dichalcogenide (TX2) which crystallizes in a hexagonal structure [1,2]. The properties of MLCs are determined by the chemical and structural interplay between MX and TX2. MLC-nanotubes (NTs) synthesized via the chemical vapor technique (CVT) offer potential applications in thermoelectrics due to the complementary properties of the two layered compounds [1]. Recently, a modified synthesis method of MLC-NTs has permitted the introduction of additional elements to form a quaternary compound starting from LaS-TaS2 [3,4]. Here, we present an in-depth electron microscopy analysis of the novel family of (SmxY1-x)S-TaS2 nanostructures [5]. In this novel family, the partial exchange of Sm(S) by Y(S) provides a pathway for the fine control of the MLC structure and its properties.

Methods
MLC-NTs made of (SmxY1-x)S-TaS2 were synthesized via the CVT technique [1-3] by varying the precursor proportions of Sm vs Y between x=0 to x=1. The samples will be designated by the Sm percentage, Sm20 corresponds to (Sm0.2Y0.8)S-TaS2 and similarly. To analyze these NTs, different TEM techniques (high-resolution (scanning)TEM (HR(S)TEM) imaging, selected area electron diffraction (SAED), electron energy loss spectroscopy (EELS) and energy-dispersive X-ray spectroscopy (EDS)) were performed. These TEM studies were developed using two aberration corrected Thermo Fisher Scientific Titan microscopes. Raman spectroscopy has also been employed to study these NTs.

Results
The detailed analysis of the NTs by electron microscopy and different spectroscopies verifies the partial substitution of Sm by Y in the (Sm,Y)S subsystem and also reveals the structural changes when compared to the pure SmS- or YS-TaS2 MLC-NTs. These structural changes can be linked to the slight difference in the lattice parameters of SmS and YS. Figure (a) corresponds to the SAED pattern of Sm40 (Sm0.4Y0.6)S-TaS2 sample where the reflections marked by the green dotted circles represent the reflections from (Sm,Y)S and reflections marked by red dotted circles represent the TaS2 subsystems, respectively. The c-axis periodicity (1.13 nm) is indicated by yellow arrows. The c-axis is perpendicular to the tube axis, which is given by the purple double arrow. A high-angle annular dark-field STEM image of a Sm80 NT is shown in Figure (b) and illustrates the repetitive layer stacking of (Sm,Y)S and TaS2. The inset of (b) shows a low-magnification TEM image of the Sm80 NT. Figure (c) depicts a Raman spectrum acquired from an individual Sm80 NT, which was fitted using a set of

Lorentz functions. In a vibrational spectroscopy such as Raman, a Lorentz line shape is used to model pure vibrational modes, which only undergo homogeneous line broadening. Raman spectroscopy measurements of the whole set of samples reveal the tunability of the vibrational properties of these NTs. The study of the elemental composition of these NTs by EDS is shown exemplary for a NT of the Sm80 sample in Fig 1(d), which reveals an average atomic weight percentage of around 17 at. % Ta, 24 at. % Sm+Y, and 59 at. % S. The EDS results obtained from all the samples show that the substitution of Sm by Y is homogeneous and in-phase with structural changes in the lattice parameter. Further low-loss EELS studies and electric properties of these samples are in progress. These investigations will also provide a more complete understanding of these systems including their electronic/optoelectronic properties.

Poster Group 2

In nanoscience, the fabrication of multifunctional nanomaterials with unique properties as well as their optimization is an ongoing challenge. The synthesis by gas cluster aggregation source (GAS) offers the opportunity to fabricate a wide range of nanoparticles in terms of particle size, morphology and chemical composition in a single preparation step.
In this work, nanoparticles from titanium oxide (TiOx) and gold (Au) are fabricated by GAS from a single multicomponent target.
The morphology of the resulting particles is analyzed by bright field transmission electron microscopy (TEM) as well as high angle annular dark field (HAADF) scanning TEM (STEM). The crystal structures are determined by selected area electron diffraction (SAED), high resolution TEM (HRTEM) as well as high resolution STEM (HRSTEM). Energy dispersive X-ray spectroscopy (EDX) is combined with STEM to gain local information on the chemistry of the particles. X-ray photoelectron spectroscopy (XPS) as well as X-ray diffraction (XRD) are applied to confirm and complement the results from TEM.
In TEM, the nanoparticles were observed to consist of several Au cores embedded in a TiOx matrix, resulting in a multicore@shell (Au@TiOx) morphology. The Au was present in its standard cubic crystal phase while TiOx was found to be in the amorphous state. Changes in the GAS source pressure were applied to alter the particle size and deposition rate. Upon heat treatment for 1 h at 500 °C in air, the TiOx crystallized to anatase TiO2 while the Au partially formed larger particles and partially diffused to the surface of the nanoparticles.
The preparation of Au@TiOx nanoparticles by GAS gives the possibility to prepare nanoparticles of complex morphology. Heat treatment of the material can be applied to tailor the crystal structure of the TiOx as well as the distribution of the Au. This approach can solve the issue of poor adhesion of Au on TiO2 since Au nanoparticles are mechanically fixed in a TiO2 matrix. The approach of GAS preparation of multicomponent nanoparticles can in principle be applied to a broad variety of materials and material combinations.

IM-03 (1), Plenary, august 28, 2024, 10:30 - 12:30

Development of state of the art electric and magnetic devices requires high resolution characterisation techniques, one such being scanning transmission electron microscopy – differential phase contrast (STEM-DPC), which gives quantitative magnetic information while allowing concurrent acquisition of structural and chemical information in the same sample area. Magnetic STEM-DPC characterization relies on detecting minute shifts of the electron probe, often in the range of a couple of microradians. At highly diffracting conditions, the electron probe can get heavily distorted, making it difficult to extract the small shifts caused by the in-plane magnetic field.
In this work, we acquired STEM-DPC datasets using a 4D-STEM detector on a monocrystalline magnetic freestanding La0.7Sr0.3MnO3 (LSMO) thin-film. We acquired several tilt orientations at a temperature of -150.0˚C, giving a systematic overview of diffraction induced distortions on probe shape and magnetic signal. Fig. 1 shows two STEM-DPC images from low- and high-diffraction conditions together with probes and line profiles as indicated on the figure, clearly demonstrating the distortive effects of diffraction. Tilt series were done at increasing angles away from the zone axis and with a constant off-axis angle but rotating around the zone axis. By examining the random variations in the STEM-DPC signal and comparing to the difference in signal between magnetic domains, a quantitative value for the signal to noise ratio was obtained.
This presentation will show which considerations and mitigation measures should be used to optimise STEM-DPC imaging in heavily diffracting samples, and how different data processing algorithms handle the distortions in the electron probe.

Operando Environmental TEM observations of SOEC Ni-YSZ fuel electrode dynamics

Mr. Magnus Björnsson[1], Mr. Søren Simonsen[1], Mr. Ming Chen[1]
[1]Department of Energy Conversion and Storage, The Danish Technical University, Kgs. Lyngby, Denmark

Poster Group 1

Power-to-X is emerging as a key player in the decarbonization of our energy infrastructure and at its core is electrolysis. The most efficient electrolysis technology is Solid Oxide Electrolysis Cells (SOEC) [1] however, large scale implementation has been halted by the concerns regarding loss of efficiency caused by degradation. The most important degradation process occurs in the Ni-Yttria stabilized zirconia (YSZ) fuel electrode. The driving factors are changes in Ni particle morphology and wetting angle, which are suggested to be correlated to the local SOEC operating conditions [2, 3]. Previous studies which have set out to investigate changes to the Ni morphology during SOEC conditions have only done so using post-mortem analysis where the sum of all the experimental parameters are observed. This makes it difficult to identify the correlation between the local test conditions and the morphological changes to the Ni particles.

To study the dynamic electrode processes occurring under standard SOEC operating conditions, we apply a newly developed operando electrochemical environmental transmission electron microscopy (ETEM) method [4, 5]. The method is adapted so that it allows us to follow the morphological changes of Ni particles in Ni-YSZ fuel electrodes, enabling us to map the degradation as a function of operating conditions. The aim of this project is to bring SOEC technology ahead by determining a so-called safe operational window which can limit, or possibly eliminate, the detrimental and irreversible degradation of Ni-YSZ fuel electrodes.

Sample preparation is carried out with a Zeiss FIB-SEM dual-beam which enables micromachining of bulk samples. The prepared samples are placed on a MEMS-chip from DENSsolutions which is capable of simultaneous heating and biasing. The finalized samples are imaged using a TITAN ETEM which allows the samples to be subjected to a reactive gas environment. Our method presents a novel way of studying the dynamic processes occurring in Ni-YSZ fuel electrodes as a function of real-life operating conditions. This will allow us to determine a safe operational window in which the most severe degradation can be avoided. This will ensure longer operating lifetimes of SOEC and make the technology more desirable in terms of large-scale implementation and ultimately advancing the decarbonization of our energy infrastructure.

Poster Group 2

Patients suffering with type 1 diabetes show a major reduction of beta cells within their endocrine pancreas. To gain deeper insights into mechanisms of beta cells, correlative electron microscopy was the method of choice to understand the ultrastructure of insulin producing beta cells. The first step of this workflow was scanning electron microscopy employing the STEM (scanning transmission electron microscopy) detector. STEM images were generated with the benefit of great overviews on the one hand and giving information on cell interaction and arrangement within the entire organ at high resolution on the other hand. For an even more detailed investigation a suitable region of interest (ROI) in the pancreatic islets was preselected on STEM images. The sample was subsequently observed in the transmission
electron microscope (TEM) which was possible without any further processing. To gather more information on the respective healthy and diabetic phenotypes, we used a deep
learning-based approach to achieve high classification accuracy when discriminating between healthy and NOD samples of beta cells. We further explored the link between the number of granules in a sample and the healthy/NOD class it belongs to. Applying this insight to train neural networks that jointly learn both classification and counting tasks or rely on transfer learning strategies, performance on classification is improved. The additional counting tasks allow for a more robust representation, which is especially useful since only limited data are available. The findings strongly support the underlying hypothesis that early onset diabetes leads to a reduction in insulin-containing granules. Nevertheless, classification on its own already delivers strong results: There are additional factors other than the number of granules that play a major role in the decision process, such as changed appearances in the granules themselves or the surrounding tissue.

Structure and Composition of High-Entropy-Alloy Nanoparticle synthesized by Pulsed Laser Ablation in Liquid

Felix Pohl[1], Robert Struckert[2], Dr. Ulrich Schürmann[1], Dr. Christoph Rehbock[2], Prof. Stephan Barcikowski[2], Prof. Lorenz Kienle[1]
[1]Institute for Material Science, Faculty of Engineering, Kiel University, Kiel, Germany, [2]Technical Chemistry I and Center for Nanointegration Duisburg-Essen (CENIDE), University of Duisburg-Essen, Essen, Germany

Poster Group 2

Background incl. aims
Recently, synthesis of colloidal alloy nanoparticles (NPs) by pulsed laser ablation in liquid (LAL) was successfully transferred to high entropy alloy (HEA) systems. HEA NPs are particularly interesting for heterogenous catalysis and form a simple solid solution structure despite their high chemical complexity. In this work the influence of the target composition, solvent and laser pulse duration on the structure as well the chemical composition of these NPs is investigated. Two HEA systems are chosen: CoCrFeMnNi (Cantor) and AgAuCuPdPt (Noble metal). While in preliminary work crystalline and amorphous NPs with oxide-shells were found, it is unclear to what extent the excess of one element in the base target leads to elemental segregation not dominated by oxidation.
Methods
The nanoparticles were synthesized by LAL in a circulating solvent (Acetone vs. Ethanol) and NIR-laser pulse durations (10 ps vs. 10 ns pulse duration) and characterized in (S)TEM. For chemical analysis methods like Z-contrast imaging and nanoprobe elemental mapping were applied, while the structural analysis was performed using methods like TEM-high-resolution phase-contrast imaging (-HR imaging) and selected area electron diffraction (SAED).
Results
All Cantor alloy systems show a pulse energy dependency of the phase structure with fcc solid solution with ps-lasers and amorphous NPs with ns-lasers, while additional core-shell and multi-core structured NPs driven by Mn and Cr oxidation are also found. Further, oxide-core-multi-shell NPs were observed where localized target oxidation could provide nuclei for their formation. Interestingly, a predominant fcc-structure without pronounced elemental segregation was found upon enrichment of Mn or Cr in the system synthesized with the ps-laser. Further, NPs synthesized by the ns- laser maintained their amorphous structure upon enrichment of either Cr or Mn however additional crystalline oxides were detectable.
The noble metal systems showed no segregation into core-shell or multi-core structured NPs. Instead, two solid solution NP fractions appear, which are Ag-rich and Pt-rich. Contrary to the Cantor alloy systems and verified by HR-imaging the noble metal NPs retain their crystalline structure when synthesized with ns-lasers, although some hints on amorphous structures in Cu-rich and Ag-rich NPs based on SAED warrant further examination.
Conclusion
In conclusion, the Cantor alloy system shows the possibility of amorphous and crystalline solid solution NPs controlled by the laser pulse duration. Segregation into core-shell, multi-core or even oxide-core-multi-shell NPs is dominated by oxidation. The noble metal system displays de-mixing tendencies between Ag and Pt resulting in two solid solution NPs fractions. This could hint towards different cooling rates during particle formation offering insights into the HEA formation mechanism by LAL.

Towards customized in situ TEM Chips for “device-like” geometries

Marthe Linnerud[1], Ingrid Hallsteinsen[2], Magnus Nord[1]
[1]Department of Physics, Norwegian University of Science and Technology, Trondheim, Norway,
[2]Department of Materials Science and Engineering, Norwegian University of Science and Technology, Trondheim, Norway

Poster Group 1

Functional nanostructures and thin films have applications within the next generation of memory storage, energy storage, quantum computers and sensor technology [1,2]. Their characteristic properties originate from the nano or even atomic scale, necessitating the combination of high-resolution techniques and imaging of functional properties to better understand their structure-property relationships. Scanning transmission electron microscopy (STEM) can be used to capture the structure, chemical composition, and functional properties of these materials.

For in situ STEM characterization, the material of interest must be transferred to an electron-transparent region of a TEM chip. For thin films, this means depositing it on the membrane of a commercial TEM chip, or alternatively, transferring it by FIB lift-out or similar techniques. However, for larger systems consisting of nano- or micro-sized structures relevant for prototyping of new device concepts, this quickly becomes challenging, as the field of view required for such geometries may be many times larger than what is feasibly prepared by plan-view FIB lift-out. An alternative approach would be to fabricate these “device-like” structures directly on the TEM membrane. However, performing advanced lithography steps on a fragile, pre-made, electron-transparent window involves a non-negligible probability of fracturing it. We aim to solve this by fabricating TEM membranes directly from the substrate, etching electron-transparent windows from its back side after processing the front side. Similar work has been performed on customizable TEM chips for nanowires [3], but here we aim to utilize this approach for specimens requiring a larger field of view. The outlook for a simple, reproducible, fabrication process is many, as the advantages stretch across customizable window sizes and tailored chip designs. Additionally, it may expand the type of material systems that can be studied in situ, as-grown and in-plane without the need FIB lift-out.

The first step in achieving a robust protocol for the fabrication of customizable TEM chips is to optimize the back-etch to release electron-transparent membranes. As proof of concept, back-etched TEM chips were fabricated for a simple ferromagnetic $Ni_{80}Fe_{20}$ thin film (Fig 1.). Starting with a double-side polished silicon wafer coated with 30 nm Si_3N_4, the etch-mask was fabricated by patterning the Si_3N_4 on the back side of the wafer by photolithography and inductively coupled plasma reactive-ion etching (ICP-RIE). A 20 nm $Ni_{80}Fe_{20}$ thin film was deposited on the front side by electron beam evaporation, and thereafter protected by AR-PC 5040 protective coating. The electron-transparent windows were released by immersing the wafer in a KOH bath, and consecutive removal of the protective coating. TEM characterization of the windows shows successful fabrication, with the $Ni_{80}Fe_{20}$ retaining its ferromagnetic properties. This provides further evidence that the sample preparation was successful and that the front side was sufficiently protected from the KOH etch.

The next steps will focus on fabricating $Ni_{80}Fe_{20}$ nanomagnet arrays by electron beam lithography on a similar Si/Si_3N_4 substrate with wires for in situ biasing. As such, this presentation will also show the next steps towards doing in operando studies of magnetic device concepts. [4]

Figure 1: a) Schematic of the TEM membrane fabrication steps. The insets show the cross-section of the wafer. b-d) Low-magnification STEM image, SAED pattern, and STEM-differential phase contrast (DPC) image of the back-etched $Ni_{80}Fe_{20}$ TEM window. Some particle contamination can be observed on the back-etched samples. e) EELS spectrum of the back-etched $Ni_{80}Fe_{20}$ thin film against a reference $Ni_{80}Fe_{20}$ specimen.

Structure of refractory high entropy alloy and high entropy nitride thin films

Doctor Dimitri Litvinov[1], Doctor Michael Stüber, Professor Sven Ulrich[1], Professor Jarir Aktaa[1]
[1]Institute for Applied Materials, Karlsruhe Institute of Technology, Eggenstein-Leopoldshafen, Germany

Poster Group 2

Refractory high entropy alloy and nitride films have attracted attention due to their versatile properties, such as satisfactory mechanical properties, excellent anti-oxidation performance, outstanding corrosion resistance, and vitally important thermostability, indicating high application potentials. In this work, microstructural characterization of VCrNbMoTaW (high entropy alloy - HEA) and (VCrNbMoTaW)N (high entropy nitride - HEN) thin films was carried out by scanning (SEM) and transmission electron microscopy (TEM). The thin films with thicknesses of ca. 5 µm were grown by magnetron sputtering from a multiple-elemental compound target. Cross-section TEM samples were prepared using focus ion beam. For the determination of the thin film composition, energy-dispersive X-ray (EDX) spectroscopy was used. For the crystallographic investigations, conventional TEM with selected area diffraction and high resolution TEM imaging (HRTEM) with fast Fourier transformation (diffractogram) were applied.
SEM-investigation of the surfaces of HEA and HEN thin films shows that the two materials exhibit different surface topographies with significantly different size of the growth features. As further TEM observation shows, they are columns with diameter on the surface much larger for HEA layer (more then 1 µm) than for HEN layer (up to 0.14 µm). The columns in HEA film are not always perpendicular to substrate surface and are elongated in <112> direction. The width of the grains increases in the growth direction and reaches a few hundred nm for the HEA films. EDX measurements on the surface in SEM show almost equal atomic concentrations of all 6 metallic elements in both layers: for HEA thin films, the individual elemental concentrations are around 16-17 %, and for HEN thin films all metal concentrations are between 9 and 11%. The measured N-concentration in HEN is ca. 42-43 at.%. EDX-maps of the surfaces in SEM (on large scale of a few µm) and in cross-section samples in TEM (on small scale of a few nm) of both HEA and HEN thin films show homogeneous distribution of all elements, also of nitrogen in HEN layer. It is found, that HEA thin films exhibit a body-centered cubic (BCC) structure with a lattice parameter of a=0.313 nm.
Incorporating Nitrogen in the 6-component HEA thin film leads to a change of the crystal structure of the HEN thin films. Figure 1 shows HRTEM images of a HEN thin film with evaluated (left hand side) and simulated (right hand side) diffractograms from areas 1-3 of the HRTEM images. The corresponding enlarged filtered point patterns of areas 1-3 are displayed in insertions of the HRTEM images. The evaluations indicate that the HEN thin film has a face-centered cubic (FCC) structure with a lattice parameter of a=0.425 nm. The areas 1-3 in Figure 1 exactly correspond to [111] (area 1), [001] (area 2) and [110] (area 3) zone axes orientations. As for the HEA thin films, we observe for the HEN thin film again a columnar growth, but with a much smaller columnar width of a few tens nm and extension in <110> direction. The length of columns in the HEN thin film is also much smaller (ca. a few hundred nm) in comparison with the HEA thin film (a few µm). As we can see in Figure 1, the width of the columns, which are limited by white dotted lines, increases in the growth direction. Moreover, the existence of 6 forbidden reflections (on the blue dashed circle) in diffractogram of [111]-zone axis orientation from area 1 in Figure 1 can be explained by diffraction from very small and misorientated grains of the HEN thin film. These reflections correspond to ¼ {422} of the first Laue zone. Due to the existence of very small and strained grains, we observe for the HEN thin film a

misorientation of sub-grains inside columns of up to 18 °. Different defects observed in both HEA and HEN thin films, such as dislocations and stacking faults were also analysed in this work. For the HEN thin film, we detect (111) stacking faults, which are typical for FCC structure.
Thus, incorporating of Nitrogen in high entropy alloy film leads to a change in the crystal structure from BCC to FCC, a decrease in grain the size with large misorientations and the introduction of many different defects.

Figure 1. HRTEM images of HEN thin films with evaluated (left) and simulated (right) diffractograms from areas 1-3 and corresponding enlarged filtered point patterns of areas 1-3 (insertions).

Fast nanoparticle passage over cell membrane identified using 3D STED cross-sectional imaging

Dr. Boštjan Kokot[1], Hana Kokot[1], Janez Štrancar[1]
[1]J. Stefan Institute, Ljubljana, Slovenia

Poster Group 1

Background

Inorganic nanosized particulate matter (nanoparticles - NPs, a.k.a. ultrafine particles) has for a long time been known to be harmful to the environment, which is supported by recent studies.[1] What raises even more concern is the inherent toxicity of many nanoparticles once they are taken up into the body via inhalation, digestion or skin abrasion,[1] from where they translocate and affect crucial organs, such as the heart, liver and even brain.[2] Air-borne nanoparticles are especially problematic, because their inhalation is difficult to avoid and because the lungs are a very thin barrier that can easily be damaged.

Currently, some of the most recognized ways of NP entry into cells are various forms of endocytosis, e.g. phagocytosis or pinocytosis that occur in several seconds to minutes. The option of direct nanoparticle entry into the cell via physical disruption of the plasma membrane is usually not considered, although simulations confirm this is possible.[3]

In the presented work, we have exposed living murine lung epithelial cells to titanium dioxide nanoparticles and employed 3D Stimulated Emission Depletion (3D-STED) microscopy to confirm that nanoparticles can pass the plasma membrane in less than a second, suggesting a faster mode of nanoparticle entry into the cell.

Methods

The presented measurements were performed using a custom-built laser scanning Abberior STED microscope with an UPLSAPO60XW 60x water immersion 1.2 NA objective. We recorded successive xz images at 30 nm lateral pixel size and 33 nm axial pixel size, the field of 7 µm and a 30 µs dwell time per pixel. The duration of the acquired time-lapse was 50 s with a time step of 1 s. For two-color fluorescent imaging, we used a 561 nm and 640 nm laser (both having 6 µW in sample plane) in combination with a 605/50 nm and 685/70 nm filter set, respectively. To increase the lateral and axial resolution, a 775 nm STED laser with a 3D STED mask was used at 46 mW.

LA-4 lung murine cells were seeded into an Ibidi µ-dish at confluency 30-40% to reach confluency of 60-80% on the day of the exposure. The medium used was Ham's F-12K medium supplemented with 15% FBS, 1% P/S, 1% NEAA, 2 × 10−3 M l-gln. Right before observation under the microscope, Live Cell Imaging Solution was added (30% of total media volume) to the cell culture media to ensure long-term cell survival although the cells were maintained at 37°C in a 5% CO2 humidified atmosphere in a custom-built stage-top incubator. The plasma membrane of cells was labelled with 1 µg/ml Cellmask Orange for the duration of the experiment..

The cells were exposed to titanium dioxide nanotubes, labelled with Alexa647 [4] at a cell/tissue normalized surface dose 10:1 (ratio between the surface of nanoparticles and the cell growth area). Nanoparticles were aerosolized onto the living cells, which were covered with a thin layer (200 nm-500 nm) of cell media. The thin layer of water was achieved by removing most of the cell media right before the exposure. Aerosolization was performed using Aeroneb Pro nebulizer that produces 4-6 µm sized drops.

Results

With a system simulating inhalation exposure in lungs, where titanium dioxide nanotubes (in red) were nebulized on top of living cells (in green) with only a thin layer of water on top, we were able to directly capture nanoparticles passing through the plasma membrane in matter of seconds. At time points exceeding 20 s, we can see nanoparticles also accumulating at the membrane, while still passing through it. We are able to see bare nanoparticles (just red color inside the cells) and membrane-coated nanoparticles (yellow color) inside and outside the cells. This fast entry of nanoparticles indicates that nanoparticles pass the membrane quickly, most probably caused by direct contact with the membrane. We propose the mechanism of entry to be nanoparticle wrapping – the direct interaction of the nanoparticle surface with membrane lipids.[5] This then also creates holes in the membrane through which other nanoparticles can pass the membrane bare.

Conclusions

By employing 3D-STED microscopy, we confirmed with 40 nm lateral and 500 nm axial resolution that nanoparticle pass over the cell membrane faster than in one second. This indicates that nanoparticles are able to enter living cells quicker than with the usual endocytotic biological uptake. This entry is quite possibly caused by direct interaction of NPs and cells, for example by nanoparticle wrapping into membrane lipids.[5]

An examination of exit-wave reconstruction algorithms for low dose imaging at atomic-scale resolution

Jacob Svane-Petersen[1], Andreas Nymand[1], Joerg R. Jinschek[1,2], Stig Helveg[1], Joakim Kryger-Baggesen[1], Sophie Kargo Kaptain[1]
[1]Center for Visualizing Catalytic Processes (VISION), Technical University of Denmark, Kgs. Lyngby, Denmark, [2]Nanolab, Technical University of Denmark, Kgs. Lyngby, Denmark

Poster Group 2

Electron microscopy is a technology which is used in many modern research fields and in cases relying on heterogeneous materials the only viable solution for achieving atomic scale resolution. High-resolution electron microscopy utilizes a parallel, broad beam of high energy electrons to probe a sample and images at high spatial resolution are obtained by measuring the intensity of the electron wave function with a loss of its phase. By acquiring a series of images at different focus values, both the amplitude and phase of the electron wave function can be retrieved at the exit of the sample surface. The reconstructed exit wave provides the maximal amount of structural information, and it also enhances signal-to-noise ratios and therefore represents powerful phase imaging technique in low-dose-rate regime for suppressing beam-induced sample alterations for chemical and biological sciences. However, several schemes are employed to reconstruct the exit wave functions and are often employed without reference to their basic assumptions. In this study we provide a quantitative comparison of the most commonly used algorithms and discuss their pros and cons. Using simulation of HRTEM images in abTEM we compare how these algorithms perform in the regime of low dose imaging. Furthermore, we implement and present an algorithm for exit-wave reconstruction using abTEM and Python based on the paper by Oxley, et al. [1].
To compare different exit wave reconstruction algorithms on an equal basis, we simulate focal series of high-resolution transmission electron microscopy (HRTEM) images of model structures. Specifically, we use the multislice algorithm included in the abTEM package for HRTEM image simulation of structures modelled with the atomic simulation environment (ASE) package. Optical parameters incudes a primary electron energy of 300 keV, spherical aberration coefficient of -12 µm, an image pixel size of 0.1 Å and a focal range of -10 to 10 nm in steps of 1 nm. The focal series were reconstructed by using the three different algorithms [1-3] as implemented in commercial and open accessible codes and the reconstructions are then compared both qualitatively and quantitatively using a sum of square error (SSE) measure. Also, for reference, we implemented our own version of the algorithm by [1].
While the three algorithms overall perform similarly, we find differences reflecting a dose-dependence. We present data showing how an increase in the length of the focal series increases the quality of the reconstruction and results indicating an optimal tradeoff between dose and focal series length.
We investigated exit wave reconstruction algorithms implemented in Python codes and commercial packages. The comparison of the reconstruction the exit wave from a simulated focal series of HRTEM image shows differences depending on the overall image signal-to-noise levels. The present finding indicates that careful optimizing of the focal series image acquisition is needed to capture the finest structural features under low dose and dose-rate imaging conditions.

Examination of the Pathophysiology of Peripheral Olfactory Dysfunction and Alpha Melanocyte Stimulating Hormone Therapy

Oğuzhan Ekici[1], Prof. Dr. Gamze Tanriverdi[2], RA Hakan Sahin[2], Prof. Dr. Hafize Uzun[3], RA Mediha Eser[4], Prof. Dr. Gonul Simsek[1]
[1]Department of Physiology, Istanbul University-Cerrahpasa, Cerrahpasa Medical Faculty, İstanbul, Turkey, [2]Department of Histology and Embryology, İstanbul University-Cerrahpasa Faculty of Medicine, İstanbul, Turkey, [3]Department of Medical Biochemistry, İstanbul Atlas University, Faculty of Medicine, İstanbul, Turkey, [4]Department of Histology and Embryology, Altınbas University, Faculty of Medicine, İstanbul, Turkey

Poster Group 1

Background incl. aims
Olfactory dysfunction occurs in various diseases such as upper respiratory tract infections, head traumas, and neurodegenerative disorders. Particularly, the impact of anosmia on human health and quality of life has become noteworthy, especially in light of the Covid-19 pandemic. Despite the widespread occurrence of olfactory disorders globally, there is insufficient knowledge regarding the pathophysiology and treatment of olfactory dysfunction. Peripheral olfactory dysfunction is characterized by damage to olfactory sensory neurons in the olfactory epithelium (OE). This study aimed to investigate the contribution of the olfactory bulb (OB) and subventricular zone (SVZ) to the recovery of olfactory dysfunction in rats with a model of peripheral olfactory disorder. Additionally, the study aimed to examine the therapeutic effect of Alpha-Melanocyte Stimulating Hormone (α-MSH) in the treatment of olfactory dysfunction.

Methods
Peripheral olfactory dysfunction was induced in rats by intranasal administration of zinc sulfate. Half of the rats with induced olfactory dysfunction were treated with α-MSH, while the other half received saline. Prior to the experiment, after the induction of olfactory dysfunction, and before euthanasia, rats underwent three rounds of olfactory tests (buried food test and odor discrimination test). After sacrifice on days 4 and 21, nasal and brain tissues were collected and examined using immunohistochemistry and immunofluorescence methods. Neurogenesis, inflammation, and growth factor markers were utilized to observe the pathophysiology of olfactory dysfunction and the effect of α-MSH treatment. For demonstrating neurogenesis in the OE, CK-14, ASCL1, GAP43, and OMP were examined. To illustrate neurogenesis in the brain, Nestin, ASCL1, DCX, and NeuN were labeled. Inflammation and growth factors were indicated by labeling TNF-α, IL-10, BDNF, and NGF in the OE, OB, and SVZ.

Results
In the group with induced olfactory dysfunction in the OE, statistically significant differences were observed in GAP43, BDNF, and NGF. In the group with induced olfactory dysfunction in the OB, TNF-α and IL-10 showed statistically significant differences. In the SVZ group treated with α-MSH, a statistical difference was detected in TNF-α immunoreactivities. The time taken to complete olfactory tests increased after the application of zinc sulfate to the rats. In olfactory tests conducted before euthanasia, the time to complete the tests decreased, approaching normal durations.

Conclusion

On the 4th day of olfactory dysfunction, a decrease in the number of immature neurons in the OE was observed. BDNF and NGF showed increases on different days during olfactory dysfunction. Additionally, it is suggested that growth factors in the OE may influence inflammation in the OB through the olfactory ensheathing cells (OEC). Based on these results, it was determined that peripheral olfactory dysfunction did not affect neurogenesis in the brain. However, it is believed that growth factors in the OE play a role in the pathophysiology of olfactory dysfunction in both the OE and OB. Furthermore, it was demonstrated that α-MSH was not effective in the applied dose and duration for the treatment of olfactory dysfunction.

Simultaneous Indexing of Spot and Kikuchi Patterns in Scanning Electron Microscopy (SEM)

PhD Student Yuxuan Zhang[1], Senior Researcher Alice Bastos da Silva Fanta[1], Professor Jakob Schiøtz[2]
[1]DTU Nanolab, Technical University of Denmark, Lyngby, Denmark, [2]DTU Physics, Technical University of Denmark, Lyngby, Denmark

Poster Group 2

Background incl. aims
Introduced in 2011, Transmission Kikuchi Diffraction (TKD) overcame the challenge in characterizing isolated nanoparticles or ultrafine grains in thin film structure, which was a limiting factor in electron backscattered diffraction (EBSD) due to the small interaction volume and insufficient scatterings [1]. Traditionally, TKD relies on indexing the Kikuchi patterns of the forward-scattered electrons from an electron transparent sample, and it can be performed using a standard EBSD detector in either an off-axis or on-axis configuration with a spatial resolution down to a few nm in on-axis configuration [2]. However, the formation of Kikuchi pattern requires sufficient sample thickness, meaning very thin (e.g. 2D materials) or very light (e.g. organic) materials cannot be investigated via the traditional TKD method in SEM. Hence, a different approach has been developed recently to acquire and analyze the spot diffraction pattern in transmission mode in SEM instead, and it has successfully been used to index 2D materials such as graphene at nm resolution across mm range [3]. Since both spot patterns and Kikuchi patterns have been individually indexed in SEM, the natural next-step is to combine the two techniques so that the on-axis TKD configuration can be applied to a wider range of sample thickness. However, when acquiring both spot and Kikuchi patterns, the intense direct beam often drowns out the spot patterns, and the drastic difference in intensity between the spots and Kikuchi patterns (up to 10^3) makes the detection of both patterns with a conventional CCD detector challenging. Here we present our methods for acquiring both patterns without detector saturation and highlight the advantage by simultaneously indexing spot and Kikuchi patterns in a multi-layered Au thin film structure.

Methods
Two methods have been experimented to address the intensity issue: (1) By applying a filter to the CCD detector screen, the intensity near the optical axis can be reduced hence revealing the geometry of the spot patterns. (2) By acquiring diffraction patterns at different exposure time at each scanned location and combining/stacking the patterns via image fusion algorithm, the dynamic range can be greatly increased and both Kikuchi and spot patterns can be revealed.

Results
We will illustrate the simultaneous acquisition spot and Kikuchi patterns using both methodologies and provide a comprehensive analysis of their respective advantages and disadvantages on single and multi-layered thin film with various thicknesses. Finally, we will introduce and evaluate the two approaches for obtaining orientation mapping with both spot and Kikuchi diffraction patterns, as well as discussing their strengths and limitations concerning accuracy, throughput, and computation power requirement.

Conclusion

Both CCD detector filtering and multi-exposure image acquisition are valid strategies to acquire both spot and Kikuchi patterns without detector saturation in on-axis TKD configuration. The simultaneous indexing of both spot and Kikuchi patterns makes up for the thickness limitation of the individual spot/Kikuchi pattern indexing, and expands the range of samples investigated with a single technique. With this approach, we aim to expand TKD from an exit-surface characterization technique into a volume information extraction technique with the diffraction information of both spot and Kikuchi signals.

Keywords:

TKD, simultaneous indexing, detector saturation.

Physical determinants of YAP mechanotransduction in multicellular assemblies

Valeriia Grudtsyna[1]

Background incl. aims
Cells within tissues constantly receive biochemical and mechanical cues. Biochemical cues are evenly distributed across a monolayer due to the uniform spread of growth factors in the culture environment. Mechanical cues are highly localized, arising from cellular processes such as cell divisions, extrusions, and interactions with neighboring cells, involving pushing and pulling. These cues are sensed and interpreted by individual cells through a process called mechanotransduction. Depending on the input, cells make decisions that impact their micro-environment, creating a feedback loop regulating tissue homeostasis.1

The Hippo signaling pathway plays a crucial role in modulating cellular responses. Various upstream affectors have been shown to regulate it. One important constituent of the Hippo pathway is "Yes-associated protein 1" (YAP). When the Hippo pathway is on, YAP is phosphorylated and is permitted to enter the nucleus. When the Hippo pathway is off, YAP can shuttle into the nucleus and regulate gene transcription by interaction with DNA binding factors. 2

Nuclear compression, either independently or by disrupting the connection between the nucleoskeleton and the cytoskeleton, has been demonstrated to effectively regulate the localization of YAP. 3 YAP enters the cell nucleus through nuclear pores. The expansion of nuclear pores is linked to the shape of the nucleus. When the nucleus is elongated and stretched, the nuclear pores tend to widen. 4

The response of YAP to mechanical cues has been studied in the context of single cells or in multicellular contexts with high and low local density conditions. However, we found YAP expression and local cell density to be highly heterogeneous across the MDCK monolayer at the two seeding densities that we chose. Thus, we decided to characterize YAP activation across the MDCK monolayer in terms of local cell density.

Methods
Madin-Darby canine kidney (MDCK) cells are cultured at a high and low global cell density. When a propper monolayer is formed, cells are fixed and immunostained with YAP antibodies and Hoechst. The samples are imaged using a spinning-disc confocal microscope. Z-stacks are taken to reconstruct the cells in 3D. The nuclear stacks are segmented using Cellpose for extraction of nuclear shape properties. The focal plane is segmented in 2D to calculate the local cell density and YAP nuclear/cytoplasmic (n/c) ratio.

By manipulating e-cadherin expression using an e-cadherin KO MDCK cell line as well as altering actomyosin cytoskeleton integrity with Latrunculin A and ROCK-mediated myosin contractility with Y-27632, we aim to untangle their individual contributions from local cell density on YAP activation.

Results
YAP activation is determined by local cell density. A clear relationship can be observed between the YAP nuclear to cytoplasmic (n/c) ratio and local cell density. On average, YAP activation steadily decreases with an increasing number of neighboring cells. In contrast to the single-cell scenario, where less spread cells have larger nuclear volumes, cells with tall and high nuclei are found at lower local cell densities. These trends are preserved when performing perturbation experiments, highlighting the importance of local cell density and nuclear shape in the context of YAP activation and potentially also other processes.

Conclusion
By manipulating e-cadherin expression using an e-cadherin KO MDCK cell line as well as altering actomyosin cytoskeleton integrity with Latrunculin A and ROCK-mediated myosin contractility with Y-27632, we aim to untangle their individual contributions from local cell density on YAP activation.

LS-04 (2), Lecture Theater 4, august 29, 2024, 14:00 - 16:00

Background
Correlative Light and Electron Microscopy (CLEM) is a useful imaging approach that allows us to obtain two types of different imaging information from the same sample. Fluorescence microscopy (FM) provides multi-color information on different proteins of interest (POIs), while electron microscopy (EM) reveals the ultrastructure of cellular organelles. As a result, CLEM, which has become an essential tool in cell biology and neuroscience, enables a comprehensive understanding of POIs and their connections to intracellular structures or subcellular organelles1,2. For fluorescence-mediated visualization of intracellular regions of interest, fluorescent proteins (FPs) are commonly used. However, the fluorescence of intracellular FPs is often lost, especially during harsh EM sample preparation, such as fixation, dehydration, heating and resin embedding3. Especially for highly dynamic organelles such as mitochondria and lysosomes, the precise localization of these organelles can change as they are observed live in the light microscope and are actively moving even during the short delay time for fixation. To overcome this problem, we developed a fluorescent reporter that can effectively maintain its fluorescence signal under harsh EM sample processing conditions and developed a method to obtain distortion-free CLEM images using it.

Methods
Given the difficulty of maintaining the fluorescence signal during EM sample preparation with conventional fluorescent proteins, we use a two-colour CLEM technique that integrates small molecule probe-based signal amplification using genetically encoded peroxidases with mEosEM4, which retains fluorescence even in strong fixatives. In particular, based on our previous findings on peroxidase-based fluorescent substrates, we synthesised and applied to CLEM imaging a newly designed JF-induced probe based on the styryl-benzothiazolium phenol probe genfluor (JF), known for its fluorescent signal amplification by peroxidase5.

Results
As a results, we developed a fluorescent probe (JFT1) that exhibits a fluorescence-amplified signal when APEX2 is expressed. Unlike conventional fluorescent labels or fluorescent proteins that lose their fluorescence upon OsO4 pretreatment, JFT1 produces a well-retained and restricted fluorescence pattern in both OsO4 pretreated and OsO4 post-treated samples. The application of FLEX targeting to lysosomes in conjunction with mito-mEosEM facilitated the visualization of interactions between lysosomes and mitochondria. It also revealed distinct contacts between these two organelles in response to the lysosomal stressors bafilomycin and U18666A. Furthermore, the

interactions observed under the influence of bafilomycin and U18666A revealed distinct mechanisms of action as indicated by CLEM imaging. Taken together, we propose that our FLEX approach is a very useful way to target different APEX-POI combinations for fluorescence and high-resolution EM imaging.

Background incl. aims

Cancer cell invasion relies on an equilibrium between cell deformability and the biophysical constraints imposed by the extracellular matrix (ECM), and multicellular spheroids are a powerful model to study biochemical and biophysical interactions between cancer cells during growth and progression. However, little is known about how the biomechanics of the three-dimensional (3D) tumour microenvironment (TME) control cancer cell behaviours. 3D TME models remain underutilised, because contemporary mechanical quantification tools are limited to surface measurements, and there is a lack of enabling technologies that can measure subcellular-scale elasticity and co-register it with the morphology and function of cells in a 3D microenvironment.

Here, we develop a multimodal mechano-microscopy system that integrates optical coherence microscopy-based elasticity imaging with confocal fluorescence microscopy. We use this multimodal microscope to quantify local mechanics of cancer cell spheroids in 3D TMEs.

Methods

Our multimodal mechano-microscopy setup integrates high-resolution interferometric detection of optical coherence microscopy (OCM), a high-resolution variant of optical coherence tomography (OCT), with compression elastography and confocal fluorescence microscopy.[1] The system utilises a supercontinuum laser, whose output was shaped to a spectral range of 650 nm to 950 nm. This spectrum corresponded to a full-width at half-maximum (FWHM) bandwidth of ~250 nm, providing a measured OCM axial resolution of 1.4 µm in air. The system was implemented as a Michelson interferometer in a dual-arm configuration with the same optics in the reference beam path to match optical dispersion. The sample arm beam was expanded to fill the entrance pupil of a 20X 0.75NA objective lens providing a measured lateral resolution of 0.5 µm. Scanning was achieved using a 2D galvanometer system. A spectrometer comprising a 2048-pixel line camera was used to detect the spectral interference at each xy location.

The integrated confocal fluorescence microscope comprised two laser lines at 405 nm and 488 nm for excitation and a photomultiplier tube as the detector. The confocal system used the same galvanometer scanning arm and optics as the OCM system to scan the focal point in the sample. The emitted fluorescence from the sample was focused into a multi-modal optical fibre, which also acted

as the confocal pinhole. The measured lateral resolution of the confocal imaging system was 0.5 µm, and the axial resolution ~8 µm.

Sample preparation is described elsewhere in more detail [1]. Briefly, MCF-7 and MDA-MB-231 cells were suspended in gelatin methacryloyl (GelMA) solution. The solution was pipetted into moulds placed on glass slides, and exposed to UV light for 15 or 60 s to produce soft and stiff gels, respectively. The cells were then cultured for 6-16 days to allow spheroid formation and growth. Prior to imaging, the cells were labelled with nuclear dye Hoechst 33342 and membrane dye CellMask Green for fluorescence microscopy.

For imaging, the gel sample with a thickness of ~400–500 µm and a 1 mm thick compliant silicone layer were compressed between the coverslip and a rigid optical window attached to an annular piezoelectric actuator (Fig 1a). Two B-scans were acquired at each y-location, one at the unloaded and the other at the loaded state. Local displacement was calculated from the phase difference between the two B-scans and strain was estimated as the gradient of the axial displacement with depth.[2] Strain in the layer was related to stress through knowledge of the stress–strain response of the compliant layer in contact with the sample. Confocal images were acquired directly after the mechano-microscopy measurement.

Results

To test the setup, Young's modulus of blank, soft and stiff gelatin methacryloyl (GelMA) samples was first measured using mechano-microscopy and was found to be in good agreement with AFM surface measurement (Fig 1b). The multimodal setup was then used to obtain volumetric maps of living breast cancer cell spheroids cultured in the gels. Fig 1c,d shows example en face and B-scan Young's modulus of a non-metastatic spheroid, and Fig 1e-g show an example of a volumetric map where (e) OCM intensity, (f) Young's modulus and (g) confocal fluorescence image of the nuclear (cyan) and membrane (red) fluorescent dyes.

By imaging both metastatic (MCF-7) and non-metastatic (MDA-MB-231) breast cancer cell spheroids cultured in both soft and stiff gels (n≥4 for each condition), we observe that non-metastatic cancer spheroids show no invasion while showing increased peripheral cell elasticity in both stiff and soft environments. Metastatic cancer spheroids, however, show ECM-mediated softening in a stiff microenvironment and, in a soft environment, initiate cell invasion with peripheral softening associated with early metastatic dissemination. This exemplar of live-cell 3D mechanotyping supports that invasion increases cell deformability in a 3D context, illustrating the power of multimodal mechano-microscopy for quantitative mechanobiology in situ.

Conclusion

We demonstrate a multimodal imaging system that integrates an OCM-based subcellular mechano-microscopy system with a multi-channel confocal fluorescence microscopy system. This multimodal mechano-microscopy presents a new opportunity for quantifying local Young's modulus in live 3D samples with subcellular resolution, directly revealing mechanical phenotypes in situ.

Transmission electron microscopy studies of ferroelectric ZrO2 thin films

Phd Student Marian Cosmin Istrate[1], Dr Corneliu Ghica[1], Dr Jose Pedro Basto Silva[2]
[1]National Institute of Materials Physics, 105 Bis Atomistilor, 077125, Magurele, Romania, [2]Physics Center of Minho and Porto Universities (CF-UM-UP), University of Minho, Campus de Gualtar, 4710-057, Braga, Portugal

Poster Group 1

INTRODUCTION
The discovery of ferroelectricity in zirconia and hafnia [1] based thin films revolutionized the research in the field of ferroelectrics and paved the way for their integration into real applications. However, the wake-up phenomenon associated with the presence of non-polar phases and/or defects in the films still hinders the reliability of the device operation. Therefore, new strategies for achieving ferroelectric single-phase orthorhombic zirconia and hafnia based thin films are welcomed.

EXPERIMENTAL/THEORETICAL STUDY
8-nm thick ZrO2 thin films were grown by ion-beam sputter deposition (IBSD) onto 0.7 wt% Nb-doped SrTiO3 substrates with (001), (011) and (111) orientations.
Cross-sectional TEM samples were made by first mechanical thinning followed by Ar+ ion milling on a Gatan PIPS machine at 4 kV acceleration voltage and 6 degrees beam incidence angle. TEM observations were performed using a probe-corrected analytical high-resolution JEMARM 200F electron microscope operated at 200 kV.
RESULTS AND DISCUSSIONS
We note the Figure inserted in the graphic area by Figure 1. Fig. 1(a), (b) show HRTEM images of a ZrO2/(011)Nb:STO thin film. The ZrO2/(011)Nb:STO structure with (111) and planes of the o-phase are indexed. The FFT pattern shown in Fig. 1(c) corresponds to an area delimited by the red square inside the ZrO2 layer in Fig. 1(a). It contains a well-defined pattern of spots, proving a high crystalline quality of the ZrO2 film in terms of grain size and preferential crystallographic orientation. The main FFT peaks were measured, indexed and assigned to the (13-1), (111) and (02-2) planes of the orthorhombic structure of ZrO2 in the [-211] zone axis orientation. [2]
CONCLUSIONS
The HRTEM investigations indicate that substrate orientation control proves to be an efficient way to manipulate the phase of the as-grown ZrO2 thin films. We also studied ZrO2 films grown on (001)Nb:STO and these second set of films showing mixed orthorhombic and monoclinic phases. Macroscopic ferroelectric measurements of the phase pure, orthorhombic (111)ZrO2 films showed a remnant polarization of ~14 µC/cm2 and a coercive field of ~1.4 MV/cm. Also, piezo force microscopy measurements showed that polar domains could be written/read and reversibly switched with a phase change of 180°.

Characterization of the structure and chemistry of solid electrolyte

Dr Kyung Song[1], Dr Abin Kim[2], Professor Byungwoo Kang[2]
[1]Korea Institute of Materials Science , Changwon, Republic of Korea, [2]Pohang University of Science and Technology , Pohang, Republic of Korea

Poster Group 1

Background incl. aims
Solid-state Li metal batteries (SSLMBs) have been of great interest for electric vehicles due to their high energy density and safety features. Garnet-type $Li_7La_3Zr_2O_{12}$ (LLZO) solid electrolyte (SE) is a promising candidate due to its high ionic conductivity and stability with Li metal. While its preparation and electrical properties have been extensively studied, research on air handleability and Li metal wettability has been relatively limited. Addressing Li_2CO_3 formation on LLZO surfaces is critical because the formed Li_2CO_3 hinders the electrical properties, creates poor interfaces, and reduces metal wettability [1]. We developed a Li_2CO_3-proof LLZO (AH-LLZO) SE that is stored and handled in humid air without compromising electrical properties and simultaneously shows excellent Li metal wettability.
Methods
To understand the air-handling ability of LLZO, we performed characterization of structure and chemistry using SEM, XPS and STEM-EELS.Two samples were prepared by a simple solid-state reaction. One sample (C-LLZO) has a known composition ($Li_7La_3Zr_2O_{12}$) with a large excess amount of Li to compensate for the expected Li loss during high temperature treatment, and the other sample (AH-LLZO) contains excess Al and the same large amount of excess Li.
Results
SEM-EDS analysis reveals a distribution of Al both in the bulk and at the grain boundary of AH-LLZO. Some Al segregates into the grain boundary, while some is doped into the bulk. Elemental profiles of the Al $L_{2,3}$- and La $N_{4,5}$-edge via STEM-EELS further confirm that the Al in present both regions. The grain shows an almost constant amount of Al, but a sharp increase at the grain boundary suggests an Al-rich environment, possibly $LiAl_5O_8$-related phases, which is the most stable Li-deficient Al-rich phase [2]. High-resolution XPS confirms the absence of carbon-related peaks at a depth of 100 nm from the AH-LLZO surface which is clearly distinguished from C-LLZO, which exhibits a strong carbonate peak. To confirm the detailed surface structure, we performed STEM-EELS analysis across LLZO grain boundary for two LLZO. Consistent with the XPS results, AH-LLZO does not have any carbonrelated peaks in the grain or at the grain boundary, indicating that there is no Li_2CO_3 propagation into the core via the grain boundary. In contrast, C-LLZO exhibits carbon signals inside the grain boundary, suggesting that Li_2CO_3 formation/propagation in the bulk through the grain boundary can be occurred [3]. The EELS peaks for the oxygen at the grain boundary are similar to the oxygen binding energy of Al-rich Li-Al-O-related compounds such as $LiAl_5O_8$. This Li-Al-O-related phase at both the surface and the grain boundary blocks against water or carbonate infiltration, leading to the suppression of the Li_2CO_3 formation/propagation.
Conclusion
The presence of excess Al and Li without charge/site balance in the LLZO causes a distinctive microstructure with Al-doped LLZO grains and Li-Al-O phases at the grain boundary/surface. In the Al-doped LLZO grain, the preferential occupation of Al at 96h sites can reduce the LiOH formation and then suppress Li_2CO_3 formation. The Li-Al-O-related phases on the surface and at the grain boundary, particularly the $LiAl_5O_8$-like phase, act as a hydrophobic barrier, blocking water adsorption.

IM-06 (2), Lecture Theater 1, august 30, 2024, 10:30 - 12:30

Background incl. aims
Liquid Phase Transmission Electron Microscopy (LPTEM) is a powerful method for investigating in-situ fluidic reactions and materials under liquid conditions. Traditionally, this involves enclosing liquids within silicon nitride membranes, thus eliminating the need for cryogenic or dry samples. However, it comes with a downfall of low spectroscopical signal due to large liquid and membrane thickness. To address this limitation, we introduce a novel nanochannel system capable of nanofluidic regulation for LPTEM. With a SiNx membrane thickness of 25 nm and a sub-200 nm liquid height, this system offers high resolution and enables excellent spectroscopic data [1,2]. This opens the possibility of developing completely new techniques with LPTEM, contributing to its rapid expansion in various atomic-scale characterization methods.
By combining the nanochannel system with existing methodologies for atomic characterization, we can observe samples in-situ during liquid transformations. This eliminates the need to remove samples from their liquid environment, allowing for direct observation of transient intermediate phases during processes like crystallization or polymorphic form changes.
To ensure accurate crystal determination inside the nanochannel, we utilize 3D Electron Diffraction (3D ED). This method enables the spatial structure determination of nano-scaled crystals.
In this work, we aim to combine 3D ED with nanochannel chips from Insight Chips, seen in Figure b to study the crystallization of glycine from liquid and characterize any observed transformations. Glycine is commonly used as a model system for polymorphism as it exhibits different polymorphic states depending on its liquid medium. Previous research has demonstrated the utility of 3D ED in tracking the crystallization of glycine from aqueous solution [3].

Methods
In this study, we utilize a TEM holder from Figure a, which has four tubes connected to four O-ring sealed in/outlets on a chip. The chips in/outlets are sealed during fabrication with a nitride membrane, ensuring the nanochannels are clean and hydrophilic upon puncturing before use. After puncturing the membrane, a 50% saturated glycine solution in deionized water was drop-casted on the inlet and the solution entered the channels through capillary forces. Pure ethanol was subjected to the other side of the chip with the same drop-casting method. Crystals of glycine were observed under an optical microscope, in Figure b, as they have a different refractive index than water and give rise to different colors due to multilayer reflection. Thereafter, the presence of crystals was observed in a TEM, displayed in Figure c.
The 3D ED data from the crystals was collected on a Thermo Fisher Themis TEM with an acceleration voltage of 300 keV. 3D ED data was obtained using a selected area aperture on individual crystals in the channels, with crystal lengths ranging from 1.5 to 4.0 µm. All 3D ED data were collected at room temperature while rotating the chip continuously between –20° and +25° in α tilt, illustrated in Figure

d. The exposure time (0.2 s) and rotation speed (0.85 s^–1) were chosen so that individual diffraction frames were integrated over 0.17° of reciprocal space. The estimated dose rate was 2 e Å^–2 s^–1, with each collection taking on average 240 s, the total estimated dose per 3D ED data collection was 480 e Å^–2.
REDp was used to determine the unit cell and space group from 3D ED data. Data reduction and integration were performed with XDS. Structures were solved via dual space methods using SHELXT and refined with SHELXL in the Shelxle interface.

Results
The phase change precipitated chip was investigated using LPTEM. A total of 18 crystals were identified and analyzed by 3D ED, and out of these, 8 were identified as α-glycine and 4 were identified as β-glycine. The remaining 6 datasets did not provide conclusive results due to limited completeness or the crystal being polycrystalline. Due to low data completeness (24.2%), ab-initio structure determination was not possible. However, 3D ED data could still be used to refine the positions and isotropic atomic displacement of all non-H atoms. The presence of SiNx windows and concentrated glycine solution surrounding the crystal led to slightly increased background noise and diffuse scattering in TEM analysis. 3D ED data collected on crystals immersed in liquid were sufficient for structure determination. The results of crystallization in nanochannels and in-situ 3D ED experiments provided us with the opportunity to capture the early stages of the glycine crystallization process.
Although the overall crystallographic information was worse than the data collected on conventional TEM grids [3], the structure model could still be accurately determined.

Conclusion
The work carried out here demonstrates that the combination of LPTEM and 3D ED was successful in studying the structure of glycine crystals in liquid. 3D ED data from crystals of α-glycine and β-glycine polymorphs, both in and out of liquid were eligible for structure analyses. Both α- and β-glycine polymorphs were identified via imaging and crystallographic data. Liquid phase 3D ED is an advanced and challenging technique, but the findings and experimental capability established here raise the prospect of future works on studying structural responsiveness to external stimuli, like temperature or even chemical processes in solution using a combination of LPTEM and 3D ED.

The negative impact of fossil fuel consumption on the environment, along with being a limited energy resource, makes fossil fuels unappealing from a standpoint of future-proof energy frameworks. Hydrogen fuel cells play an important role in such a system, mainly for energy storage and applications for transportation. Proton exchange membrane fuel cells are electrochemical devices which convert hydrogen and oxygen into water, generating electrical current. Platinum nanoparticles supported on carbon show very high activity towards the hydrogen oxidation reaction. On the other hand, the oxygen reduction reaction (ORR) proves to be more difficult in terms of finding a material with adequate performance, both in terms of activity as well as durability. The activity of electrocatalysts can be increased either by increasing their surface area, or by modifying the material composition such that the intrinsic activity is improved. However, the long term stability of fuel cells is hindered by degradation of the electrocatalyst during operation. One idea to tackle this issue is the use of catalyst supports which serve as more than just as a substrate. The metal-support interaction, in which the support influences the catalyst through strain or by changing the electronic structure, is a way of tuning performance of a nanocatalyst. At present, few methods are available that can directly characterize this interaction. A method for probing the catalyst-support interaction would be beneficial for accelerating the process of creating improved ORR catalysts. 4D scanning transmission electron microscopy (4D STEM) is a technique that can be utilized in order to locally probe and analyse the interaction between nanoparticles and their support. Namely, 4D STEM involves using a fast, pixelated electron detector which captures diffraction patterns at each probe position in a scan. The divergence of the center of mass (dCOM) of the electron probe is proportional to charge density. As such, charge redistribution occurring at the catalyst-support interface can be visualized. However, particle orientation and support thickness affect dCOM image contrast, and complicate the interpretation of dCOM directly as charge density. In the following research, a methodology for determining the charge density distribution of supported nanoparticle electrocatalysts is developed. As a model system, platinum supported on graphene was chosen for its simple composition and uniform thickness. After establishing the methodology, it is applied to platinum supported on titanium oxynitride and amorphous carbon, selected as a more complex catalyst-support system.

Background incl. aims
In the framework of hydrogen production as means for renewable energy storage, titanium-doped hematite (Ti:α-Fe_2O_3) nanorods have received renewed interest for potential use as a photoanode in photoelectrochemical cells, owing to their high theoretical photoelectrochemical activity, absorption spectrum compatible with sunlight, as well as the abundance of its constituents, allowing cost- and resource-efficient production of hydrogen by solar water splitting (SWS) [1].

In a previous work [2], a two-step synthesis for this material was developed. First, using $FeCl_3$ and $TiCl_3$ precursors, the deposition by aqueous chemical growth (ACG) of an intermediate phase, Ti-doped akageneite (Ti:β-FeOOH) on a glass/FTO substrate was carried out. This step is followed by the annealing of the intermediate phase in a controlled oxygen and nitrogen atmosphere to yield the final Ti-doped hematite photoelectrode structure.

Both synthesis steps are very sensitive to various parameters, which can change the outcome of the final iron oxide structure and its efficiency for the SWS process. Parameters such as the pH of the initial precursor solution, age of the $TiCl_3$ precursor, time and temperature of the thermohydrolysis process as well as of the annealing process, and annealing atmosphere, may all have an impact on the structure and the properties of the final material [3].

Herein, we study the as-obtained hematite nanostructures to characterize their morphology, crystalline structure, chemical composition and electronic properties, as a function of the various synthesis parameters. A correlative approach combining transmission electron microscopy (TEM), yielding images with high spatial resolution, with synchrotron-based scanning transmission X-ray microscopy (STXM) exhibiting chemical sensitivity, in the aim to extract morphological and structural features from the former, electronic structure and chemical coordination from the latter.

Furthermore, we relate the results obtained by these microscopy techniques with photoelectrochemical (PEC) results, to establish a structure-function relationship and thus to be able to optimize the synthesis of the photoanodes for yielding higher efficiency in the hydrogen production process.

Finally, in situ environmental TEM was used to study the annealing step under varying gas atmospheres to elucidate the transition mechanism as a function of gas composition, time and temperature.

Method

To characterize the Ti:α-Fe_2O_3 structures, a correlative approach combining TEM and STXM was implemented. Samples were recovered by scratching the surface of the hematite/FTO glass substrate, retrieving the hematite powder to be placed on either Cu grids or SiN membranes, both of which can be analyzed in TEM and STXM successively. In STXM, the samples were measured at the absorption edges of Ti L2,3 (450-470 eV), O K (520-560 eV) and Fe L2,3 (700-740 eV), to provide localized XAS spectra describing the chemical state and coordination of the atoms of interest.
In TEM, conventional and high-resolution images were acquired in classical TEM and in STEM (BF and HAADF) to obtain morphological and structural information, corroborated by electron diffraction data and EDX spectroscopy maps, the latter to be compared with the chemical information obtained by STXM. Also, in situ environmental TEM experiments were carried out using a sealed cell-based holder inside the microscope in which a controlled gas atmosphere and temperature can be applied to the sample, allowing to monitor changes in morphology and chemical composition in real time.
PEC measurements were carried out in a dedicated PEC cell, using the hematite-based photoanode as working electrode, a Pt foil as counter electrode and an Ag/AgCl reference electrode, under a back-side illumination of 1 sun (0.1 W/cm²).

Results

For the first step, it was found that using an aged $TiCl_3$ precursor leads to the formation of mixed phase compounds, composed of both hematite (α-Fe_2(III)O_3), i.e. only Fe3+ cations in the structure, and a reduced phase, identified as magnetite (Fe_3(II, III)O_4), containing both Fe2+ and Fe3+, in the final products. In contrast, samples prepared with a fresh $TiCl_3$ precursor, only pure hematite was obtained (as shown in Fig. 2), which is the active phase for PEC and therefore the targeted result.
A comparative study changing the composition of the annealing gas, using various ratios of O_2/N_2, ranging from 0% to 100% has shown that the partial reduction of the sample is independent from the gas composition, meaning that this phenomenon is independent of the annealing environment but rather inherent to the specific sample composition. In fact, STXM-XANES measurements on the aged precursor revealed a change in its oxidation state, from Ti(III) to Ti(IV). The Ti(IV) cations incorporated in the akaganeite structure causes the reduction of Fe(III) to Fe(II) by charge compensation, yielding a partially reduced hematite structure after annealing, independently of the gas atmosphere.
These results were confirmed by in situ TEM measurements, showcasing a similar mechanism for the annealing independent of gas composition for samples prepared with the aged precursor, confirming the hypothesis that the reduction behavior originates from precursor ageing.
PEC measurements revealed that the photocurrent Jph of the samples prepared with aged precursor were, on average, lower than samples prepared with a fresh precursor, which was linked to the presence of the reduced phased in the former samples.

Conclusion

In this work, we have showcased the impact of the precursor aging, which, despite the low concentration of the dopant (< 1 at. %), plays a tremendous role on the reduction of targeted hematite phase and thus the efficiency for the solar water splitting application.
Further work is also currently being carried out to understand the influence of other important parameters, particularly the pH of the precursor solution, for which preliminary results showed that it directly impacts the length of the nanorods, yielding to varying PEC efficiencies.

Entanglement in Bragg Scattering

Ao. Univ. Prof. Peter Schattschneider[1], Assoc.-prof. Stefan Löffler[1]
[1]TU Wien, Wien, Austria

Poster Group 2

Whenever two quantum systems interact and their state changes (in a non-separable way), they become entangled. In essence, they can no longer be seen as two separate systems, but rather as a single, large system (until they decohere). Since electron microscopy deals with elementary particles as well as structures and processes on the atomic scale – i.e., quantum objects – entanglement is fundamental. In inelastic scattering (EELS), this has been embraced fully for quite some time by the use of the mixed dynamic form factor (MDFF) [1,2]. To our knowledge, the same cannot be said for the much more widespread (and theoretically simpler) case of elastic scattering.
The strange effects of entanglement occur also in Bragg diffraction, as we are dealing with the two interacting quantum systems of the probe beam and the crystal. Take the two-beam case as an example: Measuring in the diffraction plane and detecting the probe electron in the 0 or in the g diffracted beam results in a momentum transfer of either 0 or -g ħ to the scatterer. On the other hand, measuring in the image plane leaves the scatterer in a quantum superposition of two states with different momenta like Schrödinger's cat. This shows that a measurement on one part of an entangled system can have an effect on the other [3]. Therefore, it is critical to include entanglement in the theoretical description of the process to get complete and accurate predictions.
In this work, the joint quantum state of the probe beam and crystal system is described by its density matrix [4] which captures all aspects of the state. It allows to predict the evolution of the state and the outcome of measurements on parts of the system (the beam electron in the present context) by virtue of the reduced density matrix. In the 1-dimensional case, the N degrees of freedom of the scatterer (the positions of the N atoms) can be rewritten as N-1 relative coordinates of a rigid lattice and the position of the center of mass (CM). It is shown that the diagonal elements of the density matrix in a momentum basis correspond to the well-known scattering distribution from conventional kinematic scattering theory. The relative coordinates define the amplitude whereas the CM position imprints a lattice periodic phase factor. Apart from the diagonal terms, the reduced density matrix features off-diagonal elements, which give insight into correlation and interference effects. Among other things, these can be used for determining the decoherence properties of the electron beam.
A rigorous treatment of the entangled system "probe electron/crystal" leads to the standard (reciprocal space) description of Bragg diffraction as scattering on a static periodic Coulomb potential. But on top of that, it also contains additional information on the quantum system, that is accessible in other bases (such as in position space). This work sheds light onto the quantum mechanical measuring process in the context of electron microscopy and therefore contributes to a better understanding on a fundamental level. [5]

Three-dimensional, correlative electron microscopy and immuno-labelling revealed new principles of the Golgi complex functioning

Prof. M.D.; PhD.; DcS. Alexander Mironov[1], MD, PhD, DcS Galina Beznoussenko[1]
[1]IFOM ETS—The AIRC Institute of Molecular Oncology, Milan, Italy

Poster Group 2

Goal. The Golgi complex (GC) is one of the main organelles of the cell, it has a complex organization and provides transport of proteins and lipids, as well as their glycosylation. It was necessary to understand the principles of the GC operation.
Methods. The use of three-dimensional electron microscopy (EM), immune EM, and correlative light EM made it possible to abandon the use of the old radigma explaining Golgi function and provide the new one [1, 2].
Results. We have shown that membrane spherical vesicles in the area of endoplasmic reticulum (ER) exits sites are produced mostly with the help of a COPI/ARF machine. There are no completely isolated carriers between the ER and GC. COPI-dependent Golgi vesicles contain a sharply reduced content of retrograde and anterograde cargoes. At the same time, during their transport through the GC, the concentration of soluble, membrane and mega-cargoes increases, which cannot be explained using the maturation model [3, 4].
The role of cisternal perforations for intra-Golgi transport is shown [5].
It was found that the GC may be in a state of rest or transport. The non-transporting GC does not have a cis-most and trans-most cisternae attached to the poles of the medial GC. The beginning of transport leads to their attachment to the stack of medial cisternae in a GM130 and G97 dependent manner, respectively.
The size of the exit site from the GC depends on the amount of cargo being transported [3,4]. With the synchronous movement of a large number of cargo, the exit is carried out from the last two medial cisternae and TMC. When transporting a small amount of cargo, the last medial cisterna and TMC function as the Golgi exit site.
Membrane fusion is important for both moving through and exiting the GC. Post-Golgi carriers ferrying cargoes to the baso-lateral plasma membrane are not completely isolated and always pass through endosomes to change the set of their SNAREs.
The mapping of the main protein machines involved in intracellular transport in various compartments and during various functional states, as well as their changes in different phases of the cell cycle, are presented [2, 5].
Conclusion. The intracellular transport model based on the kiss-and-ran mechanism most fully corresponds to the data obtained.

Poster Group 2

Background:
Nanomaterials, particularly those with anisotropic characteristics, have attracted significant interest in materials research due to their vast potential applications in diverse fields like optoelectronics, photocatalysis, solar cells, energy storage, sensors, and electronic devices. To unlock these possibilities, precise control over the structure, geometry, and surface arrangement is crucial. Our research group addresses this challenge by developing innovative techniques for "guided growth" of materials on surfaces.
1D van der Waals (vdW) materials, characterized by their chain-like structures connected by weak vdW forces, have emerged as promising candidates for various applications owing to their inherent anisotropic nature and intrinsic 1D dimensionality. We aim to leverage these unique properties, combined with our expertise in guided growth, to fabricate well-aligned nanowires of 1D vdW materials with superior electronic and optoelectronic functionalities. In this work, we present the successful growth of well-aligned Sb_2Se_3 and Sb_2S_3 nanowires on various substrates, including both covalent epitaxy substrates like sapphire and vdW epitaxy substrates like $ReSe_2$.
Method:
The nanowires were synthesized in our group's custom-built chemical vapor deposition (CVD) system. The structure and morphology of the nanowires were characterized using scanning electron microscopy (SEM). Compositional analysis was performed using energy-dispersive X-ray spectroscopy (EDS) and Raman spectroscopy. High-resolution transmission electron microscopy (HR-TEM) is planned to determine the crystal orientation and atomic structure. Additionally, the optical and electronic properties of the wires will be investigated through photoluminescence (PL) spectroscopy. Finally, photodetectors will be fabricated, and their optoelectronic properties will be characterized.
Results:
We successfully synthesized well-aligned nanowires of Sb_2S_3 and Sb_2Se_3 on C-plane sapphire substrates. SEM analysis confirmed the nanowire structure and revealed their oriented directions. EDS confirmed the chemical composition of the nanowires. Focused Ion Beam (FIB) milling is planned in the coming weeks to prepare cross-sectional lamellae for HR-TEM analysis, which will elucidate the epitaxial relationships and growth plane orientation. Following this, a photodetector will be fabricated to characterize the optoelectronic properties.
Furthermore, promising initial results have been obtained for guided growth of Sb_2Se_3 nanowires on $ReSe_2$ flakes, demonstrating successful vdW epitaxy. This mixed-dimensional heterostructure was characterized using Raman and PL spectroscopy. Similar to the previous case, a cross-sectional lamella will be prepared for characterization of the epitaxial relationships within this mixed-dimensional heterostructure using HR-TEM.
Conclusion:
This work demonstrates the successful synthesis of well-aligned Sb_2Se_3 and Sb_2S_3 nanowires on various substrates using our guided growth methods. Further analysis using HR-TEM and fabrication

of photodetectors are planned to fully characterize their properties. Additionally, initial results on Sb_2Se_3 nanowires grown on $ReSe_2$ flakes via vdW epitaxy are encouraging, signifying the potential for exploring novel mixed-dimensional heterostructures. This research paves the way for engineering next-generation optoelectronic devices utilizing precisely aligned 1D vdW nanowires

Poster Group 1

Background incl. aims:
The oxide misfit layered compounds (MLC) are heterostructures with complex stacking usually formed by two ceramic oxide layers. These oxides exhibit remarkable structural and chemical complexity and show very interesting electronic, thermoelectric, and magnetic phenomena [1-5]. It is interesting to mention that due to the intrinsic asymmetry of MLCs, they tend to bend and shape into tubular structures in the form of 1D nanomaterials: nanotubes (NTs) and nano-scrolls (NS) [1-5]. There are two different synthesis routes of these nanomaterials, the starting material is either a mixture of the individual constitutive elements or directly is the corresponding bulk structure. Following the latter pathway, recently, we have developed novel synthesis method based on a crystal conversion process, which parts from a bulk structure with a different, related crystal structure [4,5]. Here, we will present the detailed electron microscopy analysis of nanotubes and scrolls based on layered CoO_2 that have been obtained using this method with two different starting compounds: $Sr_6Co_5O_{15}$ [4] and $Ca_3Co_2O_6$ [5].

Methods
The synthesis procedure starts from the mentioned bulk oxide materials with a quasi 1D crystal structure, which are treated in a hydrothermal process in basic environment. Under this environment, the structure becomes unstable, leading to the dissolution of Sr (Ca) ions and leaving behind cobalt oxide chains. These chains then bend to 1D tubular or scrolled nanostructures. To investigate these 1D systems, different TEM techniques (HR(S)TEM imaging, SAED, X-EDS and EELS) were performed using two aberration corrected Thermo Fisher Scientific Titan microscopes. Furthermore, the electronic/electrical properties of these nanostructures were investigated in-depth at the individual nano-object level by patterning with electron beam lithography.

Results
A large quantity of strontium deficient misfit $SrCoO_2$-CoO_2 (SCO) nanotubes is produced [4]. In these NTs, CoO_2 layers are stabilized by intercalation between $SrCoO_2$ layers (forming a misfit unit), possibly with the aid of Na ions. In comparison to a previous study on similar nanostructures [3], the NTs obtained by the crystal conversion process are Sr-deficient, yielding a structure predominantly made of CoO_2 layers, Figure (a)-(c). These NTs are semiconducting and possess an extremely high ampacity (10^9 A/cm^2), which is the highest reported ampacity value to date in any inorganic oxide-based material, Figure (d) [4]. The nanotubes also show a breakdown power per unit channel length of 38.3 W/cm, the highest among the regularly used interconnect materials [4].
Regarding the calcium cobaltite (CCO) system, a large quantity of stable and pure CoO_2 nano-scrolls have been produced for the first time and investigated in depth, see Figure (g)-(j) [5]. These NSs possess a narrow range of diameter and wall width suggesting that the CoO_2 stabilization occurs

under specific circumstances. These nanostructures are semiconducting with a high current-carrying capacity of 4 10^5 A/cm² and an extremely high breakdown voltage of up to 270 kV/cm.

Conclusion
These detailed structural and chemical investigations at the atomic level have demonstrated the existence of new 1D systems based on layered cobalt oxide, both as pure phase and in intercalated form in misfit layered compounds. Furthermore, we have shown that these 1D nanostructures are potential building blocks for high-power electronic applications, fulfilling the requirement suggested by ITRS.

Microscopic characterization of graphene derivates in life science

Mgr. Jana Straska[1,2]
[1]Czech Advanced Technology and Research Institute - Regional Centre of Advanced Technologies and Materials, Olomouc, Czech Republic, [2]VSB Tech Univ Ostrava, IT4Innovations, Ostrava, Czech Republic

Background incl. aims
Graphene derivatives are becoming increasingly important materials in the field of biomedicine, particularly in neurosciences. Their ability to interact with cells and their potential applications in neuroapplications present an intriguing and revolutionary potential1. This study focuses on the microscopic characterization of various graphene derivatives with the aim of identifying the most suitable ones for neuroapplications, taking into account cell uptake and their biocompatibility. The objective of this study is to conduct microscopic characterization of graphene derivatives and evaluate their interaction with cellular structures. Specifically, we focus on their distribution within cells, cellular uptake, and biocompatibility.
Methods
Microscopic characterization of graphene derivatives was performed using several techniques, including the combination of scanning electron microscopy (SEM) with atomic force microscopy (AFM), transmission electron microscopy (TEM), high-resolution TEM (HR-TEM), time-lapse confocal microscopy and Raman spectroscopy. These methods allowed us to examine the morphology, structure, and interaction of derivatives with cellular structures.
Results
Our microscopic characterization revealed that different graphene derivatives exhibit distinct morphology and structure. Using SEM/AFM, we observed differences in particle size and shape. TEM and HR-TEM enabled detailed examination of the internal structure of derivatives. Time-lapse confocal microscopy will be employed to track the dynamic interaction of graphene derivatives with cellular structures over time, providing insights into their uptake kinetics, intracellular trafficking, and potential effects on cellular dynamics. Raman spectroscopy provided information about the chemical structure of derivatives. An important finding was that certain derivatives demonstrated higher cellular uptake and better biocompatibility than others.
Conclusion
Based on our results, microscopic characterization is crucial for selecting optimal graphene derivatives for neuroapplications. Certain derivatives exhibited significantly enhanced ability to interact with cells and higher biocompatibility, indicating their potential for use in neurosciences2. Further studies focusing on long-term effects and applications of these derivatives are necessary to assess their full therapeutic potential.

Poster Group 1

Background incl. aims
Graphene derivatives are becoming increasingly important materials in the field of biomedicine, particularly in neurosciences. Their ability to interact with cells and their potential applications in neuroapplications present an intriguing and revolutionary potential1. This study focuses on the microscopic characterization of various graphene derivatives with the aim of identifying the most suitable ones for neuroapplications, taking into account cell uptake and their biocompatibility. The objective of this study is to conduct microscopic characterization of graphene derivatives and evaluate their interaction with cellular structures. Specifically, we focus on their distribution within cells, cellular uptake, and biocompatibility.
Methods
Microscopic characterization of graphene derivatives was performed using several techniques, including the combination of scanning electron microscopy (SEM) with atomic force microscopy (AFM), transmission electron microscopy (TEM), high-resolution TEM (HR-TEM), time-lapse confocal microscopy and Raman spectroscopy. These methods allowed us to examine the morphology, structure, and interaction of derivatives with cellular structures.
Results
Our microscopic characterization revealed that different graphene derivatives exhibit distinct morphology and structure. Using SEM/AFM, we observed differences in particle size and shape. TEM and HR-TEM enabled detailed examination of the internal structure of derivatives. Time-lapse confocal microscopy will be employed to track the dynamic interaction of graphene derivatives with cellular structures over time, providing insights into their uptake kinetics, intracellular trafficking, and potential effects on cellular dynamics. Raman spectroscopy provided information about the chemical structure of derivatives. An important finding was that certain derivatives demonstrated higher cellular uptake and better biocompatibility than others.
Conclusion
Based on our results, microscopic characterization is crucial for selecting optimal graphene derivatives for neuroapplications. Certain derivatives exhibited significantly enhanced ability to interact with cells and higher biocompatibility, indicating their potential for use in neurosciences2. Further studies focusing on long-term effects and applications of these derivatives are necessary to assess their full therapeutic potential.

3D calibration for SEM and optical microscopy - First results with next generation 3D standards

Dr.-Ing. Matthias Hemmleb[1], Celina Hellmich[2], Lena Heinrich[2], Sebastian Buetefisch[2]
[1]point electronic GmbH, Halle (Saale), Germany, [2]PTB Physikalisch-Technische Bundesanstalt, Braunschweig, Germany

Poster Group 1

Marker based 3D standards, in the form of cascading step-slope pyramids, enable the calibration of all three scaling factors and all three coupling factors of measurement instruments using only a single sample and a single measurement [1]. They are suitable for automated calibration and therefore offer better convenience than conventional methods and are therefore increasingly applied [2]. With the introduction of a new scalable wafer-based manufacturing technology, the current application range for calibration of atomic force microscopy (AFM) and SEM can be expanded to optical 3D measurement instruments. First prototypes of these next generation 3D standards are applied for example calibrations of topographic 3D-SEM and confocal laser scanning microscopy (CLSM). The results show the easy and smooth application of the new standards as well as the high conformity of the calculated calibration parameter with conventional methods.
Currently used 3D standards are produced with FIB. Each standard is therefore a cost-intensive custom-made product that also requires time-consuming calibration. The maximum size of these standards is 80 µm with a marker diameter below 1 µm, which cannot be sufficiently resolved with optical 3D microscopes. Therefore, a wafer-based mask process for the fabrication of 3D standards was developed, allowing many structures to be fabricated reproducibly and the geometric dimensions to be adapted to the respective device to be calibrated. First results are prototypes with sizes of 400 µm and 1200 µm for use with optical microscopes, as well as standards with 80 µm size as replacement for AFM and SEM calibration [3]. Figure 1 (SEM and CLSM image with field of view about 400 µm) shows a first prototype, which was successfully used for the calibration of a CLSM (Olympus Lext OLS 4100). The calibration results were compared to the results from a conventional calibration which was carried out as a combination of a step height and a grid standard.
Compared to currently established traceability of FIB standards, which finally based on a reference measurement with a metrological large-range AFM (Met. LR-AFM), providing the required reference data for the wafer-based manufactured standards is easier and more efficient due to their better conformity. Therefore, a combination of traceable calibrated SEM and stylus profilometry was used for the measurement of the reference data [3].
For the coordinate measurement of the reference marks with subpixel methods, as well for the calibration parameter estimation with statistical methods, the dedicated software microCal was applied, which was already validated for this purpose [4].
The prototypes of the next level 3D standards can be used with the applied CLSM and the calibration software microCal without any problems and due to automatization very effective. All markers were measured with the required accuracy. In comparison with the more complex conventional CLSM calibration, the difference between lateral and height scale is below 4x10-4 and difference in lateral shearing is 1x10-4. In addition, a significant vertical shearing was determined, which is hardly possible to identify with conventional methods.
Ongoing work is on further accuracy aspects of the new calibration samples and the specification of the uncertainty budget for providing traceable reference data. Due to the promising results, it is

planned to make the new generation of 3D calibration samples commercially available in the near future.

Exit of different cargoes from the Golgi and their post-Golgi trafficking

Dr. Galina Beznoussenko[1], PhD, MD, Prof. Alexander Mironov[1]
[1]IFOM ETS, The AIRC Institute of Molecular Oncology, Via Adamello 16, 20139, Milan, Italy, Milan, Italy

Poster Group 2

Proteins and lipids are synthesized in the ER, delivered at the Golgi complex, then exit the Golgi complex and finally, delivered toward their final destination. Until now the information about the Golgi-to-plasmalemma transport (GPT) and the formation of Golgi-to-PM carriers (GPC) and their fate is controversial. For a long time, the vesicular model played a role of paradigm for all steps of intracellular transport. However, several years ago it was demonstrated that the transport from the Golgi complex to the plasma membrane (PM) is carried out by irregular GPCs [1,2]. Pathways for different cargoes are not well established. It is not clear whether there is a necessity for the fusion of the post-GC carriers with endosomes. Here, we examined mechanisms of GPT, namely, the three-dimensional structure of post-Golgi carriers, patterns of their exit from the Golgi complex, their transformation during their delivery to the baso-lateral PM and their dependency on the amount of cargo transported and fusion with endosomes.
All reagents, the cells and the cargo synchronization protocols were described in [3]. We studied conventional cargoes: PCI, PCI-GFP (PFP), tsVSVG, tsVSVG-GFP (VFP); ASGPR, albumin, and GFP-albumin (AFP) using STEM and TEM tomography, correlative light electron microscopy (CLEM), high pressure freezing (HPF), immuno-EM, focused ion beam (FIB-SEM).The GPC exit from GC depends on the amount of cargo moving through it. The temperature-sensitive glycoprotein G of vesicular stomatitis virus (VSVG) and procollagen-I (PCI) can also exit from the last two medial Golgi cisternae when a large amount of them is transported, whereas when a small amount of PCI is transported, it passes through the last medial cisterna and the trans-most cisterna (TMC) and then exits the TGN zone. Albumin exits the GC through TMC and TGN, where accumulative large vacuoles are formed. Albumin is enriched in the vacuole(s). Most of these vacuoles contain low concentration of VLDL. Smaller but distinct vacuoles are enriched in VLDL. This vacuole could be connected with the PM through thin tubule. Fusion of GPCs with endosomes and then their subsequent fission is necessary to remove resident Golgi proteins from GPCs and replace SNAREs in GPCs. Using advanced methods of the high-resolution 3D imaging (STEM and TEM tomography, FIB-SEM) after a cryo-immobilization procedure (HPF) has been shown that near the GC and during their passage to the PM, GPCs are always connected with at least one GC/TGN/endosome structure. The exchange of SNARE proteins ensures the subsequent fusion of GPCs with the PM. Thus, the kiss-and-run model is the most powerful model for the explanation of GPT.

FIB-induced nanorod formation in 2D layered crystals

Dr. Julia Deuschle[1], Dr. Tobias Heil[1], Dr. Hongguang Wang Hongguang Wang[1], Prof. Dr. Peter van Aken[1]
[1]Max Planck Institute for Solid State Research, Stuttgart, Germany

Poster Group 2

In this study, we present our findings of very unusual behavior shown by bulk crystals of 2D layered materials, such as transition-metal diselenides, when subjected to focused ion beam (FIB)-milling. During FIB preparation of lamellae for transmission electron microscopy (TEM) analysis, we encountered a very pronounced curtaining effect for this type of materials. This initially leads to thickness variations in the TEM lamella, and upon further FIB milling, to the formation of wire- or rod-like structures. The curtaining is observed on different length scales from the micro- to the nanometer range. Examples of such structures can be seen in figure 1.
Interestingly, the rod-like structures form, when the milling direction is perpendicular to the 2D layers. However, the formation of rods only occurs for some crystal orientations, whereas an in-plane rotation of the bulk crystal can lead to a homogeneous milling behavior without curtaining. Furthermore, the choice of the ion beam milling parameters seems to have an influence on the resulting structures.
We present further investigations of these wire- or rod-like structures for several 2D materials with different compositions. The goal is to expand our knowledge of the conditions that either lead to or prevent the formation of the nanorods and to gain a deeper understanding of the effect that causes these structures to form.

Poster Group 1

Over the last three decades, heterostructured semiconductor nanowires (NWs) have been in the spotlight because of their potential as nanoengineered building blocks for a new generation of electronic, photonic and plasmonic, devices for quantum, sensing, and energy-harvesting applications [1]. The nanometer-scale lateral dimensions and resulting quasi one-dimensional morphology of the NWs facilitate the release of the inherent epitaxial strain, preserving high crystal quality even when interfacing highly mismatched materials. Therefore, the characterization of plastic and elastic strain relaxation mechanisms is key to understand and gain control over the optoelectronic properties of epitaxially grown planar structures. Here we propose a methodology to correlate these optoelectronic properties, namely the bandgap, with the structural properties, namely the strain, and prove its concept with ZnSe/ZnTe core-shell nanowires as radial p-n junctions, used as electro-optic detectors among other applications. The method is based on electron energy loss spectroscopy (EELS) to take advantage of sub-nanometric spatial resolutions.
To go through this correlation, we first evaluate the strain, by means of Geometrical Phase Analysis (GPA), in different ZnSe/ZnTe planar systems, which modulate their strain relaxation mechanisms and morphology depending on the substrate (sapphire) plane exposed, determining the final epitaxy of the system. Afterwards, the low-loss EELS regime is acquired, and our methodology is applied to extract and spatially map the bandgap energy, which can be linked with the previous strain measurements [2].
The proposed novel methodology for low-loss EELS analysis can get over limiting scenarios which are affected by parasitic signals such as Cherenkov radiation and surface modes. Until now, these contributions to the low-loss regime that hide valuable signals such as phonons, bandgap and plasmons, hampered more ambitious experimental setups and limited them to low refractive index materials or off-axis EELS [3]. Interestingly, our methodology allows the data cleaning and removal of parasitic modes in any acquisition condition and for materials with any dielectric description. In summary, the method uses unsupervised machine learning for spectrally mapping distinct regions and later applies a spectrum-wise theory-supported correction. These corrections based on classical electrodynamics enable the removal of the percentage of signal attributed to parasitic signals, therefore ensuring the remaining signal is only composed of intrinsic properties of the materials.
The present proof of concept focused on bandgap mapping, which is key knowledge in optoelectronics. However, the methodology is thought to be reproducible to any property if the adequate level of theory is applied. Importantly, this methodology and EELS high spatial resolution

proved its sensitivity by allowing us to distinguish a strain-induced direct to indirect bandgap transition at the interface between the ZnSe core and the ZnTe shell of one of the studied systems. In addition, although the original methodology was developed in the ZnSe/ZnTe heterojunction, preliminary results will be shown on Ge/SiGe quantum wells for holding spin qubits [4] and Ge/Si nanowires aiming towards topological quantum computing, which push the method to more challenging scenarios with bandgaps below 1eV.

Investigating Bone Microstructure with ATUM-SEM: Implications for Pathological Conditions

Ph.d Valeria Vistoso[1], Dr. Tom Fertè[1], Dr. Federica Buccino[2], Professor Laura Maria Vergani[2], Professor Ovidiu Ersen[1], Professor Adele Carradò[1]
[1]Institut de physique et chimie des Matériaux de Strasbourg, University of Strasbourg, Strasbourg, France, [2]Department of Mechanical Engineering, Politecnico di Milano, Milan, Italy

Poster Group 2

Background incl. Aims

Bone tissue's hierarchical structure is pivotal for various mechanical, biological, and chemical processes essential to health. However, the mechanical properties of bones are susceptible to deterioration, leading to an increased risk of fragility fractures associated with ageing, vitamin D deficiency, and bone density pathologies, such as osteoporosis [1]. The prevalence of these chronic illnesses, coupled with rising life expectancy, has become a significant public health concern. Additionally, the COVID-19 pandemic potentially exacerbates bone health issues, leading to decreased bone mass and strength in long-term hospitalised patients [2]. Bone fractures result in significant psycho-social and economic burdens, yet current understanding is limited to macro- and mesoscale levels. The challenge lies in comprehending the mechanobiological perspective at the multiscale level (between the mm and nm ranges). This knowledge gap, coupled with the influence of other intricate structural parameters, underscores the need for advancements in research tools and technical approaches.

Methods

Automated Tape Collecting Ultramicrotome Scanning Electron Microscopy (ATUM-SEM) has been introduced as an effective method for capturing high-quality images of hard tissues [3]. In this case study, the choice of using ATUM-SEM was driven by the need for a non-destructive approach that could enable the examination of the largest possible volume. The method was chosen for its flexibility, which allows cutting slices sections with a chosen thickness while preserving all of them for subsequent observations. Despite a thorough literature search, no suitable protocol was found to prepare human trabecular bone compatible with the ATUM-SEM-based approach. Consequently, it was determined that the best course of action was to utilise the same workflow previously used in the analysis of biological samples, with some adapted modifications made on a case-by-case basis. Trabecular bone samples from female and male patients diagnosed with different clinical conditions, namely osteoporotic, COVID-19, and a healthy control group, were evaluated. The specimens were processed by cutting them into macroscopic shapes appropriate for applying the ATUM-SEM approach, followed by careful cleaning and dehydration to improve their embedding in the resin. The resin embedding process was optimised for efficient sectioning, and a good trimming and polishing of the face of the specimen block was crucial for a stable section collection protocol. Slices, with thickness ranging from 300 nm to 400 nm, were collected onto Kapton tape using an Ultramicrotome. The imaging workflow that was utilised to reconstruct the acquired volume was managed using Atlas 5 Array tomography software and Fiji. Creating a 3D representation requires

accurate positioning of images in a virtual volume through registration. The alignment of the image stacks was accomplished using the TrakEM2 plug-in. Finally, Data visualisation is achieved using the 3D volume rendering present in Fiji.

Results

The ATUM-SEM data sets have yielded both qualitative and quantitative analyses, revealing distinctions in lacuna size and shape between osteoporotic and non-osteoporotic cases. Specifically, the osteoporotic and COVID-19 lacunae were larger, less stretched, and more rounded, with the average dimensions ranging from 6.12 µm x 12.27 µm x 10.8 µm and 7.17 µm x 20.96 µm x 6.9 µm, respectively. In the femoral head, lacuna volume exhibited internal variability, with osteoporotic and COVID-19 cases showing pronounced differences compared to healthy specimens (Figure 1). In the femoral head, the volume of the lacunae presents internal variability, ranging from 26% in healthy specimens to 14% in osteoporotic ones and 18% in COVID-19 patients. The volume difference is more pronounced when comparing the physiological state with the two pathological conditions. The volume of the osteoporotic lacuna is approximately 39% larger than the healthy sample, while the volume of the COVID-19 lacuna is around 53%. The complexity of the COVID-19 pathology requires further cellular-level studies to isolate its direct effects on bone microstructure and understand lacunar alterations among different variants, even if the possibility of bone micro-structural deterioration due to COVID-19 is proven [4]. The results of increased lacunar sphericity in osteoporotic subjects are consistent with other research works demonstrating that lacunar stretch is reduced in patients affected by this pathology [4]. Nevertheless, image segmentation and processing still need to be improved for quantitative analysis, demanding improvements in automated segmentation routines. While there are ongoing debates regarding the impact of age on bone microstructure, the study has identified age-related variations in the characteristics of canaliculi and lacunae.

Conclusion

This study highlights the importance of examining bone microstructure at finer levels to understand bone health and disease. ATUM-SEM provides high-resolution imaging and detailed analysis of bone microstructures, leading to better diagnosis and treatment of bone-related disorders. Exploring ATUM-SEM's clinical applications for early bone pathology detection shows promise and may lead to targeted therapies. These future directions in ATUM-SEM analysis of bone pathologies pave the way for enhanced research and clinical applications in the field, leading to a future where targeted interventions can mitigate the burden of bone-related disorders

Automated Detection of Material Defects for High-throughput Electron Micrographs Analysis

Andrei Tudor Durnescu[1], Sotero Pedro Romero Morón[1], Christina Nicole König[1], Joerg R. Jinschek[1]
[1]Danish Technical University, Lyngby-Taarbaek, Denmark

Poster Group 2

Background
Detailed analysis of material's microstructure is required for predicting material properties and fine-tuning manufacturing parameters to achieve the desired characteristics. This feedback process is particularly important when it comes to developing new production techniques such as metal additive manufacturing (AM).
Our goal is to provide a holistic solution that enables reliable materials characterization using a high - throughput approach in a scanning electron microscope (SEM) with automatic detection of characteristic microstructural features, especially defects such as cracks and pores. The scope of the detection framework that we cover includes all aspects of pre-processing the raw images from the microscope, defect identification and visualization of statistical results. In this way, it serves to overcome the current need for automation, providing researchers with a transparent and customizable process for their structural analysis. The customizable definitions of the parameters used in our algorithm also enable optimizations for applications in other fields of imaging, such as optical microscopy in biomedical research.
Methods
We acquired large-area secondary electron (SE) and backscattered electron (BSE) SEM images of an additively manufactured metal sample (316L steel) thereby varying dwell times from 10 microseconds to 100 nanoseconds and pixel size (i.e. magnification) from 391 to 49 nm. This allowed us to develop our image analysis algorithm to identify structural defects across a wide range of imaging conditions and systematically investigate the loss of precision in detection as image acquisition time was lowered (i.e. lower dwell time, larger pixel size). Once the micrographs were acquired, they were passed through a boundary detection procedure which isolates the relevant sample area. Filtering was then performed using multiple thresholding and convolution layers.
Results
Preliminary results have shown great promise in comparison to the manually labelled sections and flexibility to different imaging conditions. Performance metrics have also been compared with the most widely used classical tools in the field as well as with AI tools with which our software overlaps in scope.
The defects were characterized and selected according to user specifications in order to output statistical results and sample descriptors directly from the software interface. The robustness of the detection process has been verified using methods including comparisons with manually labelled sections and results obtained at highest dwell time and magnification. In this way, the development focuses on optimizing result consistency with shorter SEM image acquisition time, focusing on high-throughput analysis.
Conclusion
We have demonstrated in a systematic study the effect of SEM image acquisition parameters, such as dwell time and magnification, on the robustness of automatically detecting defects in AM 316L. This now enables the selection of optimised image acquisition parameters and a minimised data acquisition time (high throughput).

The scope of our developed approach is more comprehensive than any currently available tool can offer. The aim of this development is to make defect analysis more transparent and reliable by providing a unifying platform.

Control of inter-particle distance between nanoparticles using DNA origami

Jannik Guckel[1,2], Dr Daesung Park[1,2], Dr Markus Etzkorn[2,3], Zhe Liu[2,3], Zunhao Wang[1,2], Dr. Birka Lalkens[2,4]
[1]Physikalisch-Technische Bundesanstalt, Braunschweig, Germany, [2]Laboratory for Emerging Nanometrology (LENA), Braunschweig, Germany, [3]Institute of Applied Physics, Technische Universität Braunschweig, Braunschweig, Germany, [4]Institute of Semiconductor Technology, Technische Universität Braunschweig, Braunschweig, Germany

Poster Group 2

Background incl. aims
Metallic nanoparticle pairs, known as dimers, have been used to enhance the excitation rate of single quantum emitters. Among other parameters, the inter-particle distance (d) has crucial impact on the electro-magnetic field around the particles, leading to enhancement of signals. Thus, precisely controlling d is desired for achieving the optimized performance for the given applications. Usually, d is controlled by using linker molecules. In this study, we alternatively utilized the DNA strands to control d. Since this technique has several independent parameters, it ensures a high degree of customization.
Methods
The synthesis of dimers was adapted by Gür et. al. [1] and consists of 2 steps. In the first step, we functionalized the nanoparticles using using single strands of poly-thymine. In the second step, selected staples of the DNA origami were extended with pieces of single-stranded poly-adenine. The complementary strands connect via hydrogen bonding, forming the strand of length (L) (Fig. 1A). We analyzed multiple secondary electron (SE) images of these self-assembled gold dimers using different L from different samples in order to verify the reliability of the control of d. Based on geometric considerations (Fig. 1B), we expect an increase in the standard deviation σ of d. We therefore required large amount of dimers to obtain statistical significance. The detailed analysis of the SE images was achieved by using a novel analysis tool developed for this task. The tool uses the intensity thresholding technique to segregate the DNA origami from the silicon wafer, and then analyzes each origami individually. We use circle Hough transform (CHT) to detect the spherical particles, with a set of novel classification routines to assign one of 4 classes (monomer, dimer, single particle on wafer, agglomerate) to each particle (Fig. 2)
Results
We analyzed the distribution of d across multiple samples using our tool, measuring more than one thousand dimers per sample. While the general trend of σ increasing with L could be observed in the experimental data, the proposed effect of L on σ is smaller than expected (Fig. 3). The deviation between the simulation and experiment can be attributed to our model only taking sample geometry with few assumptions about the DNA strands into account. However, based on our observations, more complex effects of DNA bonding and the interactions between nanoparticles, DNA strands and DNA origami led to notable change in the distribution of d. Therefore, an accurate prediction of the distribution of d requires a more complex model.
Conclusions
We investigated multiple samples, in which the different inter-particle distances of gold dimers were achieved using different DNA strand length on the DNA origamies. Based on sample geometry, we expected a significant effect of the DNA strand length on the distribution of d, with longer strands resulting in a broader distribution. Our experiments confirm the existence of this trend, even though

the effect is smaller than our initial expectations. Our results show that complex interactions within the material system have significant effects on the distribution of d, making an accurate prediction of the distribution more complex than anticipated.

LS-09, Lecture Theater 4, august 27, 2024, 14:00 - 16:00

Eukaryotic cells maintain cellular proteostasis through intricate protein quality control systems that orchestrate chaperone-mediated protein folding and protein degradation systems, preventing potential harm from accumulated misfolded proteins. The chaperone system attempts to refold the abnormal proteins and solubilize aggregated proteins; if unsuccessful, these aberrant proteins are removed through the protein degradation system.
In the ubiquitin-proteasome system (UPS), the degradation process is initiated by the recognition of ubiquitinated substrates by the 19S regulatory particle (RP), which is then followed by unfolding and translocation of substrates in the 20S catalytic particle (CP) that executes protein degradation. Aside from the canonical subunits, proteasome function is finely tuned by cofactors that contain ubiquitin-like (UBL) domains which are involved in recruiting substrates to the 26S proteasome.
On the other hand, Bag1 has been shown to interact with Hsc70/Hsp70 to modulate the chaperone activities. Through an ATP-driven conformational cycle, Hsp70 can recognize misfolded proteins, promote refolding, prevent protein aggregation, and resolubilize protein aggregates. Despite their many different roles, all members of the Hsp70 family contain two highly conserved structural domains: the substrate-binding domain (SBD) and the nucleotide-binding domain (NBD). The ADP/ATP switch is catalyzed by a group of cochaperones called nucleotide exchange factors (NEF), which bind to the NBD and favor ADP release from the active site and ATP re-uptake. Bag1 is one of such NEF and contains both UBL and BAG domains and interacts with the 26S proteasome through the UBL domain to degrade unfolded proteins. However, how cochaperone Bag1 bridges between protein folding and degradation systems, and how Bag1 enhances degradation of unfolded proteins remain unanswered.
In this work, using cryoelectron microscopy (cryoEM) and different biochemical and biophysical techniques, we have revealed that Bag1 plays a key role in Hsp70-mediated, proteasome-dependent protein degradation, not only by physically linking Hsp70 to the proteasome (through its subunit Rpn1), thus promoting protein delivery to the latter but also by inducing a series of conformational changes in the 19S that facilitate the client protein degradation.

Analysis of epigenetic modifications with the LiveMIEL (Live-cell Microscopic Imaging of Epigenetic Landscapes) approach

Alexandra Shuvaeva[2,3], Elizaveta Khvedelidze[4], Afanasii Stepanov[1,2], Dr. Lidia Putlyaeva[1,2]
[1]Center for Molecular and Cellular Biology, Skolkovo Institute of Science and Technology, Moscow, Russia, [2]Shemyakin-Ovchinnikov Institute of Bioorganic Chemistry, Moscow, Russia, [3]Moscow Institute of Physics and Technology, Dolgoprudny, Russia, [4]D. Mendeleev University of Chemical Technology of Russia, Moscow, Russia

Poster Group 2

Background incl. aims
Epigenetic modifications are reversible covalent chemical modifications of DNA, histones, and microRNAs. These modifications act as recognition sites for chromatin-binding proteins that regulate the access to the genomic DNA during replication and transcription. A clear and self-consistent picture of these modifications in dynamics is crucial for our deeper understanding of epigenetic regulation of the genome. Reader domains play a key role in the interpretation of the histone code, which is an essential part of the epigenetic regulation, because they interact with histone modifications and recruit proteins with specific activities to a given chromatin locus.
Methods
The data was obtained using the LiveMIEL (Live-cell Microscopic Imaging of Epigenetic Landscapes) analysis [1], which exploits computer vision and machine learning approaches to classify cells according to specific patterns of epigenetic modifications. The concept of image processing and analysis included segmentation, extraction of characteristic features from segmented images, and clustering of the obtained data. For this purpose, we created a HEK293T cell line stably expressing the MPP8-Red sensor based on the MPP8 reader domain fused to the Katushka fluorescent protein. We also used the Cdt1-TagBFP2 and mVenus-hGeminin plasmids (components of the FUCCI-CA cell cycle indicator system). Then we collected fluorescent microscopy images and derived texture and 98 morphological features from each segmented nucleus.
Results
Here we present our data on the redistribution of histone modification H3K9me3, which is known to correlate with the suppression of gene transcription during the cell cycle and after treatment with several drug classes. After extracting information from all of the obtained images of each single nucleus, the data clustering analysis was performed. The optimal number of clusters (n=3) was then determined using the silhouette coefficient analysis. The results of LiveMIEL analysis obtained from the HEK293T-(MPP8-Katushka + FUCCI-CA) cells showed a good agreement with the similarly processed data from the cells' cycle phases (G1, S, G2, and M) with FUCCI-CA as a fluorescent indicator. We observed the most drastic changes in the H3K9me3 profile in the G2 and M phases compared to the S and G1 phases.
Furthermore, we demonstrated a statistically significant effect of small dosages (starting at 0.01 µM) of AT9283, OTX015, EPZ-6438, and RG2833 drugs with the LiveMIEL analysis. The impact of the studied drugs on the architecture of H3K9me3 in the nucleus was confirmed with the MTT assay.
Conclusion
The approaches and models developed in this project could be found useful for analysis of biological material. For instance, such material could be obtained from patients as a part in the newly-developing pipelines for personalized medicine. The other promising option is screening of the epigenetic effects of drugs at a high throughput and low cost.

The EXCITE² Network: a European infrastructure providing transnational access to leading-edge imaging facilities

Alireza Chogani[1], Oliver Plümper[1], Geertje ter Maat[1], the EXCITE team
[1]Department of Earth Sciences, Utrecht University, Utrecht, The Netherlands

Poster Group 2

The EXCITE² Network is a leading European electron and X-ray imaging infrastructure for research into Earth materials. This network is revolutionizing Earth and environmental material science research by consolidating 19 research facilities in 12 European and associated partner countries into a unified infrastructure that will provide transnational access to advanced imaging technologies. This open access to our state-of-the-art microscopy facilities enables scientists to decipher complex processes within Earth materials across scales ranging from nanometres to hundreds of centimetres. Understanding these processes is critical to creating a sustainable, carbon-neutral society, as they govern various phenomena, including environmental toxicity and its impact on human health, critical metal extraction for renewable energies, geothermal energy extraction, subsurface energy storage, and the utilization of Earth materials for long-term storage of climate-altering gases.
EXCITE² is driving interdisciplinary collaboration and cross-fertilisation across academic institutions, scientific disciplines, and industry, propelling Europe towards a sustainable future. In addition to access to leading-edge imaging facilities, the network offers early career researchers a chance to team up with leading Earth-materials scientists, develop new collaborations, engage in cross-disciplinary initiatives, and execute progressive electron and X-ray imaging projects that contribute to the advancement of Earth-materials research. We connect with you, provide access to workshops and webinars, assist in preparing your proposals for facility access, and actively support your research goals. Moreover, the initiative offers dedicated training programmes to a new generation of researchers within the European open science landscape. EXCITE² is introducing innovative service developments, such as artificial intelligence and leading-edge imaging experiments, to increase the user's problem-solving capacity. As such, EXCITE² is paving the way towards a sustainable future, driving scientific excellence, and creating positive societal impact.
Access to EXCITE² can be requested by applying to our transnational access calls. Interested? Have a look on our website (https://excite-network.eu) – and apply for the next call!

Structural Probing of Charging Mechanism in LiNiO2 at High Voltage using Microscopy and Spectroscopy

Dr Jun Chen[1], Dr Mikkel Juelsholt[2], Dr Robert House[1], Prof Peter Bruce[1]
[1]Department of Materials, University of Oxford, Oxford, United Kingdom, [2]Department of Chemical Engineering. Columbia University, New York, United States

Poster Group 1

Background
The demand of high-energy lithium-ion batteries boosts the interest in increasing Ni content in cathodes and raising charge cutoff voltage. LiNiO2 is a critical archetypal material for high energy density Li-ion batteries, forming the basis of Ni-rich cathodes in use today. Unfortunately, LiNiO2 suffers from a number of problems at high states of charge which have been linked with oxygen redox. Substantial efforts have been made to understand the structural transitions that take place when Li is extracted from LiNiO2, but there remains considerable debate over its structural mechanisms, in particular the extend of Ni oxidation and oxygen participation when charging at high cutoff voltage. [1,2]

Methods
We use polycrystalline LiNiO2 powder to make composite electrodes into Li coin cells. After charging and discharging to specific states of charge, we disassemble the cell for following characterizations. We use the annular dark-field scanning transmission electron microscopy (ADF-STEM) to directly examine structural changes at the atomic level. We employ combined neutron and synchrotron X-ray powder diffraction analysis that takes account of the stacking faults, and quantified the Ni vacancies formed when the material is charged across the voltage plateau. High resolution resonant inelastic X-ray scattering (RIXS) at the O K-edge is used to detect the molecular O2 that could be formed associated with O-redox. Ni L-edge and O K-edge X-ray absorption spectra are collected to probe the chemical state changing in LiNiO2. Chemical analysis by inductively coupled plasma-optical emission spectroscopy (ICP-OES) is used to check if there is Ni dissolution into the electrolyte after cycling.

Results
The atomic-resolution showed the surface densification and cation mixing evolution near surface region of LiNiO2 over charging to high cut-off voltage (Fig. 1a). When charging acrossing the 4.2V plateatu vs. Li+/Li, the particles form core–shell nature, with a Ni-rich, Ni1.75O2 rocksalt-like shell approximately of 5 nm thickness at the top of charge. The refinement of neutron and synchrotron X-ray powder diffraction demonstrates 8% Ni vacancies form in the originally fully dense transition metal layer at 4.2 V (Fig. 1b). Chemical analysis by ICP shows that the Ni absent from the bulk does not leave the particles. While in principle there is sufficient Ni3+/4+ oxidation capacity to account for all the Li+ removed on charge without O2- oxidation, high resolution RIXS at the O K-edge confirms the presence of trapped molecular O2, on charging across the plateau, which is accommodated Ni vacancy clusters. Ni L-edge XAS measurements in fluorescence yield mode implies the average oxidation state of Ni of less than +4, coexisting with the presence of O-redox at the top of charge (Fig. 1c,d).

Conclusion

Our results reveal that the structural instability in LiNiO2 is more extensive than previously thought. As illustrated in Fig. 1e, beyond the 4.2 V vs. Li+/Li plateau, Ni accumulates at and near the surface of the particles, forming a Ni-rich shell approximately 5 nm thick; enhanced by loss of O2 from the surface. This shell has composition of Ni1.75O2 shell a Ni oxidation state of +2.3. The oxidation of O2− across the 4.2 V plateau forms O2 trapped in the particles and is accompanied by the formation of 8% Ni vacancies on the transition metal sites of previously fully dense transition metal layers. The overall Ni oxidation state of the particles measured by XAS in fluorescence yield mode after charging across the plateau to 4.3 V vs. Li+/Li is approximately +3.8; however, taking account of the shell thickness and the shell Ni oxidation state of +2.3, this indicates a Ni oxidation state in the core closer to +4 for compositions beyond the plateau.

Advanced acquisition strategies for lab-based diffraction contrast tomography

Florian Bachmann[1], Jun Sun[1], Jette Oddershede[1], Erik Lauridsen[1]
[1]Xnovo Technology ApS, Køge, Denmark

Poster Group 1

Background incl. aims
Non-destructive imaging of a polycrystalline material's 3D grain microstructure is key to a better understanding of the material performance and to validating computational models for predicting the material behavior. In addition, an integrated microstructural modeling approach, ensuring the handshake between modeling and experimentation, relies on adequate experimental statistics of 3D sample volumes that are representative in both size and shape.

Methods
In this study, we exploit lab-based diffraction contrast tomography (DCT) [1,2] to experimentally map the 3D grain structure. The introduction of three new advanced acquisition strategies for lab-based DCT – named Helical Phyllotaxis, Helical Phyllotaxis Raster, and Helical Phyllotaxis HART – enables grain mapping of longer, larger, as well as high-aspect ratio samples [3]. The implementation of these advanced acquisition strategies combines a golden angle rotation with vertical and horizontal translations to perform a seamless data collection that has a uniform sample illumination both angularly and spatially. Reconstruction of the corresponding data is equally seamless, simultaneously using all data to reconstruct the full illuminated volume without the need for stitching of data subsets or sample subvolumes.

Results
We will present and discuss different acquisition strategies with emphasis on how to approach a given acquisition problem inherent to the sample. Particular emphasis will be on the Helical Phyllotaxis HART (high-aspect ratio tomography for plate-like samples) strategy that enables investigations of a hitherto inaccessible class of sample geometries comprising industrially relevant materials like rolled metal sheets and electrical steels [4].

Conclusion
The advanced acquisition strategies take lab-based non-destructive 3D grain mapping to the next level of throughput, grain statistics and versatility. While the throughput warrants 4D studies of materials microstructural evolution, a representative sample volume is a prerequisite for successful model predictions, and the versatility enables studies of samples or components under more realistic in situ or in operando conditions.

Thallium and arsenic incorporation in roméite group minerals

Priv.-Doz. Dr. Tamara Đorđević[1,2], Priv.-Doz. Dr. Michael Stöger-Pollach[1], Dr. Sabine Schwarz[1]
[1]E057-02 USTEM, Vienna University of Technology, Vienna, Austria, [2]Department of Mineralogy and Crystallography, University of Vienna, Vienna, Austria

Poster Group 2

Background incl. aims
Roméite group minerals (RGM) are oxides, which belong to the large pyrochlore supergroup of minerals. The general formula of the pyrochlore supergroup is $A_2B_2X_6Y$ (A = Na, Ca, Ag, Mn, Sr, Ba, Fe(II), Pb, Sn(II), Sb(III), Bi(III), Y, REE, Sc, U, Th, □ and H_2O, B = Ta, Nb, Ti, Sb(V), W, V(V), Sn(IV), Zr, Hf, Fe(III), Mg, Al, and Si, X = O, OH, or F and Y = (OH)–, F–, O2–, □, H_2O, or even large cations, such as K, Rb, Cs). The crystal structure of RGM is build-up of BO_6 octahedral framework that forms tunnels along [110] where 8-coordinated A cations and Y anions are hosted. In the RGM, Sb(V) is the dominant cation at the B site, but on the A-site, larger cations can be incorporated where also the ion-exchange can take place. Therefore, RGM are often used for the immobilization of the toxic metals, such as Pb and Sr and have been frequently reported as weathering products in mining wastes and smelting residues resulting from Sb mining activities.
Methods
High-resolution electron microscopy, both transmission (TEM) and scanning (SEM), including energy dispersive spectroscopy (EDS), energy electron loss spectroscopy (EELS), and selected area electron diffraction (SAED), are used to characterize Sb- and As-rich samples from mining waste dumps from the Sb-As-Cr Lojane deposit, North Macedonia, and Tl- and Sb-rich samples from weathered technosols of the central part of the Sb–As–Tl–Au Allchar deposit, North Macedonia. These techniques are supplemented by X-ray diffraction (XRD) and Raman spectroscopy.
Results
RGM from the Lojane deposit are observed as extremely thin (< 10 µm) weathering crusts encircling grains of stibnite, Sb_2S_3 and realgar, AsS. Larger homogenous grains up to 500 µm are formed by Sb-dominant variants of this oxide, which are also characterized by broad dehydration cracks, indicating that they were originally formed as gels. The analysed thin crusts and aggregates are most likely poorly crystalline to amorphous, As-dominant RGM-like phases, which appear darker grey in the SEM images, and nano- to microcrystalline, Sb-dominant RGM, which appear very light grey in the SEM images. The crystallographic position of arsenic in the RGM in our samples is not fully clear. In the RGM, As(V) may occupy the octahedrally coordinated A-position, but it strongly prefers tetrahedral coordination. The distorted cubic B-position in RGM is too large for the As(V) cation. These crystal-chemical preferences explain why the As is mostly in the X-ray amorphous phases. However, EDS point analyses clearly document that the RGM may incorporate considerable As.
In the mining waste dumps of Allchar deposit, Tl dissolved during weathering is besides other Tl-oxides, such as avicennite, Tl_2O_3 and amorphous Tl-Mn-oxides, reprecipitated as tiny spherulitic aggregates (up to 2 µm) of a Tl-Sb-oxide (a new mineral species). TEM-based SAED on Tl-Sb-oxide nano-particles confirmed that the Tl-Sb-oxide is crystalline, and chemical composition analysed by EDS-line and area scans confirmed a Tl:Sb ratio of 2.5. The cell parameters calculated from the SEAD pattern show good comparison with the members of pyrochlore-type structure.
Conclusion

Understanding the potential pathways for Tl and As incorporation in pyrochlore-type structures addresses not only the growing environmental concern over these two priority pollutants, but also contributes to the larger field of waste management.

Impact of improved tracking method on structure determination of perovskites from 3D ED data

Dr. Magdalena Cichocka[1]
[1]Technische Universität Darmstadt, Darmstadt, Germany

Poster Group 2

Background incl. aims
Perovskites (ABX_3) and perovskite-related compounds are some of the most chemically diverse crystal structures with many possible substitutions at A and/or B sites, as demonstrated in oxide systems [1,2]. These materials can be produced using facile processing techniques and yield high performance devices, although they are characterized by large compositional and structural heterogeneities at multiple length scales. Even small structural changes can be induced by strain engineering and open a way to enabling new or deliberately modified material properties. XRD structure refinement requires great effort, especially in the case of accurate characterization of small structural distortions, oxygen positions, and octahedral rotations. Additionally, the contribution of several oriented domains makes structure refinement more complex.
Methods
3D electron diffraction (3D ED) technique [3,4], which may or may not be coupled with precession electron diffraction, allows not only to determine an average structural model, but also to refine it with good accuracy. Moreover, tracking methods, which have been developed in our group [5], can significantly improve the diffraction intensities and overall detailed structure description. They also provide support in answering questions about structural details.
Results
In the present work, we perform structure analysis of perovskites to demonstrate its improvement by dedicated data acquisition routines. By implementing dynamic theory in the refinement, 3D analysis of region of interest in the range of tens of nm and accounting for precession motion, it is possible to obtain reliable and accurate refinement of perovskite structures. Taking into account the selective contribution of differently oriented grains allows for a more accurate description of the structure.
Conclusions
Implementing the dedicated data acquisition strategy and improving the diffraction pattern analysis, pave the way for a new routine characterization of structure details in complex perovskite materials. This places 3D electron diffraction even closer to complementary scanning transmission electron microscopy (STEM) and convergent beam electron diffraction (CBED) techniques, which are usually a choice to map octahedral tilts or atomic vacancies at grain boundaries.

Effects of melatonin and alpha-lipoic acid on collagen and VEGF expression in palatal wound healing

Onur Kutlu[1], Gülten Kavak[1], Aslı Erdoğan Öner[2], Selen Akyol Bahçeci[2]
[1]Department of Oral and Maxillofacial Surgery, İzmir Katip Çelebi University , İzmir, Türkiye,
[2]Department of Histology and Embryology, İzmir Katip Çelebi University, İzmir, Türkiye

Poster Group 1

Background incl. aims
Reactive oxygen species (ROS) play a crucial role in the normal physiology of wound healing. The balance between high and low levels of ROS is critical during the healing process. As regulators of oxidative stress, antioxidants are proposed as targets for new therapies to accelerate wound healing. Alpha-lipoic acid and melatonin are antioxidants that have been shown to be involved in wound healing in many different organs. In addition to protective effects against oxidative stress, they also exert anti-inflammatory effects. In this study, we aimed to evaluate the effects of alpha-lipoic acid and melatonin on rat palate wound healing and whether they have a synergistic effect when used together.
Methods
A total of 64 male and female adult Wistar rats were randomly divided into 4 main groups. All rats were anesthetized with intramuscular ketamine hydrochloride (50 mg/kg) and xylazine (10 mg/kg) injections before creating a 5 mm diameter wound using a punch biopsy in the central area of the hard palate. Experimental groups were treated with daily intraperitoneal injections of alpha-lipoic acid (60 mg/kg/day) or melatonin (30 mg/kg/day) or both of them until sacrification. Control group did not get any injection. 2 sub-groups were created for each group, according to sacrification days; 5 or 10 days after wound creation. Palatal biopsies were fixed with 10% neutral buffered formalin. After decalcification for 8 days in decalcification solution, samples were dehydrated with increasing grades of ethanol, cleared with toluene, and embedded in paraffin. 5 µm thick sections were taken with microtome. Masson trichrome stain was performed to evaluate the amount of collagen fibers in sections. VEGF expression was determined using the immunohistochemistry method. After taking photographs of the sections, Image J software was used to evaluate the results of the stainings. Statistical analyses were performed using IBM SPSS version 24.
Results
Collagen fiber density in the granulation tissue in the 5th day samples of the melatonin-treated group was significantly higher than that in the control group ($p<0.008$). On the 10th day, the collagen fiber density in the granulation tissue of the alpha-lipoic acid + melatonin group was significantly higher than that of the control group ($p<0.008$). In immunohistochemical staining using VEGF, positive immunoreactivity was detected in the epithelial areas of all group samples. Cytoplasmic and widespread VEGF expression was observed in all epithelial layers (except the stratum corneum-keratin layer), especially more prominently in the stratum granulosum. No specific and significant immunoreactivity was found in the granulation tissue or subepithelial connective tissue in the wound area. VEGF expression on the 5th day was significantly higher in the alpha-lipoic acid + melatonin group compared to the control group ($p<0.008$).
Conclusion
Growth factors and collagen production are one of the key factors that determine the wound healing. According to our results, the combinatory application of alpha-lipoic acid and melatonin

might be effective in palatal wound healing via collagen synthesis in the early period and via VEGF expression in the late period.

TEMsuite – A Matlab-based software platform for TEM data analysis

Simon Hettler[1,2]
[1]Instituto de Nanociencia y Materiales de Aragón (INMA), CSIC-Universidad de Zaragoza, Zaragoza, Spain, Zaragoza, Spain, [2]Laboratorio de Microscopías Avanzadas (LMA), Universidad de Zaragoza. Zaragoza, Spain, Zaragoza, Spain

Poster Group 2

Background incl. aims
Transmission electron microscopy (TEM) can provide a wealth of information on structure and composition at the atomic level for many different kinds of samples. To obtain this information, numerous different imaging, diffraction or spectroscopic techniques are available, e.g., high-angle annular dark-field (HAADF) scanning (S)TEM, selected-area electron diffraction (SAED), electron energy-loss spectroscopy (EELS) or energy-dispersive X-ray spectroscopy (EDX) to name some of the more common ones. To perform an advanced data analysis, again a multitude of dedicated software exists, many of them being freely available, such as HyperSpy for multidimensional spectroscopic analysis [1] or PETS for analysis of diffraction data [2]. Despite the availability of these specialized software, most users, especially those that only occasionally perform TEM analysis, still use commercial, proprietary software to perform basic data treatment and the threshold to learn yet another, even more specialized software is high. With the aim to speed up my own data processing tasks, I have written a software platform based on Matlab that facilitates several basic and advanced data analysis processes and which I have made freely available [3].

Methods
The software is written in Matlab with a graphical user interface (GUI) made up of a main window, a figure window for display and several windows to control the data analysis (Figure A). The software follows a session-based approach that allows to load and process different TEM data types at the same time. The sessions can be stored and reloaded at a later point to continue the data analysis. The following list describes several of the tasks that TEMsuite allows to perform: Basic image processing (contrast settings, line scans, export images as .jpg or .tif, add a scale bar, …), alignment of images series and export to movie, FFT filtering and analysis of reflection spots in the FFT. The software possesses a comprehensive set of tools for diffraction analysis including an automatic peak detection, fitting and correlation as well as the calculation of radial or azimuthal profiles. EELS multidimensional data can be visualized and analyzed statistically (principal-component analysis (PCA), non-negative matrix factorization (NNMF)). Core-loss EELS data can be quantified using theoretical scattering cross sections and the background-subtracted spectra can be fitted to obtain chemical information of the studied specimens.

Results
Several publications contain results from data analyses conducted with TEMsuite, for example the study on quasi-van der Waals epitaxial growth of WS_2 on sapphire [4] or the investigation of iron/cobalt-oxide core-shell nanoparticles for catalytic applications [5]. Figure (B) shows the NNMF analysis of an EELS spectrum image obtained from the interface between sapphire substrate (left), WO_3 interface and WS2 and carbon protection layers. The analysis yielded the clear separation between the four contributions and the plasmon peak energies of the associated spectra correspond with expected values [4]. The chemical map (Fe: green, Co: blue, O: red) obtained by a spatially-

resolved EELS analysis of an iron/cobalt-oxide core-shell nanoparticle shows the clear formation of a Co-rich shell (top left in Figure C) [5]. The Co presence manifests itself as well in the intensity ratio of the O-K pre-peak and the following valley, as visualized in the spectrum and the corresponding map (top right) in Figure C.

Conclusion
I developed the TEMsuite software initially to speed up my own TEM data processing but improved its design and setup with the aim to obtain a version that can be used by other users. The software is thought as platform for basic and advanced TEM data analysis currently focusing on image, FFT, diffraction and mainly EELS analysis and it is planned to be further expanded to include more techniques throughout the following years. The software is freely available as source code [3].

Figure caption: (A) TEMsuite GUI with main window (top left) including the list of loaded image and spectroscopy data, figure window (right) with an example EELS-spectrum image quantification and the EELS window (bottom left) to control the EELS data analysis. (b) Example analysis of a quasi-van der Waals epitaxially grown monolayer of WS_2 by NNMF yielding four contributions of carbon protection layer, sapphire substrate, interface (WO_3) and WS_2 monolater. (C) Example analysis of an EELS spectrum image of a Fe/Co-oxide core-shell nanoparticle with chemical map (top left), comparison of O-K spectra from shell and core (bottom) and map of the intensity ratio between the O-K pre-peak at 532 eV and the following valley (top right).

NiTi shape memory alloy microstructure after high stress at elevated temperatures containing modulated M2 martensite
J. Duchon, Y. Chen, M. Klinger, P. Šittner
Institute of Physics of the Czech Academy of Sciences, Na Slovance 2, Prague, Czech Republic

Background
Nanocrystalline wires with shape memory NiTi were deformed in the martensitic state at low temperatures of -125 °C up to a stress of ~750 MPa. In the next step, the wires were heated well above the temperature Af while maintaining a constant stress of ~750 MPa. The wire was driven towards its thermomechanical stability limits under such a specific condition and finally transformed into plastically deformed austenite. Microstructure of nanocrystalline NiTi shape memory wire was analyzed in Transmission Electron Microscope (TEM) with the aim to reveal the microstructures of martensite variants and lattice defects evolving in the heated wire, and at the same time to reveal the mechanism of plastic deformation and highly constrained reverse martensitic transformation. Although the constrained NiTi martensite wire should transform back to austenite at elevated temperatures, the applied stress prevents this reverse transformation and plastic deformation of martensite occurs instead. However, the mechanism of plastic deformation of martensite under such elevated temperature and high stress conditions remains unclear.

Materials and Methods
The NiTi shape memory wire was commercially prepared by Fort Wayne Metals in cold work state with the following parameters FWM #5 Ti-50.5 at.% Ni, 42% CW, diameter 0.1 mm. Such wire was heat treated by the electric power pulse method with power density 160 W/mm3 and pulse time 15 ms. Final wire has a fully recrystallized microstructure with a mean grain size d = 250 nm and showing transformation temperatures Ms = 63 °C, Af = 93 °C.
Wire microstructure was investigated using TEM specifically FEI Tecnai TF20 X-twin equipped with a field emission gun operating at 200 keV. TEM lamellae were extract from the deformed NiTi wires by Focused Ion Beam (FIB) lift-out technique using a FEI Quanta 3D FIB-SEM microscope. TEM, HRTEM, SAED and nanobeam electron diffraction micrographs were acquired for a detailed understanding of the resulting martensitic microstructure. TEM diffraction patterns and HRTEM images were indexed using the CrysTBox [1] software. HRTEM images have been also processed by Geometric Phase Analysis (GPA), which is part of the software, and it was developed to analyze local strain fields by HRTEM, for example strain fields around dislocation cores. Nanobeam diffraction analysis of modulated martensite was also performed, to have local diffraction information.

Results
TEM analysis of the wires revealed that, when the martensite is heated under the stress towards its stability limits, so the microstructure contains mixed regular B19' and modulated M2 martensitic lattices with a high density of lattice defects, e.g., dislocations. Such a complex microstructure could

not be characterized by conventional TEM, therefore HRTEM and nanobeam electron diffraction were used.
TEM analysis showed deformation bands in the microstructure of the martensitic variants were found everywhere in the martensite microstructure. The microstructures of martensitic variants produced by kwinking consist of deformation bands in which the martensitic lattices are rotated with respect to the martensitic matrix sharing a common [010] zone axis. A large number of dislocations in the martensite microstructure were also found here. More detailed TEM analyzes showed that in addition to these commonly observed findings, abnormal diffraction patterns were also observed. Diffraction patterns (SAED, FFT of HRTEM and nanobeam diffraction) from various regions could not be indexed using the lattice parameters of the B19' monoclinic lattice, because of the additional diffraction points appeared halfway between the 000 and 001 points. The occurrence of such additional diffraction spots indicates that the martensite has a modulated lattice with a unit cell twice as long in the c-direction.
During heat treatment the oriented martensite heated at constant applied stress undergoes a B19' => M2 structure change and moreover the martensite plastically deforms before and during the transformation to austenite. The study revealed that the plastic deformation of martensite variants takes place via kwinking deformation involving coordinated dislocation slip, twinning and simultaneously created a long period modulated crystal structure. It is assumed that the modulated martensite structure arises from the B19' martensite structure through coordinated slip of partial dislocations with Burger's vector b = a/2 [100] on the (001) crystal planes. Coordinated slip was forced by kwinking deformation. The partial dislocations began to slide as the martensite was exposed to elevated temperatures.

Conclusions
To find out the deformation process of the martensitic wire, which was exposed to high stress under high temperature conditions and forced to its stability limit, we analyzed the microstructure of the wires annealed to different maximum temperatures by TEM. During this research we found that locally within the grain in some wires the diffraction patterns exhibit a modulated structure. From the diffraction patterns, it was found that the modulated structure has a unit cell twice as long in the c-direction. The formation of these areas within the grains will be due to the plastic deformation occurring in the wire under constant stress and elevated temperature, above the temperature Af.
It was revealed that the heated martensite wire plastically deformed by kwinking deformation and simultaneously transformed into a long-term modulated monoclinic structure with a high density of dislocation defects, before and while undergoing reverse martensitic transformation into plastically deformed austenite. Based on the results, it is suggested that the modulated martensite structure is formed through the coordinated slip of partial dislocations with Burger's vector b = a/2 [100] on (001) crystal planes, thereby achieving a large shear deformation of the crystal lattice, which is forced by kwinking deformation. The modulated structure will be considered as a local and temporary martensite structure that appears before it transforms to austenite under forced heating. During transformation martensite to austenite the modulated martensite generates high density of dislocation defects and a corresponding lattice strain in austenite microstructure.

Influence of the deposition parameters on properties of gold plasmonic antennas

Michael Foltýn[1], Marek Patočka[1], Rostislav Řepa[1], Tomáš Šikola[1], Michal Horák[1]
[1]Brno University of Technology, Brno, Czech Republic

Poster Group 2

The properties of plasmonic antennas depend on a variety of factors, including the antenna size, shape, and material. Although gold plasmonic antennas have been studied extensively over the last few years, the influence of parameters used for gold thin film deposition on the resulting plasmonic behaviour of fabricated antennas remains unexplored.
We deposited gold films with thicknesses of 20 nm, 30 nm, and 40 nm at various deposition rates by an ion-beam-assisted deposition. We analysed the structure of deposited films by X ray diffraction and transmission electron microscopy. We fabricated gold plasmonic antennas by FIB lithography [1, 2] and evaluated the ease of fabrication for each deposited layer used, based on the fabrication yield of three antenna types. Further on, we studied the plasmonic behaviour of fabricated antennas by EELS [3] and compared the plasmon resonance intensity and Q factors of individual antennas.
Our results [4] show, that for fabrication of plasmonic antennas by FIB lithography, the films deposited at 0.3 nm/s are optimal, as the fabrication yields of these layers are the highest. However, in terms of plasmonic properties, antennas fabricated from 20- and 30-nm thick layers deposited at 0.1 nm/s exhibit the highest plasmon resonance intensity and highest Q factors. In the case of 40 nm thick layers, the best plasmonic performance is achieved in antennas fabricated out of gold films deposited at 0.3 nm/s. Figure below shows the results for 30-nm-thick gold layer: fabrication yield (A), EEL spectra for two specific electron beam positions at the corners (B) and in the gap (C) of a bowtie antenna, and Q factros of the transverse dipole (TD) and longitudinal dipole (LD) mode (D).
This study sheds light on the interplay between gold thin film deposition parameters and the resultant plasmonic behaviour of antennas, offering valuable recommendations for optimizing the fabrication process of plasmonic devices.

LS-07 (2), Lecture Theater 5, august 28, 2024, 14:00 - 16:00

Background:
ATP2C1 gene encodes for the secretory pathway Ca2+/Mn2+ pump ATPase type 1 (SPCA1) localizing at the Golgi apparatus. Mutations on the human ATP2C1 gene, causing decreased levels of the SPCA1 expression, have been identified as the cause of the Hailey–Hailey disease (HHD), a rare skin disorder. More than 200 unique mutations have been found, with any hot-spot on the ATP2C1 gene. The HHD patients present raw, blistered areas and lesions, particularly in skin folds where there is moisture and friction. No effective cure exists. Due to reduced expression of functional SPCA1 in HHD patients, altered Ca2+ homeostasis and responsiveness in HHD keratinocytes results in creating an early defect in differentiation process due to a reduced production of involucrin. Keratin expression was also delayed in acantholytic epidermal segments of HHD skin. This results in fragile skin layers. However, no deep investigation at ultrastructural level have been never performed.

Methods:
Advanced gene sequencing has been used to identify mutations on the ATP2C1 gene of HHD patients for this study.
Using volume Scanning Electron Microscopy (SEM)-array tomography we investigated the status of the cell-cell interaction in the epidermis of five different HHD patients. Epoxy resin embedded samples have been sectioned (300nm) using the Powertome-XL ultramicrotome (RMC Boeckler, USA) and serial sections were collected on Kapton tape with an automated ATUMtome collection, and then transferred on Si-wafer support for being imaged in the SEM Gemini 450 (Zeiss, Germany). Sequential images where then managed and over-imposed to generate a 3D model of the cell-to-cell interactions.
Furthermore, using 3D-Transmission Electron Microscopy -tomography we also investigated the alterations in the secretory pathway, with particular focus on the Golgi apparatus, in the keratinocytes (epidermis) and in fibroblasts (dermis). Semi-thin sections (250nm) cut with a UltraCut-UC6 microtome (Leica, Austria) were collected onto formvar-coated copper slot grids and imaged with a Talos L120C Transmission Electron Microscope (TEM) (Thermo Fisher Sc., USA) using motorized tilt-rotate specimen holders. Tilt series datasets were collected at 13500x magnification,

using automated data acquisition and image alignment routines as the grids housing the sections were serially tilted over a range of ~130° (±65°) using the microscope Tomo program. Tomograms computed from aligned 2D views were computationally registered and combined in 3D space. All of the above procedures - along with subsequent image segmentation, surface mesh computation/generation, 3-dimensional visualization and quantitative analysis - were performed using the IMOD software package maintained and distributed by the Boulder Laboratory for 3D Electron Microscopy of Cells at the University of Colorado (Boulder, CO, USA).

Results:
We discovered that interactions among keratinocytes are significantly disrupted, leading to the formation of 'empty spaces' between them. Keratinocytes maintain their tenuous connections primarily through few reamining desmosomes. The overall thickening of the epidermis primarily results from an increase in the number of layers of keratinocytes rather than an expansion of intercellular spaces.
At subcellular level, the Golgi apparatus looks highly swollen, blebbed, and pinched off to larger “bubbles”, rather than vesiculated like previously published in in vitro studies. The overall volume of the Golgi apparatus looks sensitively increased, due to the higher number of the cisternae as well as their volume.
Identification of the heterozygous mutations in the ATP2C1 gene of the 5 patients with HHD revelaed 2 novel mutations (c.2378_2381insTTGT, c.2599A>G), and 3 previously reported nonsense mutation (c.1327C/T, c.1402C>T, c.2554insT).

Conclusions:
We proved a workflow of investigating the overall ultrastructure organization of the human skin in the HHD. For the first time, we observed intracellular morphological organization in the Golgi apparatus of the HHD which is notably different form the previous investigated studies using cell line models. Using SEM array tomography, we also give e deeper view of the general disorganization of the cell-cell contact in the epidermis of the patients. Using combines SEM and TEM methodology we present and feasible approach to deeply investigate poorly studied pathologies, like rare genetic disease.

IM-13 (2), Lecture Theater 5, august 27, 2024, 14:00 - 16:00

Background incl. aims
Cryo-TEM tomography is a well-established imaging technique for revealing intracellular ultrastructure at the level of individual molecules. However, the requirement for electron transparency limited what could be imaged. Cryo-FIB lamella made deep intracellular structures accessible by removing the excess material. This approach works very well for objects and structures that are abundant in target cells. When the region of interest (ROI) is not found in every single cell, but rather in one or a few cells within a relatively large multicellular organism, the thinking changes significantly. It is no longer effective to rely on a stochastic approach or "luck". An effective way of target identification and localizations can be provided by cryo-fluorescence imaging and image correlation. Thin samples up to a few micrometers of thickness are vitrifiable by plunge freezing into liquid ethane, directly on TEM grids, making the workflow relatively straightforward. Thicker ones require HPF to achieve vitrification, which results in bulk sample inside a metal carrier and requires cryo lift-out to get the ROI to the TEM. That not only increases the amount of effort required to manufacture every lamella, but also complicates the navigation and ROI localization. We aim to develop and demonstrate a workflow enabling cryo-TEM visualization of a specific subcellular ROI from a multicellular organism such as C. elegans.
Methods
In a nutshell, the proposed method consists of high-pressure freezing (HPF; Leica EM ICE) in transparent cryoprotectant that results in a vitrified frozen-hydrated sample attached to a suitable support, typically a TEM grid or a HPF carrier, preserved in a life-like condition. The sample is then imaged in cryo light and fluorescence microscope (Leica EM Cryo CLEM) to screen for ROIs and identifiable features and transferred to the cryo FIB-SEM machine (Tescan Amber Cryo). The ROIs are then marked and material around the intended lamella is removed with FIB. Lamella is lifted out using a nanomanipulator (Tescan cryo-nanomanipulator) and welded to a receptor grid with pre-milled slot of appropriate width and thinned down to <200nm through 2 or 3 steps of consequent fluorescent microscopy check and FIB milling.
Results
We were able to acquire a TEM tilt series on a selected part of cell nucleus containing a fluorescently labeled feature of interest. Since there were single digit nuclei expressing desired phenotype close to each other, multiple consecutive lamellae were lifted out from each processed worm and polished with a reasonable success rate.
Conclusion
The method demonstrated here enables cryo TEM processing of a fluorescently labeled feature from within large multicellular biological samples. It consists of targeted cryo FIB lift-out using Tescan cryo-nanomanipulator mounted in Tescan Amber Cryo FIB-SEM with multiple fluorescence checks performed using Leica EM Cryo CLEM during the preparation. This will provide researches with multiple high-resolution windows within context of larger volume mapped using cryo fluorescence microscopy. As a result, we can offset the miniscule volume of space visualizable by the cryo TEM

tomography which, until now, was mostly limited to abundant objects of interest. While the workflow by itself is relatively labor intensive, for rare objects and phenomena, it is much more practical than any untargeted approach.

Background incl. aims
Sodium-ion batteries are one of the best candidates to replace lithium-ion batteries for stationary applications, as a cost-effective and sustainable alternative. [1] A key role in their development and integration is the use of renewable carbon sources. Here we are characterizing the structure and chemical composition of bio-derived hard carbons, used as anodes in sodium ion batteries. We aim at a fundamental understanding of parameters that may influence Na storage in these materials.
Methods
Several samples of hard carbon materials were investigated by means of scanning transmission electron microscopy (STEM), employing annular dark field (ADF), integrated differential phase contrast (iDPC) and electron energy loss spectroscopy (EELS), as well as by vibrational spectroscopy, namely, Fourier-transform infrared (FTIR) and Raman spectroscopy.
Raman and IR measurements were carried out on powder samples. TEM samples were prepared by dispersing hard carbon powders in ethanol and drop-casting solution onto a holey carbon film grid.
Results
Previously, bright field imaging in (S)TEM has been prefered for this type of structures.[2] We show that the use of iDPC in combination with ADF STEM imaging at low voltage (80kV) has paramount benefits for the investigation of hard carbons, while no significant beam damage is observed. In iDPC STEM, graphitic layers could be readily imaged, as demonstrated by Graphic A. Moreover, measurements of the d002-spacing are feasible, either directly within images or by analysing their FFT, where also the d100- and d110-spacing of graphite can be measured. In addition, we can observe nanosized pores, which are confirmed in particular by the correlation of iDPC and ADF images. EELS spectra reveal a fine structure of the C K edge that lies between the typical signatures of graphite and amorphous carbon. Both the d002-spacing and the nanoscale pores are supposed to be the key to Na storage capabilities of hard carbons.
FTIR measurements of hard carbons using a diamond ATR crystal face challenges in achieving total reflection condition due to the similarity of refractive indexes. Using Ge with much higher refractive index should be adapted instead for accurate spectra acquisition. FTIR and Raman measurements (exemplary spectra B and C in the Graphic, respectively) allow us to detect differences in crystallinity and surface groups of hard carbon samples with prospects of using Raman in-situ during the Na loading process.
Conclusions
The microscopic and spectroscopic methods chosen for hard carbon characterization have been tested and optimized to meet the specific needs of the material. Next, the characterization results will be compared to electrochemistry measurements to see if certain morphological or chemical characteristics are influencing the Na storage properties. [3]

AllMicro, ALLiance to boost cross-border innovation through MICROscopy, project born from the core idea of an open and inclusive innovation process, allowing a free flow of knowledge and technological collaboration. This leads to the creation of technological novelty, which in turn opens up new markets and encourages entrepreneurship. Research and innovation not only improve products and services but also create investment opportunities, ultimately boosting competitiveness and generating employment [1]. Understanding cutting-edge methods in optical and electron microscopy is frequently confined to highly specialized organizations and individuals, posing a challenge for those seeking to utilize these tools to enhance their creativity and competitiveness on a global scale. Additionally, the significant expenses associated with equipment and ongoing technological advancements hinder the transition of these techniques from academic or fundamental research settings to practical applications in industries and services. This project establishes an international network focused on advanced optical and electron microscopy methods, connecting academic and research institutions with technology parks.
Technology parks Friuli Innovazione (FINN/TEC4I.FVG, Italy) and Primorski Tehnoloski Park (PTP, Slovenia) are vital hubs for fostering innovation, offering their facilities and training services to further bolster collaboration and skill development. They leverage extensive networks to identify potential partners from academia and the private sector, provide essential physical infrastructure and administrative support, cultivate vibrant innovation ecosystems to encourage knowledge exchange and idea generation, and support commercialization efforts through services like intellectual property management and access to funding [3]. Their crucial role is to identify and engage potential partners interested in exploring the opportunities presented by the new microscopy techniques.
In this joint project between Slovenia and Italy, the Universities of Trieste (Italy) and Nova Gorica (Slovenia), along with the research centers of the Istituto Officina dei Materiali (National Research Council, Italy) and the Nanocenter (Slovenia), will contribute to the network's goals. State-of-the-art facilities ranging from electron to optical to atomic force microscopy will be accessible within the target area. These facilities will be available for training and utilization across a broad spectrum of applications in materials science, biology, and various academic and industrial fields. This valuable expertise covers a wide range of knowledge areas and complements one another.
Here, the main objective is to share insights into the capabilities of optical and electron microscopy in driving technological progress and innovation, particularly within the designated region. This area, encompassing numerous small labs with limited resources, holds immense potential. By uniting these labs, a critical mass can be achieved, leading to a formidable presence for economic and innovative

development within the region. Additionally, this initiative aims to enhance the competitiveness of all businesses across the larger region by harnessing the collective strength of these united labs.
First, the project focuses on creating and maintaining the ALL-MICRO network to develop synergies among partners. It involves establishing project management infrastructure and conducting meetings for information exchange and collaboration. The next step is to outreach to stakeholders interested in advanced microscopy methodologies, facilitated by technology hub partners. Pilot projects are conducted to demonstrate the potential of advanced microscopy techniques and initiate synergistic partnerships. In this way, by forming a unified network that operates in harmony, spreading the word, and sharing information this project creates a positive atmosphere that encourages other labs to join in or fosters fruitful collaborations with companies. Moreover, the ALL-Micro network will organize and maintain a series of high-specialization courses aiming at the formation of a future class of experts able to take full advantage of advanced microscopy methodology in R&D.
In conclusion, the ALL-MICRO project not only presents a promising opportunity to bridge the gap between academia, industry, and research in advanced microscopy but also aligns with an environmental sustainability perspective. By establishing a cross-border network and leveraging expertise from academic institutions, research centers, and technology hubs in both Italy and Slovenia, the project aims to disseminate knowledge and drive innovation in microscopy techniques. Through collaborative efforts and strategic partnerships, it seeks to enhance regional competitiveness while promoting environmental sustainability. This objective necessitates the crossing of national borders to share resources and avoid duplication of costly and environmentally impactful instrumentation, ensuring a more sustainable approach to research and development. With structured management and active stakeholder participation, the project has the potential to deliver significant benefits and make a lasting impact on microscopy techniques and innovation in the region. With the success of this collaborative project, we are planning to extend the network partners and the target area to nearby countries such as Croatia, Austria, or Balkan countries. This will provide a useful precedent for potential similar approaches in regions different from ours.

Investigating nitrogen doped nanocarbon materials as potential carbon dioxide adsorbers

Ivan Musil[1,2], Venkataprasanna Kannan Sampathkumar[1,2], Jonas Haas[1,2], Kevin Strobel[1,2], Jannik Meyer[1,2]
[1]Institute for Applied Physics, University of Tübingen, Tübingen, Germany, [2]NMI Natural and Medical Sciences Institute at the University of Tübingen, Reutlingen, Germany

PS-01 (2), Lecture Theater 3, august 28, 2024, 14:00 - 16:00

Background
The climate crisis, propelled by the continuous rise of carbon dioxide emissions, has spurred research to find technical solutions for this problem. One possibility is to directly capture carbon dioxide from the atmosphere and sequester it inside suitable long-term storage. Unfortunately, the success of this method strongly depends on the efficiency of the adsorber material. Here, nanocarbon materials such as graphene and carbon nanotubes could come into play, as they offer several beneficial characteristics like high surface area and stability. However, the catch is their nonreactive nature. To enable chemical adsorption one could alter the chemical structure of the nanocarbons by inserting new elements through doping. Nitrogen is a promising candidate, as it can be exchanged with the carbon atoms inside the crystal lattice of the materials. It is known to be a crucial component in other carbon dioxide fixating mechanisms, for example in plants. One goal of this research is to find novel routes for nitrogen doping of these materials and try to understand and control the process of ion implantation. Furthermore, the nitrogen doped nanocarbons are investigated as carbon dioxide adsorbers.
Methods
Nitrogen doping is realised by different methods of ion bombardment. HRTEM is used to examine the effects of doping on the atomic level. Further investigation is conducted with STEM coupled with EDX, FIB-SEM coupled with ToF-SIMS, AFM and XPS. A self-built setup is established, dedicated to measure the carbon dioxide capture performance of the materials, a scheme of it is shown in part A of the figure.
Results
Various methods of ion bombardment were successfully used to dope graphene with nitrogen. This was verified by HRTEM, observing implanted nitrogen atoms as well as defects introduced by nitrogen ion bombardment. The same treatment is conducted with carbon nanotube films. These films are produced via filtration of carbon nanotube suspension in a controlled manner and various thicknesses, which are checked by AFM. FIB-SEM with ToF-SIMS as well as XPS verify that nitrogen is present in the upper 100 nm of the films that have been bombarded with nitrogen ions. Further investigation through STEM coupled with EDX give insight into the ion dosage dependent distribution of nitrogen in thicker carbon nanotube bundles after doping, as shown in part B of the figure. Additionally, HRTEM shows the deterioration of the carbon nanotube crystal structure after excessive ion bombardment, which can be seen in part C of the figure. Carbon dioxide capture performance of various carbon nanotube films has been measured with the dedicated setup. An increase in performance was observed after treatment with nitrogen ions.
Conclusion
Different ways of ion bombardment were used to implant nitrogen into the crystal structure of graphene and carbon nanotubes. This was verified by various microscopic and spectroscopic methods. The effects of the doping procedure were investigated on atomic as well as microscopic

level, giving insights in the doping mechanisms during ion bombardment. Furthermore, it was shown that nitrogen doping changes carbon nanotube films in a way, that improves their ability to sequester carbon dioxide from the atmosphere.

Background
To achieve higher resolution in TEM, a Cs corrector is typically employed as a hardware solution. Alternatively, software processing techniques like Maximum-likelihood (MAL), Exit-wave function reconstruction (EWFR), Iterative wave-function reconstruction (IWFR), and Phase extension offer an affordable solution without requiring expensive hardware. However, these methods necessitate acquiring multiple HREM images (3-20) for processing. HVEMs are beneficial for HREM due to their deeper sample penetration and reduced dynamical effects. PED further minimizes dynamical effects, enabling high-resolution diffraction data even for thicker samples analyzed with lower-voltage TEMs. This study employed a combined approach of HVEM, PED, and phase extension to achieve sub-Ångstrom resolution imaging of Si single crystal samples. Additionally, we conducted a comparative analysis of the results with those obtained using a conventional TEM equipped with a monochromator and a Cs corrector.
Methods
A Si single crystal was prepared using ion thinning and employed as a test specimen for high-resolution electron microscopy (HREM). High-resolution electron microscopy (HREM) imaging of the Si [211] zone axis was performed using a high-voltage electron microscope (HVEM). The high-resolution images used for comparative analysis were obtained using a conventional TEM equipped with a monochromator and a Cs corrector at an accelerating voltage of 200kV. An energy-filtered precession electron diffraction (EF-PED) pattern was obtained using an energy-filtered TEM equipped with a precession unit. The specimen thickness was estimated using the log-ratio method and information from the low-loss spectra. Image processing of the HREM data involved background noise reduction and phase extension using a combination of software programs (Digital Micrograph, CRISP, HREM filters, and VEC).
Results
A high-resolution (HR) image of the Si [211] projection with an atomic resolution of 1.2 Å was obtained using a high-voltage electron microscope (HVEM). Additionally, a precession electron diffraction (PED) pattern satisfying the quasi-kinematical condition was acquired with an enhanced spatial resolution of 0.63 Å using a beam precession system. By applying the phase extension technique to these combined data, Si atomic columns with an atomic spacing of 0.78 Å in the Si [211] projection were successfully resolved.
Conclusion
The HVEM and PED combination method has demonstrated its potential to achieve high resolution even in thick samples by leveraging HVEM's high penetration power and PED's ability to minimize dynamical effects. By employing this technique, the reduction in resolution caused by sample thickness in high-resolution imaging analysis using Cs-corrector can be partially compensated, which is expected to significantly aid in the accurate analysis and understanding of the structure and properties of nano-crystals.

Poster Group 1

A successful oxygen transport membrane (OTM) requires not only an outstanding permeation performance, but also chemical, electrical, thermal and mechanical stabilities under practical conditions. Among promising candidates, dual-phase OTMs (DP-OTMs) are attracting continuous attention, in which two ceramic phases are coupled to provide mixed ionic-electronic conductivity. In particularly, a fluorite-spinel composite CexGd1-xO2-δ-FeyCo3-yO4 (CGO-FCO) was reported to possess both a significant oxygen permeability as well as a high tolerance under exhaust gas conditions.[1] Thus, considerable efforts have been made to further push the overall performance of CGO-FCO. However, the bottleneck still lies in the inevitable phase interation and the complex grain boundary (GB) structures. In turn, modulating the phase interaction and GB properties offers the possibility of materials engineering, which requires however a precise understanding of the emerging phase and the GBs behaviors down to atomic scale.
In our work, dense pellets of CGO-FCO with different nominal compositions were prepared by solid state reactive sintering.[2] As a result of the phase interaction, an emerging phase with the structure of GdFeO3 (GFO) was often located between CGO phases. Further energy-dispersive X-ray spectroscopy (EDXS) and electron energy loss spectroscopy (EELS) studies revealed varying compositions of the GFO phase, and its formation reduces the Fe and Co segregation at the CGO GBs significantly.[3] Besides, both crystal and chemical structure at the CGO GBs were quantified down to the sub-nm scale, as they are directly related to the ionic conductivity of the membranes.[4] CGO GBs with different coherences were compared. For the Σ3[101] GB in Fig. 1 with a high coherence, only a single layer of Gd segregation can be noticed at the edge of each grain, while the non-solute segregations from Fe and Co are restricted between the two grains. Any variation of the Ce valence state is also largely limited. In contrast, for CGO GBs with a lower coherence, all the atomic-site specific lattice distortions, elemental distributions, and valence state variations were found to be much more significant.
In summary, GFO was identified as the emerging phase within CGO-FCO. Its tunable electronic properties further broaden the opportunity for membrane optimization through phase engineering. Besides, Simultaneous Gd enrichment and Ce depletion within the ending atomic layers of the adjacent CGO grains are generally observed, while Fe and Co are segregated into the CGO GBs with varying amounts and phases. The comparison between GBs with different coherencies indicates that the valence states of Ce, and the enriched Gd, Fe and Co are all sensitive to the local structural defects at the GB. A more coherent GB would thus be beneficial for an improved GB conductivity. Our findings constitute a crucial piece for the complete picture of structure-property relationship of CGO-FCO, which may also shed light on the understanding towards other oxide heterointerface phenomena.

The reversible phase transition of Gd-doped ceria by in situ TEM

Dr Ke Ran[1,2,3], Dr Fanlin Zeng[4], Dr Lei Jin[2], Dr Stefan Baumann[4], Prof Wilhelm Meulenberg[4,5], Prof Joachim Mayer[1,2]
[1]RWTH Aachen University, GFE, Aachen, Germany, [2]Forschungszentrum Jülich GmbH, ER-C, Jülich, Germany, [3]Advanced Microelectronic Center Aachen, AMO GmbH, Aachen, Germany, [4]Forschungszentrum Jülich GmbH, IEK-1, Jülich, Germany, [5]University of Twente, Enschede, The Netherlands

Poster Group 1

Owing to the flexile valence switching between Ce4+ and Ce3+ cations and the facile formation of oxygen vacancies, ceria has been recognized as one of the best candidates for catalysts and solid electrolytes. The formation and migration of oxygen vacancy under external stimuli thus constitute the fundamental processes of the functional oxide materials and their associated devices, which are often linked with modification in the ceria structure and subsequent phase transitions. Typically, ceria crystallizes in a fluorite-type (F-type) cubic structure (space group Fm-3m, a≈5.42 Å). Transition from F-type to the so-called C-type (space group Ia-3) takes place when enough oxygen vacancies are introduced to the system, in Fig. 1. As a result, the cell parameter is doubled, the M site is six-coordinated to O, and the crystallographic positions are split. However, given the challenges in visualizing oxygen dynamics with adequate temporal and spatial resolution, the structural evolution of ceria in response to external stimuli remains rarely explored.[1] Questions pertaining to transition details, including the selection of external stimuli, the behaviors of oxygen vacancies, the feasibility of fine tuning as well as the underlying mechanism remain unsolved.[2]
For our study, the Gd-doped ceria (CGO) with high oxygen ion conductivity as well as giant electrostriction under external electric field is chosen. Dense pellets of Gd-doped ceria were prepared by solid state reactive sintering.[3] The phase transition of CGO is in situ probed down to sub-Å scale by transmission electron microscopy (TEM), where the electron beam (e-beam) is also serving conveniently as an external stimulus. Negative spherical aberration imaging (NCSI)[4] and integrated differential phase contrast (iDPC) imaging are employed, enabling high contrast for both light oxygen and heavy metal atoms, as well as facilitating the measurement of atomic positions with ultra-high precision. Fully manageable transitions are achieved through adjustments to the electron dose rate (EDR). Quantifying lattice distortions also allows a direct estimation of the local oxygen vacancy concentration. The electron energy loss spectroscopy (EELS) reveals varying Ce valence within the CGO. Finally, a collective rearrangement of the oxygen vacancies is proposed to account for our observations, and the simulated HRTEM images show a good agreement with the experimental results. Further numeric calculation would then be necessary to establish a solid theory.
In summary, the reversible phase transitions of CGO were explored in situ with picometer precision. Unique insights into the transition process are gained, such as anisotropic ordering of the oxygen vacancies, direct interpretation of the local oxygen vacancy concentration, and feasible modulation of the transition efficiency. These findings showcase great promise for diverse energy-related applications, including enhancing the performance of ceria-based catalysts and advancing next-generation memristors. The same principle could also be extended to other functional oxides.

In-Situ Manipulation of Growth Mechanisms in Ni-Seeded GaP Nanowires

Tianyi Hu[1,2], Dr. Yuanyuan Cao[1,2], Dr. Sara M. Franzén[2,3], Dr. Daniel Jacobsson[1,2,4], Dr. Michael S. Seifner[1,2], Prof. Maria E. Messing[2,3], Prof. Kimberly A. Dick[1,2,3]

PS-01 (2), Lecture Theater 3, august 28, 2024, 14:00 - 16:00

III-V semiconductor nanowires (NWs) have emerged as a promising class of materials for next-generation nanoelectronics and photonics due to their unique electronic, optical, and mechanical properties.[1] The ability to grow III-V NWs with high precision and controllability has led to the development of numerous applications in the fields of electronics, photonics, and energy conversion.[2] Thus, precise control over the growth of III-V NWs has been a major topic that enables the creation of uniform and reproducible nanostructures with tailored properties.
So far, the bottom-up approach is widely used for synthesizing the semiconductor NWs, where an intrinsic or foreign metal (called as seed particle) is often used to promote the anisotropic one-dimensional growth. There has been abundant research focusing on the influence of seed material, preparation and dynamics on NW growth.[3] However, most of such research are carried out in a post-growth condition, where the NWs are cooled and transferred from the synthesis equipment for further analysis. Thus, there is a lack of understanding on the dynamic interplay between seed particles and NWs under the growth environment, such as the real-time crystal structure and composition of the seed particles and their impact on the corresponding NWs.
This conference contribution reports a detailed investigation on the growth of gallium phosphide (GaP) NWs using Ni as seed material. An aberration-corrected environmental transmission electron microscope (ETEM) integrated with a metal-organic chemical vapor deposition (MOCVD) system was used. Ni nanoparticles were transformed into Ni_5P_4 crystals by the supply of phosphine. After adding trimethylgallium (TMGa) to the precursor supply, the nucleation of GaP NWs was observed and captured by high-resolution TEM (HRTEM) movies. The phases involved in the nucleation and NW growth process were characterized via energy-dispersive X-ray spectroscopy (EDS) and power spectra obtained from the HRTEM images.
In the investigated range of partial pressures, two types of seed particles were observed: At low V/III ratios (defined as corrected partial pressure ratio between group V and group III supplies), NWs grew from two Ni-Ga phases at a similar growth rate, namely the solid NiGa phase, as well as the Ni_2Ga_3 phase. In contrast, at high V/III ratios, NWs grew from Ni_2P particles, where interdiffusion through Ni_2P contributes to multiple nucleation and leads to a much higher growth rate. The ability to manipulate the seed particle phases offers the potential for precise control over the growth of compositionally abrupt heterostructure NWs, where group III or V elements can be individually switched. Our research results represent a significant step forward in the replacement of Au as a conventional seed particle material, as well as in the ability to locally modify the composition, doping levels, and morphology within the same NW.

Poster Group 1

Background
Vitamin A and its derivatives, the retinoids, are involved in tissue regeneration as they can modulate cell proliferation, differentiation, apoptosis (1) and the inflammatory response (2). A single injection of cyclophosphamide (CP) in rodents disrupts the blood-urine barrier of the urinary bladder by causing injury to the urothelium, which is followed by rapid regeneration (3–5). We used a mouse model for CP-induced urothelial injury, which is also a model for the inflammation of the urinary bladder known as cystitis. The aim of our study was to investigate the effects of a vitamin A-enriched diet on CP-induced cystitis. We analysed the proliferation and differentiation of urothelial cells as well as the transcriptome of the urinary bladder.
Methods
We randomly divided 80 female BALB/c mice (8 weeks old) into 8 groups of 10 mice each (permit No. U34401-4/2022/18). 4 groups received a vitamin A-enriched diet (containing 566081UI retinyl-acetate per kilogramme; VitA groups) 1 week before intraperitoneal (i.p.) injection of CP or saline (S) and the other 4 received a normal diet (N groups). Urinary bladders were collected 1 or 3 days after i.p. injection (VitA CP1d, N CP1d, VitA S1d, N S1d, VitA CP3d, N CP3d, VitA S3d, N S3d groups) and then dissected and prepared for RNA isolation followed by RNA sequencing (RNAseq) and for scanning electron microscopy (SEM). Half of each urinary bladder was embedded in paraffin for immunolabelling. The proliferation index was determined by quantification of Ki67-positive urothelial cells, while differentiation was determined by the percentage of uroplakins' (UPs) positive apical membrane length of superficial urothelial cells. We also determined the presence of highly differentiated superficial urothelial cells by immunolabelling of keratin 20 (Krt20). SEM was used to analyse the differentiation stage of the superficial urothelial cells by assessing the percentage of microridges (terminal differentiation stage) on the entire surface examined.
Data analysis was performed with ImageJ and statistically analysed with Excel and GraphPad Prism 8.01. Results are presented as mean values and standard deviations (mean ± SD) unless specified otherwise.
Results
The RNAseq results showed higher expression of genes involved in the cell cycle and PI3k-Akt signalling in the VitA CP1d group compared to the N CP1d group, indicating higher proliferation in this group. Genes involved in cell cycle (Bub1, Bub1a, Ccna2, Cdc25b, Cdk1, Knl1) and PI3k-Akt signalling (Itga3, Epha2, Spp1, Ereg, Areg and Il6) were significantly up-regulated, as revealed by Kyoto Encyclopaedia of Genes and Genomes (KEGG) enrichment analysis. The higher proliferation indices were subsequently confirmed in the urothelial cells of the VitA CP1d group (29.5% ± 20.5%) compared to the N CP1d group (19.6% ± 16.1%). In the VitA CP3d and N CP3d groups, the proliferation indices were 42.2%±17% and 38.4%±14.3%, respectively. In comparison, all groups with S injection (VitA S1d, N S1d, VitA S3d and N S3d group) had lower proliferation index of 1 to 2%.

All groups with S injection (VitA S1d, N S1d, VitA S3d and N S3d) had terminally differentiated superficial urothelial cells with positive UPs and Krt20 immunolabelling and microridges on their apical surface. One day after CP injection (VitA CP1d, N CP1d groups), the differentiation stage of superficial urothelial cells was significantly lower compared to the S injection groups (VitA S1d, N S1d), as indicated by the presence of microridges. The VitA CP1d group exhibited a slightly higher differentiation stage (13.9%±25.1% of microridges) than the N CP1d group (9.1%±13.6% of microridges). On the other hand, 3 days after CP injection, the VitA CP3d group showed a slightly lower UPs-positive apical surface length of superficial urothelial cells (76.6%±15.4%) than the N CP3d group (88.1%±13.5%), while no difference was observed in the presence of microridges (VitA CP3d - 6.1%±14.8% and N CP3d - 7.0%±10.3%). There was no difference in Krt20 positive superficial urothelial cells between the CP-treated groups (VitA CP1d, N CP1d, VitA CP3d and N CP3d).
Conclusion
Our results suggest that increased vitamin A intake before the onset of CP-induced cystitis influences urothelial injury and regeneration. A vitamin A-enriched diet resulted in upregulation of several genes involved in the cell cycle and PI3k-Akt signalling and increased proliferation of urothelial cells during the initial stages of regeneration (day 1). These events accelerated the formation of the initial blood-urine barrier. We were able to demonstrate that proliferation remained increased in groups with VitA-enriched diet also in the later phases of regeneration (day 3), while no difference was observed in the differentiation stage of the superficial urothelial cells. We can conclude that vitamin A influences the initial regeneration, but its effects are no longer observed in the later stages of regeneration.

4D-STEM Optical Sectioning of Dopants in Diamond

Mr. Aidan Horne[1], Mr. Jacob Lewis[1], Mr. Emmanuel Tegegne[1], Dr. Peng Wang[1]
[1]University of Warwick, Coventry, United Kingdom

Poster Group 1

Due to improvements of aberration correctors in scanning transmission electron microscopes (STEM), larger convergent semi-angles can be used as more of the probe can be collected without introducing aberrations to the image. These larger convergent semi-angles lead to two notable improvements in the reconstructed image; an improved lateral resolution and a reduced depth of field [1]. The benefits of a better lateral resolution are immediately obvious, but by reducing the depth of field, new methods of imaging can be obtained, namely optical sectioning [2]. Optical sectioning involves collecting many micrographs of a sample with varying defocus which allows for investigation into the third dimension of the material instead of the two lateral dimensions as in conventional STEM. Four dimensional scanning transmission electron microscopy (4D-STEM) builds on conventional STEM by using superfast pixelated detectors to collect the entire diffraction pattern which allows us to reconstruct the sample using different methods such as conventional reconstructions like high angle annular dark field (HAADF) as well as more advanced methods, only available to 4D-STEM such as centre-of-mass (COM) imaging and ptychography. Here we present a body simulation work to investigate the efficacy of optical sectioning through a range of 4D-STEM data reconstruction techniques and a range of dopants within the sample.
Simulations are done using the ab initio simulation software plugin abTEM which utilizes the multislice algorithm [3]. Using this software we generate 4D-STEM datasets with a 200kV accelerating voltage and a convergence angle of 30mrad. For this work, the probe aberrations are set to zero to match ideal imaging conditions. The samples used were diamond crystal of 15nm thickness with different substitutional and interstitial dopants of masses ranging from 14Si to 82Pb. The location in the z direction of these dopants was also varied to investigate efficacy of the techniques dependent on the depth of the dopant within the sample.
The reconstruction techniques used here consist of HAADF which has been the standard for imaging heavy elements within materials since the contrast of HAADF reconstructions follows a power law of z^n where 1≤n≤2 [4]. Common 4D-STEM techniques are also implemented. COM which works by finding the average deflection of the probe by the sample in the diffraction plane, as well as its subsidiaries, integrated centre of mass (iCOM) and differentiated centre of mass (dCOM). Furthermore, the recently proposed technique of symmetry STEM (S-STEM) which involves investigating the symmetry of the diffraction pattern by rotating or reflecting the diffraction pattern and cross correlating it with the original diffraction pattern to reconstruct [5].
Using the techniques described we find that different imaging methods excel depending on the relative weight of the dopant compared to the bulk crystal. As expected, HAADF provides a simple and effective method for imaging heavier atoms regardless of position in the crystal. The comparison is less clear when investigating lighter atoms such as silicon. In these regimes methods such as iCOM and dCOM prove themselves to be powerful tools for finding the location of the atom within the structure. We find that S-STEM is less of an effective tool than the others described, but this may be a poor representation of the true case, since relaxation of the crystal lattice may lead to strain in the sample for which S-STEM has been suggested to be a useful tool for identifying point defects [5]. It still may be an unreliable tool for optical sectioning though since S-STEM is robust at reconstructing

atomic resolution images regardless of defocus as we have demonstrated with our results, as symmetry is independent of defocus.
The methods here result in a detailed analysis of how utilizing all the variables and tools available when imaging these materials using 4D-STEM can be leveraged to obtain the best results for optical sectioning. This work focuses on diamond as a bulk crystal within which dopants are placed so could be used as an effective framework for investigating the composition of colour centres such as nitrogen and silicon vacancy centres.
Figure 1: (a), (b) and (c) shows COM, dCOM and iCOM reconstructions of diamond respectively with germanium dopant within box drawn on (a). (c) and (e) show line profiles of (b) and (c) along the line drawn. Poster Group 1

We present a comprehensive study of nanophotonic materials by correlative electron and optical microscopy and spectroscopy. We focus on a phase-changing material vanadium dioxide, which is relevant for active plasmonics and optical metasurfaces [1], and on lead-halide perovskite ($CsPbBr_3$) [2]. We performed a comprehensive analysis of a VO_2 nanoparticle and $CsPbBr_3$ nanocrystals using a combination of analytical transmission electron microscopy and optical methods like ellipsometry and transmission.

We have explored the metal-insulator transition (MIT) in the single vanadium dioxide nanoparticle caused by in-situ heating and we have identified the dielectric and the metallic phase of the nanoparticle by imaging, diffraction, electron energy loss spectroscopy, and optical transmission. Our results show that differences in high-resolution images and diffraction patterns obtained at high and low temperatures confirm that MIT is related to a modification of the crystal lattice. In low-loss EELS, the MIT is manifested by the emergence of the plasmon peak in the high-temperature metallic phase. Moreover, we have shown that the transition can be observed directly using imaging techniques such as STEM-ADF and DF-TEM with no need for in-situ spectroscopy. This finding allowed us to study the hysteresis of the MIT in vanadium dioxide with a high spatial resolution. We have observed that the transition from the dielectric to metallic phase is smooth and spans a rather large temperature range while the backward transition is abrupt.

Further, we analyzed $CsPbBr_3$ nanocrystals using correlative microscopy allowing the examination of structural, chemical, and optical properties from identical areas. Moreover, the use of 4D-STEM in a FIB/SEM allowed us to determine the crystallographic orientation of individual nanoparticles. Our results show that their stoichiometry is uniform and independent of their morphology. The photoluminescence peak emission energy is dependent on the dimensions of nanocrystals, with a blue shift up to 9 nm in wavelength with a decreasing size due to the confinement effect [2].

To conclude, our results provide a comprehensive analysis of the MIT in the single vanadium dioxide nanoparticle and pave the way to phase-changing devices made of vanadium dioxide. Further, we have shown that our $CsPbBr_3$ nanocrystals are of high quality, exhibiting bright and size-tunable PL emission [3].

Birefringence analysis of hemozoin with surface plasmon microscopy towards malarial species distinction

Dr. Ipsita Chakraborty[1], Prof. Andreas Offenhäusser[1]
[1]Forschungszentrum Jülich GmbH, Jülich,, Germany

Poster Group 1

I. Introduction

Female Anopheles mosquitoes carrying the Plasmodium parasite are the primary vectors of malaria mostly prevalent in countries exhibiting tropical climate [1]. The parasite species Plasmodium falciparum, Plasmodium vivax, Plasmodium malaria, Plasmodium ovale, and Plasmodium knowlesi are the five that can infect humans. Plasmodium falciparum is responsible for 70% of the infections, whereas Plasmodium vivax is responsible for 20% of them [1]. WHO reports that 249 million cases were recorded in 2022, of which 233 million (about 94%) were reported in Africa. Nearly half of all cases were reported in Nigeria (27%), the Democratic Republic of the Congo (12%), Uganda (5%), and Mozambique (4%). Malaria is expected to have caused 608,000 fatalities worldwide in 2022. Just four nations accounted for more than half of all deaths: Tanzania (4%), Niger (6%), the Democratic Republic of the Congo (12%), and Nigeria (31%). Eleven countries namely Burkina Faso, Cameroon, the Democratic Republic of the Congo, Ghana, India, Mali, Mozambique, Niger, Nigeria, Uganda, and Tanzania account for almost 70% of the world's malaria cases [2].

There exist many techniques for detection of malarial species. Conventional light microscopy involves examining blood smears with Giemsa stain has been the golden standard, while other techniques including rapid diagnostic test and polymerase chain reaction (PCR) have also been utilized. Most of these techniques require a long processing time and are not quantitative in general. Further, label free techniques are scarce in malarial detection.
This work is based on the anisotropic characterization of hemozoin utilizing surface plasmons. We explicitly studied the difference in the birefringence of whole blood with and without hemozoin.

II. Methods

Focused surface plasmon microscopy [3] is a technique that measures light-matter interaction at sub-wavelength level to investigate local optical properties of the sample at the metal-dielectric interface. It relies on optical near-field effects to map the refractive index profile of the samples with high spatial resolution. Numerous samples (i.e., thin films and liquids) have been probed (probe size:180 nm) by this technique to reveal circular absorption pattern at the exit pupil of the high numerical aperture microscope objective. By correlating the radius of the absorption pattern one can determine the refractive index of the sample. Further, anisotropic characteristics of the sample (if present) can be extracted from the elliptical absorption pattern to reveal the magnitude of birefringence and orientation of its fast axis respectively [4].
NLAF21 coverslips (refractive index: 1.78) were cleaned with ethanol, acetone, and isopropanol for 5 mins each. Then the coverslips were subjected to oxygen plasma for 5 mins. Then a chromium layer (~2 nm, r.i.: 3.316+i3.312) followed by gold layer (~ 47 nm, r.i.: 0.18377+i3.4313) were deposited by E-beam vapor deposition. The chromium layer was added for a better adhesion of the gold layer. The thickness of the subsequent layers was correlated with X-ray diffraction analysis. Artificial blood (~1

µl) was added on top of the substrate. Later various concentrations of hemozoin were mixed in the artificial blood and pipetted on top of the substrate.

III. Results

The reflected spatial frequency distribution at the exit pupil of the high numerical aperture objective lens was recorded. When artificial blood was used as sample, we observed a circular absorption pattern at the exit pupil plane indicating the absence of any anisotropic components. The refractive index was recorded from the radius of the circular absorption pattern with a semi-automated custom developed software. When hemozoin was mixed in artificial blood, we observed an elliptical absorption pattern at the exit pupil plane. The birefringence was extracted from these images with the developed software as stated before.

IV. Conclusion

In this proof-of-concept study, we conclude that refractive index and more so birefringence can be used as a label-free estimator differentiating healthy blood and malarial blood. Further this approach can be used to distinguish between various malarial species as reported previously based on the refractive index [5]. We believe the quantitative characterization of the hemozoin crystals from various plasmodium species could be used in future to easily distinguish the species.

Poster Group 2

Background incl. aims
Understanding the coupling effect between lattice strain and the energy required to create oxygen vacancies is crucial for the rational optimization of the catalytic performance of thin film perovskite electrocatalysts. However, contradictory results have been reported regarding the impact of lattice strain on both the oxygen vacancy content and formation energy, differing in terms of extent, direction, and mechanism. Theoretical studies have indicated that oxygen vacancy defects may either increase or decrease with increasing tensile strain. Additionally, the formation energy of oxygen vacancies has been observed to follow either a curved or nearly linear trend as the strain state transitions from compression to tension. These theoretical findings suggest that the energetics of oxygen vacancy formation could be highly complex and material dependent. Therefore, our study aimed to experimentally investigate the concentration and distribution of oxygen vacancies in epitaxial thin films of LaCoO3 (LCO), a highly active perovskite oxide material, for both the oxygen reduction reaction and the oxygen evolution reaction. We observed the formation behavior of oxygen vacancies at the atomic level in real time using in situ transmission electron microscopy (TEM) with an electron beam exposure function. This technique allowed us to study the dynamic behavior of oxygen vacancies under compressive and tensile lattice strains. Additionally, we utilized high angle annular dark field (HAADF) scanning transmission electron microscopy (STEM) images to directly analyze the local mapping and visualization of oxygen vacancies at the unit cell level in the LCO thin films.
Methods
On (001) LaAlO3 (LAO) and SrTiO3 (STO) substrates, LCO thin films were synthesized using the sol-gel technique. Cross-sectional TEM specimens were prepared using a focused ion beam (Quanta 3D FEG, FEI), and HAADF STEM images were acquired using TEM (Mono ARM 200F, JEOL) operating at 200 kV. The beam convergence semi-angle was set to 23.81 mrad, and the collection semi-angles ranged from 68 to 280 mrad. A consistent electron dose rate was maintained during electron beam irradiation. Wiener filtering, implemented via the HREM-Filters software package (HREM Research), was utilized to enhance image clarity.
Results
Atomic-scale HAADF STEM images depicting the initial conditions of the LCO thin films on the LAO and STO substrates are presented in Figs. 1 (a) and (f), respectively. A 15 × 15 nm region within the LCO thin film was monitored for changes in lattice parameters, encompassing 1,444 unit cells. HAADF STEM images were obtained from identical pristine regions of the LCO thin film at various time intervals as the electron beam irradiation time was increased. Figs. 1 (b–e) and (g–j) exhibit high-resolution HAADF STEM images selected at 20-minute intervals in the LCO thin film on the LAO and STO substrates, respectively. The time series of the HAADF STEM images for both LCO thin films revealed the appearance of dark strip patterns over time. The modulated contrast patterns observed in the HAADF STEM images of the LCO thin films are attributed to the ordering of oxygen vacancies, leading to localized lattice expansion and the formation of modulated dark stripe patterns. The onset time of the first dark-strip pattern differed between the two LCO thin films. Specifically, the first dark

strip pattern emerged after approximately 60 minutes of continuous electron beam exposure in the LCO thin film on the LAO substrate and after 20 minutes in the LCO thin film on the STO substrate. The red arrows indicate the first dark-strip pattern in Figs. 1 (d) and (g). Subsequently, dark-strip patterns emerged at various positions and continued to grow in the out-of-plane direction. The maximum growth of dark strip patterns in the two LCO thin films occurred after 80 minutes. Furthermore, the distribution of dark strip patterns was observed more frequently in the LCO thin films on STO substrates.

Conclusions

HAADF STEM images confirm uniform thickness and initial conditions of LCO thin films on LAO and STO substrates. With increasing electron beam irradiation time, distinctive dark strip patterns emerge, indicating oxygen vacancy ordering. Variations in pattern appearance and behavior are noted between substrates, with higher tensile strain accelerating pattern onset and distribution frequency. Quantitative analysis of lattice parameter changes corroborates these observations, confirming expanded unit cells associated with oxygen vacancies. Notably, films under higher tensile strain exhibit more uniformly distributed enlarged unit cells and significantly higher oxygen vacancy concentration. These findings support previous studies suggesting reduced formation energy of oxygen vacancies under tensile strain. Overall, this research provides valuable experimental insights into oxygen vacancy formation and distribution mechanisms in LCO thin films under strain, advancing our understanding and informing tailored material design for electrochemical applications.

Background

A catalytic cycle in heterogeneous catalysis involves the adsorption, reaction, and desorption of species on the surface of an active catalyst. This cycle repeats as long as the catalyst remains active and is inked to the concept of turnover frequency - defined by chemists to estimate the number of conversions per active site per unit of time. The cyclic behavior that occurs at the molecular or atomistic level involves catalyst restructuring and cannot be separated from the larger scale processes involving collective phenomena of heat and mass flow. Under reaction conditions, the coupling of processes dominating at different time and length scales can give rise to complex dynamics that are observable at both microscopic and macroscopic levels [1,2].
The aim of this work is to investigate how catalytic function emerges in the interplay between reactive species and catalyst. We employ operando scanning electron microscopy to study the simple model system of hydrogen oxidation. This reaction is known to exhibit oscillatory behavior characterized by periodic variations in the reaction rate [3]. This is primarily due to the dynamic and cyclic interplay between the adsorption of reactants, the formation of water, and the autocatalytic formation and reduction of nickel oxide.

Methods

The experiments were conducted using a FEI Quanta 600F Environmental Scanning Electron Microscope (ESEM) at pressures between 20 to 30 Pa. The instrument is attached to a home-built gas feeding system and equipped with a home-built laser heating stage. For reactivity studies, an electron ionization quadrupole mass spectrometer was used. Images were recorded using the gaseous secondary electron detector.

Results

As hydrogen and oxygen are adsorbed and react to form water, the surface periodically transitions between a highly active metallic state and a less active oxidized state. Changes in the oxidation state of the surface result in a change in the secondary electron yield and are detected as brightness variations. In the case of reactions carried out on polycrystalline nickel foils, a dependence of the reactivity on the grain orientation is observed, as well as spillover coupling at grain boundaries and a complex, spiral-like pattern of propagating reaction fronts on some of the grains. Superimposed on the grain dependent surface dynamics are collective oscillations associated with reaction induced variations in gas phase composition. By varying the oxygen flow or temperature, i.e., one of the key control parameters, we are able to systematically follow the transition of the system from a steady state to oscillatory, and ultimately chaotic behavior. Notably, bifurcations are observed, marking shifts in the system's behavior. Switching from a polycrystalline foil to single crystals removes coupling effects due to grains with different activity and shows the formation of intriguing spiral waves under otherwise steady state conditions. Our results reveal the complexity of simple reactions and provide valuable insights into the most relevant coupling mechanisms. It furthermore demonstrates that catalysis cannot be understood based on ex-situ studies.

Conclusion
On the polycrystalline Ni foil, oscillatory behavior between oxidized and reduced states correlates with significant changes in catalytic activity. The reactivity is influenced by the orientation of the surface grains. In contrast, the single crystal (100) Ni surface exhibits initial oscillations that stabilize into spiral-like reaction fronts. Unlike the transient patterns observed on the polycrystalline foil, these spirals are persistent. The stability is attributed to the absence of neighboring grain interactions which typically introduce complexities and destabilize reaction fronts on polycrystalline surfaces.

In recent years, Transmission Electron Microscopy (TEM) has emerged as an indispensable tool for crystallography1, offering unparalleled insights into the atomic structures of complex materials. This is particularly relevant for Metal-Organic Frameworks (MOFs), whose intricate architectures and diverse applications in areas like gas storage, catalysis, and drug delivery depend heavily on their precise atomic arrangements.
Our study employs a TEM-based approach, three-dimensional electron diffraction (3DED)2, to probe the crystal structures of targeted MOFs. While 3DED offers powerful capabilities, challenges such as crystal drift can hinder its efficiency. To overcome these obstacles, we developed LibraEDT, a software for electron diffraction experiments on the Zeiss Libra 120. LibraEDT introduces several key advancements, including automated crystal tracking to maintain sample alignment within the electron beam, thereby reducing beam damage and enhancing data quality. Additionally, LibraEDT facilitates extended data collection range, above 120º, with precision tracking, ensuring optimal results. The software interfaces seamlessly with ASI Timepix single electron detectors allowing for precise crystal screening, tracking and automatic diffraction screening on a predefined crystal set, all while minimizing radiation exposure.
We applied LibraEDT to the structural analysis of two distinct new MOFs. First, we investigated a MOF synthesized through an environmentally friendly mechanochemical process using water and biocompatible precursors. The structure, solved via 3DED, was dynamically refined to reveal the presence of water molecules within its channels, a key insight for understanding its properties. Second, we studied a novel heterometallic MOF exhibiting a complex and highly disordered structure. It shows an orthorhombic structure with a spacegroup of Cmmm and a cell volume above 11000 A^3, which can be advantageous for certain applications. The 3DED analysis revealed a unique tetranuclear metallic cluster composed of both titanium (IV) and calcium (II) centers, offering a potential platform for tailored functionality.3
This work was carried out with the support from the European Union's Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No 956099 (NanED – Electron Nanocrystallography – H2020-MSCAITN)

Poster Group 1

Background
For conventional transmission electron microscopy, biological samples are treated with heavy metal salt solutions to enhance contrast, either by staining ultrathin sections with lead citrate, uranyl acetate or lanthanoid salts, or by staining tissue blocks before embedding, using similar substances. However, we found that these substances are insufficient for imaging collagen fibrils and collagen VII anchoring fibrils. The latter are critical structures for a stable attachment of the epidermis to the underlying dermis, and accordingly the subject of studies concerning skin defects such as epidermolysis bullosa. Their structure and exact position can only be imaged by electron microscopy. Phosphotungstic acid (PTA) is known to interact with nucleic acids and positively charged proteins, and is widely used for light histologic staining procedures of connective tissue. It is also used in TEM, but mainly for negative staining. Only a few protocols for section or block staining are available in the recent literature. We tested PTA staining of collagen for TEM and were able to establish a block staining procedure that can be integrated in the dehydration steps.
Methods
Human and murine skin and in vitro skin equivalents were fixed in paraformaldehyde and glutaraldehyde, and postfixed in osmium tetroxide. Blocks were stained in 1% PTA in 70% ethanol, followed by further dehydration in ethanol, embedding in epoxy resin and ultrathin sectioning. Sections were analyzed in a Zeiss EM910 at 80kV.
Results
The combination of osmiumtetroxide and ethanolic PTA resulted in a versatile staining of all tissue components. We observed strong contrast of all intracellular compartments, well characterized chromatin, dark mitochondria, strong staining of ribosomes and very intensive staining of desmosomes and hemidesmosomes. Collagen fibrils, anchoring fibrils and other fibrous extracellular materials including the basal lamina were depicted in high quality.
Conclusion
Ethanolic PTA staining is a fast, easy and non-radioactive block staining method for structurally precise TEM tissue analysis. It provides good results for both, intracellular structures and extracellular fibres such as different types of collagen. This protocol may be an interesting option for various studies on cell and tissue microstructure since there is, for example, an increasing demand for reliable block staining techniques for 3D analysis of serially sectioned and scanned resin blocks.

In batteries, electrochemical reactions take place at the interfaces (electrodes-electrolyte, etc.), inducing more or less reversible change such as poor ion transport, dendrite formation, electrochemical degradation and chemo-mechanical degradation[1]. Among the new-generation systems under development, all-solid-state batteries (ASSBs) are no exception to this rule. Understanding the phenomena at interfaces that lead to premature battery ageing is therefore crucial to understanding and finding ways of improving the battery. Thanks to the emergence of in-situ and operando techniques, these complex, constantly evolving interfaces can now be studied by live, battery-scale observations using SEM[2].
To carry out this type of study, we have developed a simple electrochemical cell (Figure 1) that can be used to operate all-solid state lithium metal batteries inside the SEM. The use of lithium metal, which is an air-sensitive compound, led us to fabricate a sealed box enabling the battery to be transferred between the glovebox and the SEM (and vice versa). Morphological (secondary and backscattered electron imaging) and chemical (X-ray energy dispersive spectroscopy) changes at solid-state interfaces could thus be monitored in real time and during battery operation.
In this study, we focused on sulfide-based solid electrolyte (SE) particle size distribution and its impact on electrochemical performance. A batch of Argyrodite (Li6PS5Cl (LPSCl)) was sieved to obtain two batches of particles range (0,5-20µm and 50-150µm). The AASBs were prepared using the two particles size distribution while keeping the anode (lithium metal), cathode (active material: NMC) composite formation and the fabrication process constant.
From the two particles sized distribution, the one with the large particles have better electrochemical performance. From morphological point of view at the cathode composite electrode, the formation of a cathode electrolyte interface is visible in the different batteries but is more developed in the case of small sized particles. In the solid electrolyte, the type of cracks differs with relatively strait feature for small particles and sinuous one for large one. At the anodic interface, a lost in contact between the SE separator and the lithium is observed and increased with the cycling process with a higher impact for the small particles (Figure 2.a and b). By investigating further, the formation of dendrites with different morphologies are visible at the anodic interfaces (Figure2.c).
We categorized the observed changes into three modes: (i) electrical failure by the formation of lithium dendrites of different morphologies following the ES going up to short circuit in the case of small particles, (ii) mechanical failure by the formation of cracks in the electrolyte whose shape and propagation strongly depend on the distribution particles size and (iii) electrochemical failure with the formation of solid electrolyte interphases on the surface of the active material. The main obstacles for the use of lithium metal are related to the propagation of lithium dendrites and thus to the mechanical instability of solid electrolytes.

Poster Group 1

Background:
A key issue with the established method of cryo-electron tomography (Cryo-ET) often lies in the challenge of accurately locating complexes or proteins of interest within the crowded cellular environment of the generated tomograms. This project aims to use cryo-scanning transmission electron microscopy (STEM) to highlight regions of tomograms containing the protein of interest by tagging with a minimally-sized heavy atom nanoparticle for downstream processing. A fine balance must be achieved between resolution, signal-to-noise ratio (SNR), depth of focus, and damage to the lamella.

Methods:
A scan generator offers alternative (non-raster) methods of scanning the beam to offset damage and allow higher electron fluences to be used without compromising ice quality. Small raster and interleaved scans (< 200 nm) were compared in the same quantifoil hole of vitreous ice, using an equal overall electron fluence and flux.
Analysis of elastic scattering cross section theory yields an approximate minimal size of nanoparticles for detection in STEM of vitreous amorphous specimens. Single particle-like sample preparation was employed to freeze varying sizes of gold nanoparticles (0.8-4 nm) in different thicknesses of ice. These were subsequently exposed to STEM to assess a drop-off in SNR with increasing collection angles using an annular dark field detector.

Results:
Scanning in an alternative fashion using long dwell times demonstrated a significant reduction in mass loss. Raster scanning appeared to be marginally better than interleaved scanning when using shorter dwell times (20 µs), as evidenced by greater loss of intensity in the scanned areas, normalised to reference areas taken within the same hole of vitreous ice. However, using longer dwell times (250 µs or 500 µs) reversed this effect, showing raster scanning to be significantly more damaging than interleaved, melting the ice completely in thin samples for raster scanning, whilst maintaining the ice intact using an interleaved sequence.

Conclusions:
These findings provide valuable first steps toward optimizing cryo-STEM imaging for detecting nanoparticles and correlating these findings with in-situ Transmission Electron Microscopy (TEM).

Poster Group 2

Background
Invasive insects, in addition to several already established species, are a serious threat to crop production and an important hazard as vectors of pathogens of severe diseases. This is an increasing problem due to trans-continental trade, travel and climate change. Therefore, new strategies for crop protection and new approaches to minimize the adverse effects of pathogen spread are needed. A better understanding of insect functional ultrastructure during animal development and under stress conditions is crucial to facilitate formulation of new innovative solutions. Microscopic analyses enable comprehensive characterization of the structure of insect organs and localization of selected molecules at different scales, and in combination with biochemical analyses that unravel selected aspects at the molecular level, constitute a toolbox for the integration of structure and function and for an in-depth evaluation of the effects of xenobiotics. The first aim of our study was to establish a procedure in which micro-computed tomography, light and transmission electron microscopy will be used in combination to image insect digestive system in larvae and adults, spanning the range from molecular resolution to imaging of the whole organisms. Our second aim was to apply the method to characterize the midgut of two insect species that are important from the perspective of crop protection, spotted wing drosophila (Drosophila suzukii) and Colorado potato beetle (Leptinotarsa decemlineata).
Methods
The insect gut is positioned at the interface between the external and internal environment and it is a likely target of xenobiotics. As the midgut epithelium plays a central role in digestion, nutrient absorption and protection against toxins and pathogens, we have characterized the midgut functional ultrastructure in larvae and adults to get insight into changes during development and to evaluate the alterations of the gut epithelium due to exposure to selected xenobiotics - fungal lectins and protease inhibitors. Micro-CT imaging was performed on whole animals that were chemically fixed. Subsequent processing and segmentation of the micro-CT data was performed using Neoscan80 and Dragonfly software. Sections of the whole larvae or dissected gut samples were imaged by LM and TEM in different regions along the anterior-posterior axis, focused on the characterization of the luminal surface of the epithelium, the distribution of stem/progenitor cells and alterations of the epithelium architecture after exposure to selected xenobiotics.
Results and conclusions
The digestive system in insects consists of foregut, midgut and hindgut. The highly convoluted midgut is the longest part of the alimentary canal and occupies a large part of D. suzukii larva body volume (Figs. 1A, B). The midgut epithelium comprises several cell types (Fig. 1C), enterocytes bear numerous microvilli on the apical surface (Fig. 1D). Stem cells are abundant and appear as clusters of cells in the basal region of the epithelium (Fig. 1E). In the midgut of Colorado potato beetle larvae columnar enterocytes with dense apical microvilli prevail and numerous stem cells reside in clusters in the

basal part of the gut epithelium. Stem cells do not form septate junctions with neighbouring cells, while enterocytes display abundant intercellular junctions. Our current work is focused on the determination of the effects of entomotoxic fungal proteins on the digestive system by a combination of imaging methods and biochemical approaches to identify the target molecules and elucidate their mode of action.

Poster Group 2

Transition-metal (TM)-based van der Waals (vdW) materials ("2D – materials") recently received particular attention due to their tunable magnetic properties arising from unpaired magnetic moments due to the partially filled d-shells of the TM ions. The subclass of TM phosphorous trisulfides (TMPS3) has attracted significant interest due to its wide range of TM elements, resulting in diverse properties [1]. The structure of TMPS3 is defined by its vdW nature. Layers exhibit the monoclinic crystal structure, space group 3 C2/m, and are only bound by weak vdW forces [2], which allows for easy exfoliation and leads to 2D-like properties being observable in 3D crystals.
In this study, transmission electron microscopy (TEM), energy dispersive X-ray spectroscopy (EDX), electron energy loss spectroscopy (EELS), and continuous rotation electron diffraction (cRED) have been combined to study the cation-mixed (Fe,Mn,Ni)PS3 van der Waals single crystals with different Fe, Mn, and Ni concentrations produced in a bulk state by chemical vapor transport (CVT) [3].
The high-resolution (HR) TEM image (a) shows the cross-section of a (Fe,Mn,Ni)PS3 single crystalline sample, prepared by Cryo-Ultramicrotome. An amorphous oxide layer formed on the edge of the sample is highlighted with a yellow dashed line. It has a thickness of 5 nm. The magnified HRTEM image (b) shows the layered structure with a layer distance of 0.65 ± 0.02 nm. Bright spots (atomic columns) correspond to S and P. The darker lines are the planes of TM ions. Ultrasonically exfoliated layers are shown on TEM image (c) on which selected area electron diffraction (SAED) (d) and EDX mapping (e) have been performed. The lattice parameters a = 0.647 nm, b = 1.072 nm, c = 0.698 nm, $\alpha = \gamma = 90°$ and $\beta = 111.22°$ were estimated from the SAED pattern and slightly deviate from earlier reported FePS3, MnPS3 and NiPS3 mono-compounds [4,5].

STEM-EELS and Image simulations of inelastic spin-scattering of magnons in confined geometries

Julio Do Nascimento[1,2], Dr. Demie Kepaptsoglou[1,4], Prof. Quentin Ramasse[2,4], Prof. Vlado Lazarov[1,2]
[1]School of Physics, Engineering and Technology, University of York, York, United Kingdom, [2]York-JEOL Nanocentre, University of York, York, United Kingdom, [3]SuperSTEM Laboratory, SciTech Daresbury, Daresbury, United Kingdom, [4]School of Chemical and Process Engineering & School of Physics and Astronomy, University of Leeds, Leeds, United Kingdom

PS-08 (2), Lecture Theater 2, august 27, 2024, 14:00 - 16:00

Background incl. aims
Application of magnons requires generation, manipulation, and their characterisation in high resolution in both energy and spatial scales. Magnons are commonly studied by inelastic neutron scattering techniques, time-resolved Kerr microscopy, and Brillouin light scattering. While these techniques probe the energy-momentum dispersion of magnons with high energy resolution, their spatial resolution is fundamentally limited to hundreds of nanometres.
Progress in electron beam monochromators in scanning transmission electron microscopy (STEM) has enabled the use of electron beams to study magnons with nanometer and sub-nanometer spatial resolution. Previous studies have successfully collected signals of scattered electrons through electron energy loss spectroscopy (EELS), demonstrating the detection of collective excitations like phonons [1]. The energy range of phonon modes, extending up to a few hundred meV in solid-state materials, aligns qualitatively with magnons, hence efforts aiming to detect magnons using STEM-EELS are ongoing.
Although the interaction strength between magnons and electrons is known to be three or four orders of magnitude weaker compared to the Coulomb interaction, experimental evidence has shown that magnetic ordering can be detected through Bragg reflections of electrons [2]. Furthermore, recent theoretical predictions suggest an EELS signal from thermal magnons in bulk specimens [2, 3], supporting the potential use of STEM-EELS for measuring magnons in confined geometries, including interfaces and surfaces.
Methods
In this study, we employ the second quantization of the Heisenberg Hamiltonian to calculate the dynamics of magnon modes in finite systems, allowing the inclusion of thin films, interfaces, and heterostructures between ferromagnetic (FM) and antiferromagnetic (AFM) layers, with different relative orientations between the electron beam and the Curie/Neel vector. We then employ the general formalism by van Hove [4] to calculate the double cross-section accounting for the spin-spin interaction of the electron probe with the system, as well as the effect of the system's vector potential on the charged probe's canonical momentum. In addition, by using the multislice method, we simulate high resolution STEM images due to the electron-magnon interaction.
Results
We present our result on simulations using Fe, NiO and YIG as prototypical examples of the effects captured by the method, Figure 1. By quantifying separately, the spin-based and charge-based interactions in STEM-EELS, we reveal distinct behaviours: charge-based interaction shows a linear dependence on beam momentum, while spin-based interaction follows an inverse relationship akin to phonons, suggesting potential magnon-related peak enhancement compared to phonon peaks at higher acceleration voltages. Additionally, charge-based interaction exhibits an inverse square

dependence with a scattering vector. Furthermore, the image simulations show a dependence with the magnetic moment's orientation relative to the electron beam.

Conclusion

Overall, our study advances our understanding of electron-matter interactions in EELS, offering insights for designing and interpreting experiments probing the magnetic properties of nanomaterials. The magnon EELS calculations suggest that these interactions would be dominant for higher beam acceleration and within the first Brillouin zone, while the image simulations point to the possibility of probing the local magnetic moment's orientations.

Microscopy of body surface sculpturing in terrestrial crustaceans

Ana Žuran[1], Dr. Miloš Vittori[1]
[1]Department of Biology, Biotechnical Faculty, University of Ljubljana, Ljubljana, Slovenia

Poster Group 1

Background
Terrestrial isopods (Oniscidea) are a successful group of terrestrial crustaceans, partly due to their finely structured exoskeletal cuticle. The cuticle is an elaborate extracellular matrix deposited by epidermal cells and consists of several layers. The epicuticle, the thinnest and outermost layer, forms remarkably diverse and complex structures, such as scales and other micrometre-sized ornaments that influence the surface properties of the cuticle and the interaction of isopods with their environment [1, 2]. However, not much is known about the formation of the epicuticle and these structures. The aim of this study was to develop a simple protocol to investigate dorsal epicuticle formation in terrestrial isopods during molt. For this purpose, a combination of scanning electron microscopy (SEM) and confocal laser scanning microscopy (CLSM) was applied to image the deposition of the new epicuticle during molt in the terrestrial isopod Porcellio scaber.
Methods
Tergites of P. scaber specimens in different stages of cuticle deposition during preparation for molt [3] were dissected, fixed in a mixture of paraformaldehyde and glutaraldehyde, and decalcified with EDTA. For SEM imaging, the samples were osmicated and embedded in paraffin. At this stage, the old cuticle was cut off with a razor blade to expose the ecdysial space for observation. Paraffin was then removed, and samples were air-dried in hexamethyldisilazane and sputter-coated with platinum. Prepared samples were imaged using a JSM-7500 field emission scanning electron microscope (JEOL). For CLSM imaging, the decalcified samples were incubated in methyl green, a far-red emitting fluorescent DNA dye, to visualize cell nuclei [4]. Subsequently, the samples were cleared and mounted in ProLong™ Glass Antifade Mountant (Invitrogen). Series of optical sections were acquired using a Stellaris 8 confocal microscope (Leica).
Results and conclusions
Using the described procedure, we were able to expose the ecdysial space and the surface of the epidermis and observe the new epicuticle in different stages of its formation with SEM from a perspective never seen before. In the late stage of cuticle deposition, we observed the fully sculptured new epicuticle with numerous scales and sensory tricorns (Fig. 1A), whereas in the early stage, the surface of the underlying epidermis was exposed, showing stubby apical cell membrane protrusions and only the outlines of the edges of new scales. Using CLSM, we were able to observe cuticle autofluorescence in relation to DNA-bound methyl green fluorescence and thus determine the position of epidermal cells in relation to the position of emerging epicuticular structures (Fig. 1B). In this way, we established that each scale is likely deposited by a single epidermal cell. The presented protocol allowed us to observe the complex architecture of the epicuticle during its deposition and to gain information about the mechanism of epicuticular sculpturing by the epidermal cells that secrete it. In the future, we plan to extend this protocol by analysing the changes in epidermal cell ultrastructure during epicuticle formation using transmission electron microscopy.

Toxic buffers used in microbial sample preservation for SEM can be replaced by PBS

Indra Banas[1], Noel Kleber[1], Dr. André Soares[1], Prof. Dr. Alexander Probst[1,2,3]
[1]Environmental Metagenomics, Research Center One Health Ruhr of the University Alliance Ruhr, Faculty of Chemistry, University of Duisburg-Essen, Essen, Germany, [2]Centre of Water and Environmental Research (ZWU), University of Duisburg-Essen, Essen, Deutschland, [3]Center of Medical Biotechnology (ZMB), University of Duisburg-Essen, Essen, Deutschland

Poster Group 1

The structural preservation of uncultivated, oxygen-sensitive microorganisms for imaging via scanning electron microscopy (SEM), often relies on toxic buffers like cacodylate. As such, studies on certain archaea named Candidatus Altiarchaeum which can dominate deep biosphere ecosystems by forming biofilms using hook-shaped cell appendages (hami), currently heavily rely on cacodylate buffers. However, the twelve principles of green chemistry state that researchers should strive to minimize the use of toxic substances and ideally replace them entirely with non-toxic alternatives. Following these principles, we here tested the influence of alternative, less toxic buffers (phosphate-buffered saline (PBS) and PHEM (PIPES-HEPES-EGTA-MgCl2)) for the preservation of Ca. Altiarchaeum hamiconexum for SEM and compared them with preservation using cacodylate for subsequent imaging.

Fixation of Ca. Altiarchaeum hamiconexum was conducted immediately after the collection of the biofilm from a cold sulfidic spring located in Regensburg (Bavaria). Samples were preserved using 4% formaldehyde final concentration in cacodylate, PHEM or PBS, respectively. For SEM preparation, 2.5% glutaraldehyde in cacodylate, PHEM or PBS, were used, after which samples were rinsed four times with the corresponding buffer and post fixated with 1% osmium tetroxide in cacodylate, PHEM or PBS. A dehydration gradient was then applied with 10%, 20%, 40%, 60%, 80% and 100% acetone. Quality of preservation was examined using SEM after critical point drying and sputter coating with platinum/palladium. The so prepared archaeal cells were analyzed in comparative manner by experienced scientists used to investigate Ca. Altiarchaeum hamiconexum ultrastructure prepared with cacodylate buffer.

The preservation with cacodylate and PBS revealed no noticeable differences. The hami displayed a high degree of preservation and no visible difference in the thickness and length of those structures. However, all cells, independent of the preservation buffer used, showed deformations. The samples preserved in PHEM exhibited the least preservation of the hami, with many cells showing complete absence of appendages.

To reduce risks for researchers and the environment, the use of toxic substances in laboratory conditions should be avoided if less dangerous alternatives exist. In this study, no visible differences were observed for the quality of hami preservation between toxic buffer cacodylate and PBS. PBS can effectively replace cacodylate for preserving the ultrastructure of hami of Ca. Altiarchaeum hamiconexum for the purposes of high-resolution microscopy.

Python's widespread adoption is supported by a wide community that has developed an extensive toolkit of open-source libraries. Electron microscopy vendors have introduced Application Programming Interfaces (APIs) enabling users to design sequences for comprehensive control over electron optics, detectors, sample positioning, and data acquisition. [1,2,3]
These Python-accessible libraries facilitate classical image processing tasks, including object detection, drift correction, and feature tracking, which have been pillars of electron microscopy scripting for over twenty years. Applications range from Focused Ion Beam (FIB)/Scanning Electron Microscopy (SEM) defect analysis and Transmission Electron Microscopy (TEM) lamella preparation to semiconductor metrology, with TEM image processing and data analysis being particularly prominent.
The adoption of closed-loop image processing in electron microscopy is driven by the increasing volume of multimodal data generated by these instruments. Direct data offloading is inefficient and risks post-processing error identification, leading to valuable time losses.
Recent advancements in machine learning and deep learning have significantly enhanced their performance and integration speed, facilitating their inclusion in closed-loop automation sequences for complex tasks such as object detection, classification, and feature extraction.
ThermoFisher Scientific's AutoScript, a cross-platform Python-based API, streamlines and refines electron microscopy workflows by harnessing deep learning techniques. This paper highlights two applications:
1. SEM Feature Analysis: Utilizing a Thermo Scientific Helios microscope, this experiment automates the creation of binary masks for feature analysis on aluminum powder samples. Instance segmentation enables feature separation, counting, and property analysis (e.g., size and shape), allowing real-time experimental optimization based on material properties identified by deep learning algorithms.
2. TEM Atom Detection: Demonstrated with a Thermo Scientific Talos F200, this application automates the detection of atom positions and diameters in HR-STEM images of SrTiO3. Neural networks facilitate rapid atomic structure predictions and interface identification, optimizing imaging parameters on-the-fly.
These cases exemplify the transformative impact of cross-platform, Python-based APIs in electron microscopy, showcasing their potential to enhance efficiency, accuracy, and the scope of achievable experiments through automation and advanced data analysis.

Exploring Role of Voltage-Gated Ion Channels in LGI1 Autoantibody-Induced Epilepsy: Insights from a Mouse Model

Dr Jacqueline Montanaro[1], Hana Stefanickova[1], Dr. Mary Muhia[1], Prof. Dr. med Christian Geis[2], Claudia Sommer[2], Josefine Sell[2], Prof. Dr. Hans-Christian Korna[3], Prof. Dr. Harald Prüß[3], Prof. Ryuichi Shigemoto[1]

Poster Group 1

Epilepsy is a debilitating condition affecting 0.5% to 1.0% of the world's population (1), but its underlying etiology often remains unknown, hence most anti-epilepsy therapies aim for reduction in seizure symptoms. Nevertheless, recent studies suggest that up to 1 to 7 out of 20 individuals with new onset seizures may have an autoimmune cause (2). Although rare, the most common epilepsy-associated autoantibodies target different proteins in the brain, such as N-methyl-d-aspartate receptor (NMDAR), leucine-rich glioma-inactivated protein 1 (LGI1), and glutamic acid decarboxylase 65 (GAD65) (3).
LGI1 is a soluble secreted protein which links Adam22/23 proteins across the synaptic cleft. LGI1 is also abundant in the axon initial segments of in the hippocampus, in particular, in the dentate gyrus (4). Anti-LGI1 autoantibodies have been found in both cerebral spinal fluid and serum of acquired epilepsy patients with symptoms of limbic encephalitis with amnesia and seizures. The specific mechanisms how any autoantibody leads to epileptic seizures is unknown. However, previous studies showed human LGI1 autoantibodies co-precipitated with voltage-gated (VG) potassium channel complexes in rodent tissue (5). Since VG-ion channels help maintain homeostasis in neuronal excitability, we hypothesize that dysregulation of these channels may be triggering LGI1 autoantibody-induced neuropathophysiology. In this study, our aim is to detect a possible mechanism for seizure onset after LGI1 autoantibody exposure. To do this, we are investigating if changes in either the distribution or numbers of VG-ion channels occur when mice are exposed to LGI1 autoantibodies.
Methods:
In mice injected with monoclonal LGI1-antibody into the hippocampus, epileptic seizures were induced, while no symptoms were observed in mice injected with control serum only. Ultrastructural observation of immunolabeled freeze-fractured replicas with colloidal gold antibodies quantified Cav2.1 calcium channels and Kv1.1 potassium channels in axon initial segments and active zones (AZ) of the dentate gyrus granule cell axons (mossy fibers).
Results:
LGI1-autoantibody-injected animals showed that Cav2.1 was slightly reduced in AZ, compared to control animals, while Kv1.1 density was low in control groups. This suggests that neither Cav2.1 and Kv1.1 could be causing mossy fiber hyperactivity at synapses. However, many other VG-ion channels remain that can be investigated using these same methods. Importantly, we observed a significant reduction in synaptic vesicle numbers in mossy fiber boutons in LGI1-autoantibody-injected mice with epilepsy symptoms compared to asymptomatic controls. The synaptic vesicle depletion has implications for presynaptic hyper-excitability and altered neurotransmitter release, and could serve as a marker for affected AZs in epilepsy.
Conclusions:

These results suggest that our mouse model will be useful in investigating if alteration of VG-ion channels trigger hyperexcitability of neurons and contribute to epilepsy in LGI1 autoimmune encephalitis. In the future, these investigations may have useful implications for helping to find triggers of epilepsy with unknown etiologies.

Ultrastructural analysis of liver injury and regeneration after microcystin-LR intoxication in whitefish

PhD Natalia Szyrynska[1], Bogdan Lewczuk[1], Maciej Wozny[2], Pawel Brzuzan[2]
[1]Department of Histology and Embryology, Faculty of Veterinary Medicine, University of Warmia and Mazury in Olsztyn , , Poland, [2]Department of Environmental Biotechnology, Faculty of Geoengineering, University of Warmia and Mazury in Olsztyn, , Poland

Poster Group 2

Microcystin-LR (MC-LR) is a cyanobacterial hepatotoxin that is produced in large quantities during algal blooms. It poses a health threat to aquatic organisms in particular, but also to non-aquatic animals because it contaminates drinking water. MC-LR is an extremely dangerous toxin, as the LD50 for intraperitoneal administration in mice is only 25–150 µg/kg body weight (1). MC-LR acts on mature hepatocytes expressing organic anion transporting polypeptides, which are responsible for the uptake of the toxin, but not on cells of the bile duct system (2). Our previous study has shown that the high dose of MC-LR (100 µg/kg body weight) caused severe injury of hepatocytes at the beginning of the post-exposure period, while the low dose (10 µg/kg body weight) caused less, probably reversible, hepatocytes damage and its effects were observed later in the post-exposure period in whitefish (3). Transmission electron microscopy (TEM) showed that the main targets for the cytotoxic effects of MC-LR were endoplasmic reticulum, cytoskeleton, and chromatin. The high dose of toxin induced massive hepatocyte death within 24–48 hours after administration. Histological examinations showed that the liver regenerated after this damage. Unfortunately, the samples for ultrastructural examinations were not collected during the regeneration phase, so that the details of this process remain unknown. The aim of the present study was to characterize the processes of liver injury and regeneration after single administration of a high dose of MC-LR to whitefish. For TEM-like imaging of large sample areas, we used highly sensitive, high resolution detection of backscattered electrons (BSE) in a field-emission scanning electron microscope (4).
Juvenile whitefish (29.9±1.6 g) were anesthetized in MS-222 solution and received an intraperitoneal injection of MC-LR solution (100 µg/kg body weight) or phosphate buffer saline (control). Randomly selected fish were euthanized by immersion in overdosed MS-222 solution 1, 2, 6, 9 and 14 days after administration of the toxin or saline. Liver samples were immediately fixed in a mixture of 1 % paraformaldehyde and 2.5 % glutaraldehyde in 0.2 M phosphate buffer for 2 hours at 4°C, then washed and post-fixed in 2 % osmium tetroxide for 2 hours. After dehydration, the samples were embedded in Epon 812. Ultrathin sections were cut using the PT3D PowerTome ultramicrotome with ASH2 (Boeckeler Instruments, USA), placed on silicon wafers, and contrasted with uranyl acetate and lead citrate. Sections were imaged using a SenseBSD backscatter electrons detector in SEM Gemini 450 at 1.4 kV, controlled by Atlas 5 software (Carl Zeiss, Germany).
The liver parenchyma of the control fish consisted of polygonal hepatocytes arranged in cords running along the capillary blood vessels. The vascular domains of hepatocytes were covered by very long, irregular microvilli. Hepatocytes were characterized by a euchromatin-rich nucleus, long, parallel cisterns of granular endoplasmic reticulum, a well-developed smooth endoplasmic reticulum and numerous mitochondria, usually with electron-dense matrix. Lysosomes were mostly located close to the lateral domain. The glycogen particles and lipid droplets were infrequently noted. In the samples taken 24 hours after the toxin administration, hepatocytes had lost their polygonal shape and were oval or irregular. Oval cells usually had a low electron density, while irregular cells had a moderate or high electron density. Microvilli were absent both on the vascular domain and on the

cell membrane creating the bile canaliculi. The endoplasmic reticulum was present in the form of large, differently shaped vesicles that filled the entire cytoplasm. The nuclear envelope was usually dilated. Mitochondria remained unchanged in majority of cells. The lipid droplets with different diameters were frequently observed. Some hepatocyte nuclei showed chromatin clamping. The next day, 48 hours after MC-LR administration, the majority of hepatocytes, usually of high or moderate electron density, showed prominent condensation and marginalization of chromatin. Mitochondria in these cells were swollen with electron lucent matrix or condensed with electron dark matrix. Oval, electron lucent necrotic cells and typical, round, electron-dense apoptotic cells were also observed. Some areas of the liver parenchyma contained cell debris. Despite the severe damage of hepatocytes, the capillaries retained their continuity, but cell debris was sometimes found in the blood vessels. Single macrophages were also found. On day 6 after exposure, the liver parenchyma contained numerous phagocytes located between cell debris and remnants of apoptotic cells. The cells of the bile ducts formed short cords with numerous intercellular canaliculi. The apical parts of these cells were filled with keratin filaments. The cords of epithelial cells originating the bile ducts were much more numerous on the day 9 after intoxication. The cells forming the cords were rich in cytoplasm, which contained well-developed rough endoplasmic reticulum and Golgi apparatus as well as numerous myelin-like figures. Mitoses were observed in these cells. The liver parenchyma on day 14 after administration of the toxin consisted mainly of immature hepatocytes with well-developed endoplasmic reticulum, numerous mitochondria and glycogen particles. Hepatocytes were poorly equipped with microvilli, both in the vascular domain and in the bile canaliculi. Like the epithelial cells of the bile ducts, hepatocytes showed an accumulation of keratin filaments under the cell membrane of the biliary pool. Macrophages were observed between hepatocytes.
In conclusion, three phases can be distinguished in the course of changes in liver induced by a single administration of the sublethal dose of MC-LR: damage of hepatocytes, infiltration of macrophages and phagocytosis of cellular debris, and proliferation of progenitor cells located in the bile duct system and their differentiation into hepatocytes. The neighbouring hepatocytes differ in their response to MC-LR and take the pathway to apoptotic death or necrosis. Macrophages remain in the regenerating liver for a long time, suggesting their role in the control of transformation of liver progenitor cells into hepatocytes. Liver regeneration after damage of the majority of hepatocytes occurs via the proliferation and differentiation of progenitor cells located in the bile duct system. Our results have also showed that the highly sensitive detection of BSE is an extremely powerful technique for study of tissue ultrastructure.

Effect of chloroquine and naringin on the relationship between ER stress and mitochondria in trophoblasts

Research Associate Zehra Sezer[1]
[1]ISTANBUL UNIVERSITY-CERRAHPASA, Istanbul, Turkey

Poster Group 1

Background incl. aims
The placenta is an interface that transports nutrients, oxygen, and waste products between the mother and the fetus. Trophoblast cells in the fetal part of the placenta differentiate for the development of a healthy placenta and the continuity of pregnancy and perform functions such as invasion and secretion. It is known that autophagy plays an essential role in these functions. Autophagy is a process responsible for degrading damaged structures to maintain cellular homeostasis. Suppression of autophagy, oxidative stress, and apoptosis in trophoblasts can lead to pathologies such as implantation failures, spontaneous miscarriages, and preeclampsia. Naringin (Nar) is a bioflavonoid with anti-apoptotic, anti-inflammatory, and antioxidant properties (Bharti ve ark., 2014). Previous studies have shown that Nar stimulates ER stress-mediated apoptosis in colon and cervical cancer cells and inhibits mitochondria and ER stress-mediated apoptotic pathways in endothelial cells. This study aims to investigate the effect of Nar on endoplasmic reticulum (ER) stress (Grp78 and PERK), mitochondria dynamics (Fis1 and MFN2), and the ER-mitochondria relationship after hydrogen peroxide (H2O2)-induced oxidative stress and the inhibition of autophagy (chloroquine; CQ) in trophoblast cells.
Methods
IC50 analysis was performed using the data obtained after the CCK8 experiment to determine the most appropriate H2O2, CQ, and Nar doses to be applied to the cells. Seven experimental groups were constructed: Control (C), H2O2, CQ, Nar, H2O2+Nar, CQ+Nar, and H2O2+CQ+Nar. To examine both ER stress and mt dynamic protein levels in cells and the relationship between ER and mitochondria, Grp78 and Fis1 and p-Perk and MFN2 proteins were double labeled by immunofluorescence (IF) method. In addition, apoptosis was evaluated by Caspase-3 protein labeling using IF, and the ER-mitochondria relationship was assessed by electron microscopy.
Results
As a result of IF, while Grp78 expression increased in CQ-treated trophoblasts, no change was observed in Fis1+ mt fission. There was a significant increase in Grp78 and Fis1 protein levels in the Nar-applied groups. Also, the p-Perk level decreased significantly in the CQ+Nar group, while MFN2+ mt fusion increased dramatically in the Nar-applied groups. Moreover, it was observed that the autophagy inhibition in trophoblasts did not show any change in the mt dynamic balance, but Nar had the opposite effect. In addition, Caspase-3 labeling showed a significant increase in apoptosis in the CQ group compared to the C and Nar groups. Nar decreased Caspase-3-mediated apoptosis combined with CQ but was ineffective when administered with H2O2.
Conclusion
ER stress (GRP78) and apoptosis increased by inhibiting autophagy (CQ), but apoptosis decreased after CQ and Nar application, although GRP78 increased. This decrease may be due to mt fission. Increased ER stress may reduce Caspase3-mediated apoptosis by triggering fission in the mitochondria, which is closely related. In addition, Nar applied to trophoblasts with inhibited autophagy caused a severe decrease in the level of p-PERK, an important protein in the ER-mitochondria relationship, and this decrease affected the level of apoptosis. Still, p-PERK did not

show any effect on mt dynamics. In conclusion, it has been observed that ER stress and mt dynamic-induced cell death may occur in pathological conditions due to autophagy in trophoblasts, and Nar may be effective in these mechanisms. The experiments regarding the study are still being conducted; ER stress mechanism and mitophagy affecting mt dynamics will be investigated by immunolabeling ATF6 and IRE1, Pink and Parkin.

Understanding field evaporation sequences by in-situ correlative microscopy and simulation

Mohammed Ilhami[1], Prof. Williams Lefebvre[1], Prof. Francois Vurpillot[1]
[1]Groupe De Physique Des Matériaux, Saint Etienne Du Rouvray, France

Poster Group 1

Background
Atom Probe Tomography (APT) provides detailed information on a material's microstructure and its chemical composition. This technique enables access to the 3D position and chemical nature of each atom in a sample. The process involves evaporating the atoms using an electric field and reconstructing a 3D model of a needle-shaped specimen. However, the resolution of APT can be degraded for heterogeneous materials by artifacts potentially associated with the reconstruction methods. Furthermore, the geometric model of the hemisphere on a truncated cone used for APT reconstructions relies on assumptions about variations in the tip curvature along the evaporation sequences. These fluctuations depend on variations in the evaporation field, which are governed by the distribution of areas of higher or lower evaporation field in the sample. This is for instance illustrated in Figure 1.
Tracking the shape of the APT tip during evaporation can provide valuable information about the tip radius, which can help improve the reconstruction algorithm, mapping the electric field around the tip can also indicate areas of higher or lower electric field. In-situ correlative electron microscopy, achieved by performing APT experiments in a STEM can consequently help understanding the evaporation sequences.

Methods
4D-STEM [1] experiments were carried out on a polarized Al-Fe APT tip subjected to 1 kV. A CheeTah Timepix3 pixelated detector was used to record a diffraction pattern for each pixel as the tip was scanned. To mitigate dynamic diffraction effects, a precession angle of 0.7 degrees was used.
Data analysis was performed using the Libertem [2] software. For simulating the field evaporation process, we utilized the Robin-Rolland [3] algorithm that calculates the electric charge on each atom and predicts evaporation events by identifying atoms that reach a critical evaporation field threshold.

Results
Our experiments showed variations in electrostatic fields around a polarized Al-Fe tip, subjected to a voltage of 1 kV. This variation is shown in Figure 2. The analysis shows a constant electrostatic field inside the tip, indicated by the blue color. A high field was observed near the apex of the tip, indicating a high probability of evaporation, confirmed by the results of simulation, represented in Figure 3.

Conclusion
In this study, we have developed an approach that makes it possible to follow the shape of an APT tip during evaporation, by performing APT experiments in a (S)TEM. In situ correlative microscopy was achieved by developing a sample holder capable of applying a voltage of up to 8 kV. In addition, 4D-STEM experiments made it possible to visualize the electrostatic field on a polarized APT tip. These results could help improve the accuracy and 3D reconstruction of atom probe data. The integration

of numerical modeling can be used to predict material behavior during APT analysis and to confirm experimental results.

FTIR-Imaging of a Tintoretto-Fresco

Dr. Maximilian Ries[1], Barbara Bravo[1], Eleonora Balliana[2]
[1]Thermo Fisher Scientific, , Germany/Italy/USA, [2]Ca' Foscari University of Venice, Venice, Italy

Poster Group 1

Background incl. aims
Molecular spectroscopy tools are employed to investigate the vibrational properties of a wide variety of samples. The chemical composition and physical properties of materials are stored in the molecular bonds and can be read from the vibrational spectrum. Fourier transform infrared (FTIR) spectroscopy has long been utilized to investigate materials present in artwork. This study of Tintoretto's work at the Scuola Grande di San Rocco (Venice, Italy) aims to understand the composition of its pictorial layers.
Methods
The cross-section of the Tintoretto painting sample was embedded in resin to assess the five layers. The sample was analyzed in several regions using a Thermo Scientific Nicolet RaptIR FTIR microscope in corroboration with scanning electron microscopy with energy-dispersive x-ray spectroscopy. All mappings were performed in ATR mode with a Germanium micro-ATR.
Results
The cross-section of the painting revealed the existence of a lipidic preparation layer and finishing layer. The preparation layer contains traces of proteins, pointing to the use of animal glue. The sandwiched layers contain different pigments and filler materials. The study confirmed assumptions and knowledge on the use of materials and techniques in the 16th century. In contrast, semiconductor nanostructures are state-of-the-art technology of the 21st century.
Conclusion
All materials that were expected to be found in the paint sample were successfully identified using the Nicolet RaptIR FTIR Microscope, combined with the multicomponent search function of OMNIC Paradigm Software. The power of spectroscopic techniques is pivotal in the creation, conservation, consolidation, and understanding of materials across all scientific fields.

Raman-Imaging of the Strain-Distribution in Semiconductors

Dr. Maximilian Ries[1,2], Fabian Heisinger[2], Dr. Imad Limame[2]
[1]Thermo Fisher Scientific, , Germany/USA, [2]Technische Universität Berlin, Berlin, Germany

Poster Group 1

Background incl. aims
Molecular spectroscopy tools are employed to investigate the vibrational properties of a wide variety of samples. The chemical composition and physical properties of materials are stored in the molecular bonds and can be read from the vibrational spectrum. This poster is dedicated to the influence of a buried stressor on the strain-dependent site control of InGaAs quantum dots. Raman spectroscopy is highly sensitive to subtle changes in the crystal lattice structure. Under strain, its molecular bonds shift slightly, altering the vibrational frequencies of the lattice. The resulting shifts in Raman peaks contain information about the amount and type of strain present.
Methods
The quantum dot sample was analyzed with a Thermo Fisher Scientific DXR3xi Raman imaging microscope and a 532 nm laser. The results are correlated with atomic force microscopy assessments of the sample height profile.
Results
InGaAs quantum dots grow at sites exhibiting a considerably larger strain than their surrounding. Tuning of the buried stressor size results in the precise control of the distribution, emission, and density of the quantum dots. The overlay of Raman strain mappings with atomic force microscopy height profiles allows for a deeper understanding of the physical properties. In combination with computational simulations, the results forecast the design of new devices with distinct emission patterns.
Conclusion
Besides the chemical composition, Raman spectroscopy is powerful in assessing the physical properties such as the strain in semiconductors. The power of spectroscopic techniques is pivotal in the creation, conservation, consolidation, and understanding of materials across all scientific fields.

Towards electron beam shaping in an Ultrafast Transmission Electron Microscope

Valentin Rollo[1], Sebastien Weber[1], Arnaud Arbouet[1]
[1]CEMES - CNRS, Toulouse, France

Poster Group 2

Background incl. aims
In 1933, Ernst Ruska developed the first Transmission Electron Microscope (TEM) which became the primary tool for studying matter. The picometer De Broglie wavelength and the numerous signals generated by an electron allow us to probe many properties of a sample at the atomic scale. Indeed, by analyzing the amplitude, phase, deflected angle and the energy of the electron beam after its interaction with the sample we can fully reconstruct its chemical composition or its magnetic/electric properties. However, unlike conventional optics, where the amplitude, phase and polarization of a light beam can be fully controlled using e.g. a Spatial Light Modulator (SLM), the electron beam cannot be easily manipulated in a TEM, making electrons insensitive to certain fundamental properties such as chirality. The development of Ultrafast Transmission Electron Microscopes (UTEM), whose working principle is illustrated on figure 1, has opened new possibilities. In 2020 it has been proposed to shape the electron beam through inelastic electron-light interactions in Photon-Induced Near field Electron Microscopy (PINEM) experiments [1] as sketched in figure 1. The PINEM interaction, based on a pump-probe experiment, relies on energy exchanges between an ultrashort electron pulse and a strong optical near-field induced on a sample by a femtosecond laser pulse. One of the main properties of this interaction is to imprint the laser beam phase on the wavefunction describing the electron after the interaction. Two years later, a first practical demonstration [2] illustrated the capability of this technique to generate Gaussian/Hermite-Gaussian electron beams.
The aim of our work is to develop an experimental set up for electron beam arbitrary shaping on a brand-new UTEM developed at CEMES [3]. This new 300 keV UTEM based on a modified Cold Field-Emission Electron Gun (CFEG) has been equipped with two sample stages that will enable us to use the shaped electron beam to probe a sample of interest.
Methods
This work is divided in three mains parts. First, we will develop the optical set up to spatially shape the laser beam by means of a Spatial Light Modulator (SLM) and fully characterize (amplitude and phase) the laser beam before its injection into the Ultrafast TEM (UTEM). In order to use the full potential of the SLM, we will implement various phase retrieval algorithms depending on the needs i.e. control over the intensity/phase distribution or both. In the second part of the project, we will perform Electron Energy Gain Spectroscopy (EEGS) experiments on our UTEM with a standard spatial shape of a laser beam i.e. a gaussian beam. The last step is to add the laser beam shaper set up in order to use the properties of the inelastic electron-light interaction in PINEM experiments to shape the electron beam.
Results
For the time being, the optical set up already enables us to generate any desired spatial distribution of a laser beam such as vortex, Laguerre-Gaussian beams or more generally any intensity and phase distribution – characterized thanks to a Mach Zehnder interferometer - in excellent agreement with the numerical simulations. Moreover, our new 300 keV UTEM based on a modified CFEG is operational and allows us to perform PINEM experiments. The electron beam shaping experiments

are currently under active development. In parallel, we have developed numerical simulations which combine diffraction theory and electrodynamical simulations using the Green Dyadic Method (pyGDM (python package) [4]) to anticipate our future experiments. These calculations allow us to compute the electron wave function after its interaction with the shaped laser beam and its subsequent propagation in the TEM column.

Conclusion

The double sample stage available on our UTEM will allow us to use the properties of the inelastic electron-light interaction in PINEM experiments to shape the electron beam on the first sample stage in order to probe a sample of interest on the second stage. This poster presentation will mainly be focused on the optical part of the experiment i.e. the generation of shaped laser beams with arbitrary amplitude and phase distributions and also on the numerical simulations of the electron beam shaping experiments that will be realized on our brand new UTEM.

Deconvolution of SBF-SEM images improves quality of data in volume electron microscopy

Amin Khosrozadeh[1], Adolfo Odriozola[1], Hans van der Voort[2], Yury Belyaev[3], Benoît Zuber[1]
[1]Institute of Anatomy, University of Bern, Bern, Switzerland, [2]Scientific Volume Imaging, Hilversum, The Netherlands, [3]Microscopy Imaging Center, University of Bern, Bern, Switzerland

IM-12, Lecture Theater 5, august 26, 2024, 10:30 - 12:30

Introduction
The serial block face scanning electron microscopy (SBF-SEM) is a state-of-the-art method for volume imaging of biological objects. Despite many advantages, it suffers from an unavoidable trade-off between acquisition time and image quality: faster acquisition gives noisier, and consequently less resolved images. This problem is known in light microscopy and solved there by applying different image processing methods such as denoising and deconvolution with classical and AI algorithms. We transfer this concept to electron microscopy by designing SBF-SEM point spread function (PSF) and using it for deconvolving the images with the aim of getting less noisy images with higher resolution.
Methods
First, we model 3D SBF-SEM PSF with Monte Carlo simulations of the electron penetration and scattering in an EPON resin with CASINO software for beam energies ranging from 1kV to 15kV. Second, we image the sample with FEI Quanta 250 FEG scanning electron microscope equipped with a 3View2.XP in situ ultramicrotome using the beam energy within simulated values. Finally, we deconvolve acquired images with Huygens Professional software (SVI, the Netherlands) using simulated PSF and custom-made script with 3D CMLE algorithm and corresponding rescaling of SBF-SEM PSF to light microscopy range.
Results
The simulated SBF-SEM PSF has a characteristic pear-shaped form with additional difference to light microscopy, that it only exists in the lower half-space due to the nature of electron scattering in the sample. We applied simulated SBF-SEM PSF in deconvolution of biological specimens. Deconvolved images have higher quality and consequently reveal finer structures, for example allowing for an improved definition of z-lines in skeletal muscle of a mouse, see picture. As the quality of the image is significantly improved after deconvolution, developed methodology can be applied for improving images with lower beam energy and higher imaging speed.
Conclusions
Transfer of the 3D deconvolution concept from light microscopy to SBF-SEM allows for improvement in resolution and speed of imaging in volume electron microscopy in life sciences.

Poster Group 2

Understanding the relationships between microstructure and properties under various conditions is essential for further material development. SEM is suitable for studying not only microstructure but also changes in these materials under different and variable conditions. In the case of elevated temperatures, phenomena associated with diffusion, phase transformations, grain boundaries and precipitation are particularly significant in materials science [1]. Several limitations of in situ experiments in SEM are related to the vacuum environment, which acts as an electrical and thermal insulator. The thermal insulating property of vacuum reduces the risk of damage to microscope components during heating experiments but also complicates sample heating and cooling and temperature measurement. Vacuum prevents both sample oxidation and equipment oxidation during experiments at high temperatures. The development of specific detectors has been necessary to carry out in situ studies under extreme conditions, such as high pressure and temperature [2]. The aim of these experiments was to verify the possibilities of observing phenomena characteristic of materials science using in situ SEM at elevated temperatures. In addition to the phenomena themselves, the aim was to verify the visualization of structure by thermal etching [3]. Pilot experiments were conducted, including melting of the AlMgSi1 alloy, dissolution of secondary phases and visualization of primary austenite grains of TRIP steel, dissolution of intermetallic phases and melting of the AlSi9Cu3(Fe) alloy, phase transformation of the Ti6Al4V alloy, precipitation of phases during artificial aging of CuBe2 and AlMgSi0.5 alloys, and thermal etching of ZrO_2 ceramic for grain visualization.
The samples underwent a complete conventional metallographic procedure, including cutting on the precision metallographic cutter, followed by mounting in resin, and successive grinding and polishing steps. Grinding was performed using SiC papers with grit sizes of 220, 500, 1200, 2000, and 4000, while polishing utilized diamond pastes with abrasive sizes of 3 µm, 1 µm, and 0.25 µm, concluding with chemical-mechanical polishing using the colloidal suspension with SiO_2 particles. Before heating, the samples were chemically or color etched to reveal the real structure. Some samples underwent imaging in the SEM using the LOM Zeiss Axio Observer 7 before heating for correlative imaging. In situ heating experiments took place in the SEM Thermofisher Scientific Quattro S, utilizing the Newtec Scientific FurnaSEM 1300 stage for heating up to 1200 °C. The sample was restrained to a 12 mm diameter by a platinum pad, ensuring uniform heating. To enhance thermal conductivity and dissipate charge, samples were affixed to the platinum pad using a carbon suspension. Subsequently, a thermal shield with a 4 mm diameter aperture was installed above the sample to mitigate thermal stress on the microscope chamber components. In addition to the ETD detector, samples were also imaged during heating using the BSE detector Crytur Karmen, equipped for in situ experiments at elevated temperatures. The scintillation crystal of the Karmen detector is coated with a thin layer of aluminum, 100 nm thick, designed to prevent penetration of external light signals into the photomultiplier, such as light emitted by the heated sample [4].
During the melting of the AlMgSi1 alloy, an Al_2O_3 pad was inserted between the sample and the platinum pad. Upon reaching a temperature of 700 °C, microdendrites were observed at the edges of

the sample, indicating localized melting. However, this temperature is approximately 150 °C higher than the theoretical melting temperature of the alloy. In the case of TRIP steel, reaching a heating temperature of 900 °C made the boundaries of primary austenite grains visible. With prolonged exposure at this temperature, secondary phases began to dissolve, gradually increasing the contrast of the grains. Further experiments were carried out using a carbon suspension, and it was verified with an optical pyrometer that the heating temperature and the sample surface temperature could differ by approximately 50 °C. For the AlSi9Cu3(Fe) alloy, at a heating temperature of 550 °C, the dissolution of $CuAl_2$ was observed. During exposure at a heating temperature of 900 °C for the Ti6Al4V alloy, it was possible to observe the transformation of the globular α phase with an HCP lattice to the β phase with a BCC lattice. While a transformation to the α phase was expected during cooling, there was no observed change in morphology. Artificial aging of the CuBe2 alloy occurred at a temperature of 315 °C (Fig. 1). Precipitation of the γ phase likely began before reaching the selected temperature. During exposure, the precipitated particles slightly increased in size. Apart from precipitation, the contrast at the boundaries of some grains began to increase, resulting in their expansion. In the case of artificial aging of the AlMgSi0.5 alloy at a heating temperature of 180 °C, no structural changes were observed. The feasibility of in situ thermal etching was confirmed on ZrO_2 ceramic. The sample was imaged at room temperature and then continuously during exposure to heat. During heating, unstable behavior was observed due to sample charging, the evaporation of water from the carbon suspension used to adhere it to the platinum pad, and thermal expansion. Upon reaching a heating temperature of 750 °C, the contrast of grains in both detectors began to increase slightly. There was no sample charging. Already at a heating temperature of 900 °C, the contrast of grains substantially increased, remaining largely unchanged throughout the exposure period for both detectors.

The in situ SEM experiments at elevated temperatures were successfully conducted, demonstrating the potential applications of this method in materials science. During the experiments, partial insights were gained, and practical procedures were developed, leading to greater validity of the results. The window for pyrometer measurements allowed for further refinement of surface temperature measurements. Direct temperature measurement on the sample may lead to further precision. The carbon suspension for high temperatures improved heat conduction and charge dissipation from the sample. Under specific conditions, samples can also be melted. Thanks to special metallographic preparation, it was possible to observe the real structure already at room temperature; however, further experiments are needed to verify the introduction of artifacts from the preparation process.

Poster Group 2

Background
Cryogenic ultrastructural imaging techniques such as cryo-electron tomography have produced a revolution in how the structures of biological systems are investigated. This has been done by enabling the determination of structures of protein complexes immersed in a complex biological matrix within vitrified cells and model organisms. However, so far successes have mostly been limited to highly abundant complexes or to structures that are relatively unambiguous and easy to identify through electron microscopy.

To realize the full potential of this revolution, we need to be able to pinpoint lower abundance species and obtain functional annotations on the state of objects of interest. This would then be correlated to ultrastructural information to build a complete picture of the structure-function relationships underpinning biological processes. Fluorescence imaging at cryogenic conditions has the potential to meet these demands. However, wide-field images acquired at low numeric aperture (NA) using an air immersion objective have a low resolving power and cannot provide accurate enough three-dimensional (3D) localization to enable the assignment of functional annotations to individual objects of interest or target sample debulking to ensure the preservation of the structures of interest. It is therefore necessary to develop super-resolved cryo-fluorescence workflows capable of fulfilling this role and enabling new biological discoveries.

Here, we will present the current state of our development of super-resolution solid immersion lens stochastic optical reconstruction microscopy (superSIL-STORM) [1]. The superSIL lens can go to larger magnifications than regular air objective lenses, with the advantage over traditional oil immersion lenses that they are cryo compatible. We will show the application of superSIL-STORM to various protein clusters in E. coli cells and discuss the advantages and limitations of the technique. We will then further discuss its future applicability to cryogenic correlative light and electron microscopy (cryo-CLEM) workflows.

Methods
Our SIL assemblies were made in-house using nanolenses (Hyper Hemispheric Ball lens, Cubic Zirconia, 1.0 mm diameter x 0.73 mm thickness, λ\4 flatness - Knight Optical, LBB2018-C), stainless steel foil (FE22-FL-000120) and cryo-compatible adhesive (Loctite Stycast, 2850 FT) [1,2].

We used 100 nm TetraSpeckTM microspheres as fiducial markers. For plunge-freezing of the samples we used an FEI Vitrobot Mark V, using manual blotting. SuperSIL assemblies were glow discharged before use. A 1% PEI solution was applied to the substrates before adding the cells and then the fiducial markers.

For fluorescence imaging an in-house built super-resolution cryo-STORM setup was used, as described in [1]. STORM analysis was conducted using standard STORM software: the preinstalled ImageJ plugin for ThunderSTORM, the source code from https://github.com/ZhuangLab/storm-analysis for DAOSTORM. For ThunderSTORM, an initial Lowered Gaussian filter was applied before a maximum likelihood Gaussian fit searched for the single molecule PSFs. For DAOSTORM the value for "model" was set to "2D". Drift correction of the sample was done through in-house constructed algorithms [1].

Results
To demonstrate the capabilities and limitations of the superSIL-STORM technique, we study two different protein clusters in E. coli cells.

We assess the ability of single-colour superSIL-STORM to analyse protein clustering in VNp-LZ-mNeonGreen expressing E. coli. VNp-LZ is a short recombinant peptide which is introduced in bacteria to favour the formation of internal vesicles and has been shown by EM to cluster around them. Our superSIL-STORM analysis reveals clustering of the protein around empty spaces within the cells, which are likely to correspond to the internal vesicles shown previously [3]. Through further data analysis, we estimate most of the protein clusters in 100 nm large patches, with an overall distribution of nearest neighbours ranging between 25 nm - 200 nm. Future studies combining these results with EM work for cryo-CLEM will help to reveal the nature of these clusters.

Next, we assess proteins in E. coli cells that are involved in the outer membrane protein (OMP) secretion pathway: the BAM complex. Various mechanisms for how the BAM complex translocates proteins across the outer membrane have been suggested before, but more information is needed for a complete understanding of how this is done. We look at clustering of the major BAM complex subunit BamA with either the periplasmic chaperone SurA or the client OmpA. Overall, we find strong co-clustering of BamA with OmpA, but not of BamA with SurA. The first indicates an agreement with previous findings that OMPs are turned over in patches, away from the original OMP insertion sites. The latter indicates that the co-location of BamA with the chaperone is transient in nature and may depend on a variety of factors, including the metabolic state of the imaged cell.

Conclusions
We have developed workflows for the use of superSIL-STORM. We present here the basic principles of this technique and we show its application to study membrane protein complexes in E. coli. Further work is taking place to integrate this technique in cryo-CLEM workflows.

Characterization of a multiphase nucleus of spheroidal graphite cast irons by transmission electron microscopy techniques

PhD Alessandro Pugliara[1,2], PhD Lydia Laffont[1], PhD Claudie Josse[2], PhD Teresa Hungria[2], PhD Jacques Lacaze[1]
[1]CIRIMAT, Toulouse INP, Université Toulouse 3 Paul Sabatier, CNRS, Université de Toulouse, 4 allée Emile Monso, 31030, Toulouse, France, [2]Centre de microcaractérisation CASTAING, Université Toulouse 3 Paul Sabatier, Toulouse INP, INSA Toulouse, CNRS, Université de Toulouse, Espace Clément Ader, 3 Rue Caroline Aigle, 31400, Toulouse, France

Poster Group 2

Background incl. aims
Spheroidal graphite cast irons are obtained by submitting a cast iron melt to a spheroidizing treatment with a Fe-Si-Mg alloy, followed by so-called post inoculation with a Fe-Si alloy. These additions contain other elements which are mainly strong deoxidizers and/or desulfurizers. It is well established that these two treatments interact to give the final particles acting as graphite nuclei [1]. Accordingly, many of the observations made on graphite nuclei reported the presence of oxides, sulfides and/or oxysulfides [1], though nitrides have been reported from times to times [2]. The fact that the nuclei appear multiphase in most of the reported examples complicates the analysis of the sequence of phase transformations leading to the nuclei. Microstructural, chemical and crystallographic characterization on a multiphase nucleus of a spheroidal graphite in a cast iron manufactured by thin-wall casting is the aim of this study. To describe many phases constituting it, scanning transmission electron microscopy (STEM) coupled with energy dispersive X-ray spectroscopy (EDS) and electron diffraction analyses are carried out. The nucleus contains two parts, one multi-phase rounded "head" encapsulated in an Al-Mg-Si nitride and an elongated "tail" consisting of the same nitride. The central part of the head seems to be related to the inoculant added to the cast iron melt. From this, the precipitation process leading to the final graphite nucleus is inferred.

Methods
A cast iron, i.e. mainly a Fe-C-Si alloy (final composition: 3.8 C, 1.9 Si, bal. Fe, wt.%) was spheroidized with a Fe-Si-Mg alloy. A commercial Fe-Si inoculant was added to the melt at the time of pouring in a thin-wall casting. Because of the high cooling rate, the material contained metastable carbides which were eliminated by a heat-treatment at 950 °C for 15 minutes.
A sample cut perpendicularly to the casting surface was prepared by standard metallographic methods. The microstructure consisted in graphite nodules within an iron-rich matrix. Focused ion beam (FIB)-lift out technique was used to prepare a thin foil of a selected nodule in a FEI NanoLab HELIOS 600i FIB/SEM. A transmission electron microscope JEOL cold-FEG JEM-ARM200F equipped with a probe Cs corrector and a SDD CENTURIO-X EDS detector was used for characterization. Selected area electron diffraction (SAED) and nano-beam diffraction (NBD) were employed to record diffraction patterns.

Results
Bright field (BF) STEM image of a thin diametric section of a graphite nodule prepared by FIB shows the presence of a nucleus in the middle of the nodule. This nucleus appears composed of two parts: a round head loosely connected to an elongated tail. High-angle annular dark-field (HAADF) STEM

images evidence a grey contrast of both parts, with bright areas in the head which are indicative of the presence of at least one element much heavier than carbon in the nucleus. Also, the head presents different grey contrasts indicating a multi-phase nature with a fan-like faceted precipitate. To determine the chemical nature associated with these various contrasts, STEM-EDS mapping was carried out. The elongated tail having an almost uniform grey contrast appears mostly composed of Al, Mg, Si and N, with however a few isolated small bright spots rich in iron. In contrast, the rounded head exhibited at least four different phases: 1) an inner facetted center rich in Fe; 2) a shell rich in S and Mg surrounding the center; 3) the fan-like precipitate mainly composed of Ti and developing outwards from this shell; and 4) a structure having the same composition as the elongated tail. Finally, SAED and NBD were performed on different parts of the nucleus after appropriate rotation of the sample for each of the phases. The Al-Mg-Si-N phase present in both the elongated tail and the outer area of the head has been indexed as trigonal nitride $A_2Mg_5Si_5N_{12}$ according to Solberg and Onsoien [3]. Concerning the other phases in the rounded head, the center could be indexed as bcc-Fe [4] and the fan-like precipitate as cubic carbo-nitride $Ti_2(C,N)$ [5]. Unfortunately, the shell rich in S and Mg could hardly be characterized.
Observing the spatial distribution of the phases and considering their chemical composition and crystallographic structures, we may suppose a formation sequence of the nucleus as follows: bcc-Fe is the center of nucleus on which a shell rich in S and Mg precipitates; then, the Ti carbo-nitride fan-like structure develops from this shell; and finally (Al,Mg,Si) nitride precipitates from all around this carbo-nitride and appears to be the actual substrate for graphite nucleation. It is conceivable that the tail developed together with the graphite nodule during the graphitizing heat-treatment.

Conclusion
Transmission and analytical electron microscopy allowed determining the multi-phase nature of a graphite nucleus in a spheroidal graphite cast irons. This nucleus was composed of two different parts:

- A rounded multi-phase head organized as follows: 1) an inner facetted center rich in bcc-Fe; 2) a shell rich in S and Mg surrounding this center; 3) then a fan-like fcc Ti carbo-nitride developing from this shell; and finally 4) an external trigonal nitride rich in Al, Mg and Si around the aggregate.
- An elongated tail having the same composition as the outer nitride in the head.

In the literature, it is generally considered that the inoculant fully dissolves in the cast iron melt to lead to precipitation of oxides, sulfides and nitrides. In contrast to previous studies, this study shows that the center of the rounded head which was indexed as bcc-Fe could be a remaining of the Fe-Si inoculant.

Poster Group 2

Background incl. aims.

Microbially-induced calcium carbonate precipitation (MICCP), a bio-geochemical process, is a promising technology for eco-friendly applications particularly in the restoration of ornamental limestones.
This study explores the efficacy of the biorestoration treatment using Lysinbacillus fusiformis 3.20 strain as a carrier for the MICCP on three different lithotypes: calcarenite (MC), travertine (TR), and marble (MA). Despite sharing similar mineral compositions, these lithologies originate from different depositional settings, resulting in different petrophysical properties and microstructural features. To understand the biomineralization of the three different lithotypes the surface alterations and nanostructural changes were characterized by SEM (Scanning Electron Microscopy) and AFM (Atomic Force Microscopy).

Methods.

Small bricks of the three lithologies were treated spraying the bacterium culture twice a day for seven days at 28°C. Nanocaracterization of the surfaces of the three lithotypes was performed pre- and post-treatment using the Zeiss Auriga (SEM) operating at 1.5 keV and Bruker's Dimension Icon (AFM) using RTESPA-300 probes in tapping mode.

Results.

SEM micrographs revealed significant differences between the untreated and treated samples, particularly on the surfaces of the MC and TR stones. The treated samples showed the presence of calcified bacterial cells and newly formed crystals. In the MC samples, the crystals presented rhombohedral shapes, while the TR samples showed less homogenous aggregates. However, the treatment showed no significant effect on the MA samples, as no visible crystals or bacterial cells were observed after treatment. AFM analysis confirmed these results, showing the presence of bacteria and new crystals on the MC and TR samples post-treatment, with the bacterium being able to deposit calcium carbonate on the pore edges and covering the surfaces.

Conclusion.

The results obtained in controlled laboratory conditions emphasize that for the same treatment, the morphological variations of the bioprecipitation changes are strongly dependent on the lithology. Thus, for a future in situ application of this technique for stone conservation and restoration, the treatment will be optimized depending taking into account the differences of the lithologies.

Numerical study on high orbital angular momentum vortex electron beams in hafnium dioxide

Christian Bick[1], Dr. Dorothee Hüser[1]
[1]Physikalisch-Technische Bundesanstalt (PTB), Braunschweig, Germany

Poster Group 2

Background incl. aims
Electron vortex beams (EVB) are electron beams that have a quantized orbital angular momentum (OAM) along their propagation axis. These beams have found applications in electron magnetic circular dichroism (EMCD) and beam focusing, and have attracted new attention with the development of programmable phase plates [1, 2]. In this study we aim to improve our understanding of the behavior of vortex beams and their OAM in complex electronic materials.
Methods
We present a numerical study of vortex electron beams modeled as Bessel beams [3, 4]. The commonly used multislice algorithm is utilized to propagate the beam through crystalline material.
Results
We compare our results with previous work [3, 4] for OAM with quantum number l=1 and make predictions for higher angular momentum beams in new materials. The results indicate a reduction in the expectation value of the OAM with propagation depth inside the crystal potential, which depends on the initial value of l. We present simulation results for HfO_2 systematically investigating different beam shaping parameters. Furthermore, we investigate the numerical limits of our method.
Conclusion
Our method is capable of reproducing previously published work for low OAM. It shows physically conclusive results for higher angular momentum vortex beams.

Free electron spectroscopy seen through the prism of quantum optics

Tom Fraysse[1], Hugo Lourenço-Martins[1]
[1]CEMES-CNRS, Toulouse, France

Poster Group 2

Background incl. aims
Photon Induced Near-field Electron Microscopy (PINEM) denotes the modulations of free electrons by a sample – typically an optical cavity – pumped by a laser source. This effect has been theoretically predicted and experimentally demonstrated in an ultrafast transmission electron microscope (UTEM) more than a decade ago [1]. Following these seminal developments, PINEM has been used to reconstruct the temporal dynamics of nano-optical systems with an attosecond temporal resolution [2].
Due to recent experimental developments in integrated photonics [3], the problem of PINEM in the low occupation regime – i.e. when the cavity is populated by a weak number of photons - has drawn an increasing theoretical interest. Indeed, in this situation, the classical description of the electromagnetic field falls short to describe the electron-cavity interaction, and a full quantum description becomes required. Several works have already pioneered this problem [4,5] and predicted strong quantum mechanical effects in PINEM. The goal of our work is to pursue this effort and provide an alternative and intuitive approach to this problem by using tools borrowed from the field of quantum optics.
Methods
The goal of our study is thus to determine the electron-cavity state before and after inelastic interaction. To do so, following a standard quantum optics description, we describe the cavity state as a quantum superposition of number (or Fock) states. We then apply perturbation theory to calculate the electron Wigner function after interaction with the cavity state. The latter is the central object of our theory and represents - roughly speaking - a probability distribution of the electron in the phase space (energy-time). It constitutes a powerful visualization tool enabling us to understand the mechanisms of electron-light interaction at the quantum scale, as shown on figure 1.
Results
In this contribution, we will introduce our approach and demonstrate its efficiency on several problems.
In a first part, we will illustrate the influence of the cavity quantum optical state on the energy and temporal structure of the electron beam during the PINEM interaction. For example, after interaction with a number state – i.e. when the initial number of photons is perfectly known – we will show that the electron-cavity coupled state becomes a coherent superposition of entangled (electron-photon) energy-number states. On the other hand, if the electron interacts with a coherent state – i.e. a Poissonian superposition of number states – one would only obtain correlations between the electron energy states and the photon number states.
In a second part, we will show that a PINEM measurement in the quantum regime is deeply connected to the standard quantum limit to the temporal resolution in a UTEM. Indeed, the Heinsberg uncertainty principle governs the inelastic interaction between the electron and the cavity, making impossible to exactly know the number of photons and the temporal dynamics of the field in the cavity at the same time. We will show that this uncertainty relation has a dramatic influence on the quantum path interferences otherwise observed in the classical regime of PINEM. In that regard,

the Wigner function appears to be an ideal tool to visualize the effect of the uncertainty principle in phase-space.
In a third part, we will tackle the question of the quantum to classical transition in free electron scattering and show that the Wigner function elegantly highlight the transition between the stimulated and spontaneous scattering regimes in electron energy-loss spectroscopy (EELS).
Finally, in a fourth part, we will introduce to PINEM a central basis of quantum optics: the displaced number state (DNS). This basis will allow us to shade a new light on the interaction between electron and a coherent state of light. In particular, or calculation demonstrate that in this configuration, the final electron-cavity state is a coherent superposition of DNS entangled with similar electron states than the one predicted by the classical model. This creates a bridge between the classical and the quantum description of PINEM.
Conclusion
In this work, we present a complete phases-space description of inelastic fast electron-light interaction, in which the central object – the Wigner function – provides a powerful visualization tool. Using this approach, we tackle important problems in the field of EELS and PINEM, such as the quantum to classical transition, or the distinction between stimulated and spontaneous processes. In that respect, our work demonstrates the central role played by the number-phase uncertainty relation. Beyond these fundamental questions, our approach will find application in the description of future experiments in the field of EELS and PINEM, such as the probing of non-linearity in EELS or the realization of atom-cavity coupling in a TEM.

Poster Group 1

Background incl. aims
C/SiC composites are non-oxide Ceramic Matrix Composites (CMCs) highly sought-after for high-temperature applications in the aerospace industry. These composites consist of a silicon carbide matrix and carbon fibers, which contribute to their excellent mechanical performances.
Although there is common awareness of the influence of raw materials selection - as well as of manufacturing and processing methods - on the thermo-mechanical properties of C/SiC composites, the impact of manufacturing parameters on microstructures is not widely documented in the literature. This is particularly true for C/SiCs produced by means of Liquid Silicon Infiltration (LSI).
Additionally, for many aerospace applications, exposure to oxidative environments is often involved, which can cause material recession due to the rapid oxidation of carbon. Such oxidation can determine a change in the microstructure and a consequent degradation of the mechanical properties. An in-depth knowledge of the microstructure of such composites can help foresee their evolution in oxidative environments and therefore their potential failure in use.
This study focuses on IsiComp® and OxyComp®, two C/SiC composites produced through LSI. Due to the selection of processing parameters, the two composites show different microstructures. IsiComp® has a laminate structure, in which fiber bundles are wrapped by the SiC matrix. In OxyComp® the SiC matrix penetrates within the fiber bundles and the ceramic matrix is highly cross-linked, almost resembling the microstructure of a pure ceramic. Despite its peculiar microstructure, OxyComp® has good mechanical properties and shows a pseudo-ductile behavior under stress, which is unusual, considering that ceramics retain a brittle behavior under mechanical stress.
In this frame, this research aims to quantify microstructural changes due to varied manufacturing parameters and their impact on microstructures, and therefore, on the thermo-mechanical properties of the composites. Another aim is to delineate the property and microstructure evolution during oxidation in aerospace-like environments - including vapor-rich combustion-type atmospheres. Understanding these relationships is crucial to predicting the behavior of C/SiCs under operating conditions and selecting the most suitable material for certain applications.
Methods
Samples are produced using vacuum bagging techniques, then pyrolyzed and converted into a CMC via LSI. Physical, thermal, and mechanical properties (bending) were tested before and after exposure to oxidative environments according to standard procedures.
Oxidation experiments were conducted in a vertical furnace equipped with a water vapor-gas mixing system and a Quadrupole Mass Spectrometer (QMS) for the in-situ analysis. The structural evolution is quantitatively described using 2D electron microscopy images and 3D images from X-ray tomography. Image analysis is conducted using quasi-automated tools provided by Fiji and Wolfram Mathematica.
Results

As for IsiComp®, the molding pressure strongly affects the size of residual pores in the pyrolyzed preform and the thickness of the ceramic channels in the CMC. The higher the molding pressure, the higher is number of thin (typically less than 30 µm) vertical fractures in the pyrolyzed preform, and no large pores are observed. This enhances silicon infiltration, leading to a homogeneous LSI microstructure. Circular isolated pores resulting from gas generated during the resin polymerization can be eliminated by adjusting the curing cycle parameters.
Surprisingly enough, despite processing parameters having a strong impact on the texture of the pyrolyzed preform, no major effect can be detected in terms of thermal and mechanical properties of the CMC after LSI.
Under oxidative conditions, ISiComp® performs similarly to 2D-C/SiCs described in the literature.
As for OxyComp®, the fiber-to-matrix ratio within pyrolyzed preforms can be tuned by changing certain processing parameters, which eventually affect the pervasiveness of silicon penetration during LSI. The size distribution of SiSiC channels in the CMC reflects the intensity of silicon penetration within fiber bundles. The higher the fraction of thin channels (<7.5 µm-thick), the greater the residual deformation under a fixed mechanical stress. Thermal properties are less affected by the extent of silicon penetration within fiber bundles, as they are more influenced by the continuity of ceramic matrix in a specific direction.
Thanks to its microstructure OxyComp® performs very well under oxidative conditions.
For both composites, it was observed that prolonged exposure at relatively low temperatures causes intra-bundle fiber oxidation, which undermines both material integrity and mechanical properties more strongly than short-term exposure at higher temperatures does.
Conclusion
This study investigates the relationship among manufacturing/processing parameters, microstructures, and thermo-mechanical properties of IsiComp and OxyComp, two C/SiC composites developed by Petroceramics S.p.A.
The manufacturing pressure significantly influences the microstructure of ISiComp®, but no major effects were observed in terms of mechanical and thermal properties measured. It can be supposed that the observed differences in the pyrolyzed preform are attenuated in the CMC, which indicates the final material is highly reproducible despite any difference in the processing parameters.
Conversely, variations of the microstructure of OxyComp® strongly affect its mechanical behavior (bending) but have a weaker impact on the thermal conductivity. The effect of differences in the texture of OxyCOmp® on the oxidation resistance is still under investigation.
The microstructural description derived from 2D-SEM images is consistent with the one obtained from 3D X-ray tomography images.
The pervasive presence of SiC matrix within the fiber bundle makes OxyComp® better oxidation-resistant than ISiComp®, both in air and in a H2O-vapor-saturated atmosphere.
OxyComp shows superior oxidation resistance compared to IsiComp, mostly due to thin intra-bundle channels which slow down the oxidation progression. For both composites, it was observed that prolonged oxidation at relatively low temperatures has a major impact on the mechanical properties of the composite in use.

Poster Group 2

Background incl. aims
Metal-oxide semiconductor (MOX) layers are frequently used as gas sensors since they can detect different types of gases, such as CO, CO2, CH4, NO2, etc. and also due to their increased sensitivity, quick response times and reduced fabrication costs. The main challenge for this type of materials is to improve their selectivity [1].
Morphology and structure play an important role during the interaction between the target gas and the sensing layer since porosity, grain size, grain faceting, crystal phase and elemental composition can influence the sensor signal. All these properties depend on the synthesis route.
Our study is focused on the synthesis and determination of the structure, morphology and electrical properties of different MOX systems, such as NiO (p-type semiconductor), SnO2 and Gd2O3 (n-type semiconductors).
Methods
NiO was synthesized by hydrothermal route followed by calcination at 400 °C and 500 °C [2,3], while SnO2 (doped with different concentrations of Gd: 5%, 10% and 20%) and pure Gd2O3 were synthesized by co-precipitation [4].
The morphology and the structure of these samples were investigated using analytical TEM techniques: CTEM, SAED, HRTEM and STEM-EDS. These results were correlated with X-ray Diffraction (XRD), Electron Paramagnetic Resonance Spectroscopy (EPR) and X-ray Photoelectron Spectroscopy (XPS) data as well as with the electrical response of the fully characterized materials to CO and CO2 target gases.
Results
p-type semiconductors (NiO)
Increasing the calcination temperature induced visible morphological changes, as suggested by XRD patterns and observed by TEM imaging. One notable difference consists in the fact that the calcination temperature increased the nanoparticle size from ~9 nm to ~20 nm, with the formation of intragrain structural defects (e.g. twin boundaries), as revealed by HRTEM imaging (see graphic, [2]).
The electric response was tested in the CO atmosphere. Considering the observed morphological differences, a decrease in the sensor response was expected, but the opposite effect was observed [2].
To understand this phenomenon, an in-depth analysis was performed, using spectroscopic techniques: STEM-EDS, EPR and XPS. The EPR investigations revealed the formation of metallic Ni clusters in the sample calcined at 500 °C and the analytical TEM techniques (SAED, CTEM and STEM-EDS) confirmed their presence. The formation of these metallic clusters, corroborated with the morpho-structural properties, could explain the different sensing properties of the samples calcined at different temperatures [3].
n-type semiconductors (SnO2 doped with Gd, Gd2O3)

The increase in the dopant concentration had a notable effect on the morphology and the structure of the samples. The TEM analyses correlated with the Rietveld refinement of XRD patterns revealed the formation of SnO2-Gd2O3 nanocomposites. The presence of the two crystallographic phases was analyzed using different analytical TEM techniques: CTEM, SAED and STEM-EDS, which confirmed the formation of the cubic Gd2O3 secondary phase. The electric response was tested in the CO2 atmosphere, at different values of relative humidity, to determine the sensing mechanism of the SnO2-Gd2O3 nanocomposites [4].

Conclusions

Analytical TEM techniques correlated with XRD, EPR, XPS and electrical measurements offered valuable information for understanding the sensing mechanism of metal-oxide semiconductor materials in the presence of different gases, i.e. NiO in the presence of CO and SnO2/Gd2O3 exposed to CO2.

Three-dimensional ultrastructure of ovine pinealocytes

Prof. Bogdan Lewczuk[1], Dr Natalia Szyrynska[1]
[1]Department of Histology and Embryology, Faculty of Veterinary Medicine, University of Warmia and Mazury in Olsztyn, , Poland

Poster Group 2

The pineal gland via secretion of melatonin plays an important role in the regulation of processes that occur in the daily and seasonal rhythms. Significant differences between species have been described in ultrastructure of the pineal gland in mammals. Mammalian pinealocytes differ mainly in the structure of endoplasmic reticulum and mitochondria as well as in the presence of clear and granular vesicles, lipid droplets, vacuoles, dense bodies and synaptic ribbons. In addition, depending on the species, both capillary vessels with a continuous wall and those with pores were found. The organization of the pineal parenchyma is very complex due to the presence of numerous cell processes. Based on classical two-dimensional transmission electron microscopy, mammalian pinealocytes have been described as cells with the main process running towards the capillary vessels and forming the bulbous ending close to or inside the perivascular space, and with some small, short processes. The improvement of backscattered electron imaging and the development of volume electron microscopy open the way for a more reliable and precise characterization of the pineal gland structure.
The pineal glands of domestic sheep aged 9 months were prepared according to the modified protocol of Deerinck et al. (1). For high-resolution imaging of the large sample areas, ultrathin sections were cut with the PT3D PowerTome ultramicrotome with ASH2 (Boeckeler Instruments, USA) and placed on silicon wafers. Some sections were additionally contrasted with uranyl acetate and lead citrate. The sections were imaged using the SenseBSD backscatter electron detector in SEM Gemini 450 at 1.4 kV, controlled by Atlas 5 software (Carl Zeiss, Germany). Serial block face imaging was performed with the 3View 2XP and the OnPoint detector (Gatan, USA) operating in SEM Gemini 450 with the focal charge compensation system (Carl Zeiss, Germany). Stacks of 1000 - 2000 images (15,000 x 15,000 pixels, pixel size 5 nm, section thickness 50 nm) were segmented manually and automatically using Microscopy Image Browser software. The models were visualized with Amira 3D (Thermo Fisher Scientific, USA).
The imaging of ultrathin sections on silicon wafers allowed ultrastructural visualization of large sample areas (1 x 2 mm) with a resolution 5 nm/pixel. The pineal gland capsule and the connective tissue trabeculae running from the capsule into the gland were completely separated from the parenchyma by the basement membrane. They contained blood vessels and nerve fibers. The parenchyma comprised pinealocytes and glial cells, mainly astrocytes. The cell bodies of pinealocytes formed small groups. Similar groups formed cell bodies of astrocytes. The large areas of parenchyma between the cell bodies were filled with the cellular processes, which in most cases contained intermediate filaments. Processes of pinealocytes, which distinguished by the presence of microtubules, were much less frequently found in these areas. There were also round or oval structures ranging in size from 0.2 to 5 µm filled with fine granular material of low electron density, the origin and character of which cannot be recognized on 2D images. The capillary vessels running through the parenchyma were surrounded by a thick layer of collagen fibers separated from the rest of the parenchyma by the continuous basement membrane. From the outside, this membrane was covered by ending of astrocytes.

The three-dimensional reconstruction of the pineal parenchyma revealed that pinealocytes of the sheep consisted of an irregularly shaped cell body and two types of processes: “large” processes and “small” processes. The surface of the cell body formed conspicuous invaginations to adapt to the numerous processes of other cells running in its vicinity. The shape of the cell body and the localization of the nucleus within it differed greatly between pinealocytes. The cell body comprised the Golgi apparatus, which consisted of 3 – 6 dictyosomes, a very dense network of tubules and cisternae of endoplasmic reticulum, numerous elongated mitochondria and a few lipid droplets. The number of “large” processes growing out of the cell body varied between 3 and 5. These processes often divided dichotomously into secondary processes, which form further branches. The “large” processes consisted of alternating wider and narrower parts. The wider parts, with a size of 1 – 3 µm, comprised large mitochondria, tubules of endoplasmic reticulum, vesicles and microtubules. Narrower parts, with a size of 0.2 - 1 µm, contained only a few tubules of endoplasmic reticulum and microtubules. The “small” processes grew out of the cell body in a number of 3 - 10. They form branches and contain tubules of endoplasmic reticulum, vesicles, microtubules and sometimes small mitochondria. The pinealocyte processes did not form bulbous endings.
The results obtained indicate that the descriptions of ovine pinealocytes based on transmission electron microscopy (2) should be revised. These cells have a few “large” processes of similar size that form branches, instead of the main process. The processes of ovine pinealocytes did form neither bulbous endings nor any ending close to perivascular spaces. It appears that the wider parts of pinealocyte processes play an important role in melatonin synthesis and secretion, increasing the area in which a pinealocyte realises the hormone. Our morphological observations are consistent with previous physiological data showing that melatonin concentration in cerebrospinal fluid is about 20-fold higher than in blood and that it is higher in the pineal recess than in the ventral part of the third ventricle (3). The differences in melatonin concentrations suggest that pineal hormone is released from the ovine pineal gland to the third ventricle in greater quantities than to the blood. Taken together, the morphological and biochemical data seem to indicate that the ovine pinealocytes realize melatonin into the extracellular space around the cell body and the cell processes, from where this lipophilic hormone enters the third ventricle and the intrapineal blood vessels, which are separated from the parenchyma by the blood-brain barrier. Comparison of the results of 3D studies on rat (4) and ovine pinealocytes shows that the differences between the species may be even more pronounced and important than previously thought based on 2D data.

Mass microscopy allows for high throughput, high spatial resolution mass spectrometry imaging

Aljoscha Körber[1], Dr. Bryn Flinders[1], Frans Giskes[1], Prof. Ron M.A. Heeren[1], Dr. Ian G.M. Anthony[1]

Poster Group 1

Background:

Mass spectrometry imaging (MSI) is an untargeted technique that maps the spatial localizations of 100s to 1,000s of molecules on complex surfaces.[1] MSI has shown great potential in tissue diagnostics for personalized medicine,[2] yet suffers from low throughput. For instance, state-of-the-art commercial matrix-assisted laser desorption/ionization (MALDI) MSI instruments measure up to 50 pixels/s.[3] Thus, acquiring images consisting of millions to billions of pixels can require days of measuring time, which would be impractical for clinical diagnostics. The low throughput of MSI is due to the way images are acquired, namely in microprobe-mode, in which a focused ionizing beam scans a surface and acquires pixels sequentially. This approach is especially time-consuming at high spatial resolution, as every linear decrease in pixel size is accompanied by a quadratic increase in the amount of pixels to be scanned. An alternative approach that bypasses this nonlinear relationship is mass microscopy. Here, a larger area is ionized simultaneously, the resulting ion image is pushed into the gas phase, analyzed by time-of-flight (TOF) mass spectrometry, and magnified onto a pixel-based spatially sensitive detector. Each pixel of this detector records its own mass spectrum allowing for the parallel acquisition of tens of thousands of mass spectra. Yet in the past, mass microscopy has not been a practical approach due to the lack of spatially-sensitive detectors with sufficiently short time resolution.
Here, we show that combining mass microscopy with a Timepix3 based detector with 1.56 ns time resolution turns mass microscopy into a viable approach that simultaneously allows for high throughput and high lateral resolution. As a first proof-of-concept, we published secondary ion mass spectrometry (SIMS) images at acquisition speeds up to 600,000 pixels /s with 2.5 µm lateral resolving power.[4] At this speed, we could record a gigapixel image within 34 minutes. Still, SIMS is an ionization technique primarily suited for elements and small molecules. Thus, we developed a laser setup that allows performing MALDI fast mass microscopy. We show early proof-of-concept images of TEM grids and tissues acquired at up to 5,230 pixels/s. Furthermore, we optimized our detector with a novel scintillator screen that enhances sensitivity and mass resolution.

Methods:

A TRIFT II mass spectrometer (Physical Electronics, Chanhassen, USA) equipped with a C60 ion gun (Ionoptika, Chandler's Ford, UK) was modified by adding a TPX3CAM (Amsterdam Scientific Instruments, Amsterdam, The Netherlands), an optical setup with a homogenized laser beam (Explorer One, Spectra-Physics, Stahnsdorf, Germany), and a Cry 60 scintillator (Crytur, Turnov, Czech Republic). First tests were conducted on TEM grids (Agar Scientific, Stansted, UK) placed on top of dried sodium acetate, crystal violet, and sprayed 2,5-Dihydroxybenzoic acid (DHB) films containing cetrimonium chloride. Later, a mouse brain section was measured using DHB matrix. All samples were coated with gold to improve surface conductivity. Data processing was performed with custom software.

Results:

We performed MALDI mass microscopy on TEM grids at intentionally slow speeds of 2,000 pixels/s with a spatial resolving power of at least 4 µm. This resolving power is comparable with state-of-the-art instruments that operate at or below acquisition speeds of 50 pixels/s and independent of matrix crystal size. Encouraged by these results, we imaged a mouse brain at 5,230 pixels/s, detecting lipids up to 1,000 Da. Yet, this image suffers from poor sensitivity in the higher mass range and from artefacts, which we attribute to surface charge effects. Thus, we explore charge-compensation methods, including gold coating on the surface and adding conductive additives to the matrix. Meanwhile, the implementation of the novel scintillator screen enhanced detector sensitivity tenfold, and in combination with optimized data processing improved our time resolution from 290 to <45 ns.

Conclusions:

The advent of the Timepix3 turns mass microscopy into a viable approach for high throughput, high spatial resolution SIMS MSI. The novel laser setup extends the applicability of mass microscopy to MALDI MSI and will in future allow for fast mapping of lipids, peptides, and even proteins. Meanwhile, the novel scintillator screen enhances detector sensitivity and allows for improvements in mass resolution. In the future, we strive for even higher mass resolution and throughput. For MALDI mass microscopy, it will be essential to develop better methods that prevent surface charging.

Poster Group 2

Background incl. aims

In nanomaterials research, the analysis of heterogeneous ensembles of nanocrystals presents a significant challenge, often requiring the extraction of information from diverse classes of particles or phases, in a process that is often prone to operator bias and poor statistics. Lead Halide Perovskite (LHP) nanocrystals (NCs) are a promising class of materials for optoelectronic applications that feature a broad compositional flexibility and are often the subject of extensive studies that cover a broad parameter space for the synthesis or modification of the basic structures. Here we focus on CsPbCl3 NCs where the halide is replaced through exposure to increasing amounts of iodine and using STEM-EDX to track ex situ the change in halide [1]. Our primary objective is to extract compositional information at the single-particle scale while minimising the electron dose onto the sample, a critical consideration to preserve sample integrity and minimise carbon contamination. The analysis of nanocrystals poses unique challenges due to their heterogeneous nature and varying chemical compositions. To address this gap, our research seeks to leverage the capabilities of TEM hyperspectral imaging coupled with machine learning algorithms. The primary objective is twofold: first, to develop a robust framework capable of extracting detailed compositional information from individual nanocrystals within a large ensemble, and second, to enable high-throughput analysis.

Methods
The proposed methodology entails the integration of a machine learning-assisted algorithm (Segment every grain – SEG [2]) within HyperSpy [3] , a versatile environment designed for the analysis of hyperspectral datasets. SEG can reliably identify features in STEM micrographs, and the algorithm is designed to process datasets with a low signal-to-noise ratio (SNR), mitigating the risk of sample damage or alteration.
The algorithm is designed around modular Python scripts to construct adaptable analysis pipelines. These scripts facilitate seamless integration with existing workflows, allowing researchers to tailor the analysis to specific datasets or scientific inquiries. The modular nature of the scripts enhances flexibility and scalability for samples that produce a very low signal due to their limited thickness or beam sensitivity.

Results
Preliminary results demonstrate the efficacy of the proposed approach in extracting detailed compositional information from a population of nanocrystals in sets of STEM hyperspectral datasets. A halide replacement effect through a jump-the-gap mechanism is observable as the nanocrystal population generally splits into the two populations, with some outlier values that can be studied in detail in further work. A study of the lateral size distribution is carried out across all the nanocrystals

of different chemical compositions of multiple samples, tracking the morphology through chemical conversion. Furthermore, a frame-by-frame analysis is employed to study the effect of the electron dose damage on the chemical composition of the nanocrystals, finding similar behaviour for different halide species.

Conclusion
The integration of machine learning with STEM hyperspectral datasets represents a significant advancement in nanocrystal analysis. By combining state-of-the-art algorithms with open-source platforms and modular scripting, researchers can unlock new insights into the complex world of nanomaterials through high-throughput data processing algorithms. This flexible algorithm can be customised and developed towards automated in-line analysis in the future.

Simulating iDPC tomography of CeO2 nanoparticles with experimentally realistic parameters and conditions

Miss Ella Kitching[1], Dr Thomas Slater[1]
[1]Cardiff Catalysis Institute, School of Chemistry, Cardiff University, Cardiff, United Kingdom

Poster Group 1

Background incl. aims
Electron Tomography (ET) is a 3D analysis technique that produces a 3D reconstruction from a tilt series of microscopy images at 1-5° increments. Electron tomography can be used to characterise the 3D structure of nanoparticles at atomic resolution from an input of 40-150 images, depending on the specific reconstruction algorithm and parameters. Atomic electron tomography has been possible with HAADF-STEM for over a decade (Scott et al., 2012) . However, a limitation of the technique is that prolonged exposure to the electron beam can cause damage or changes to samples, prohibiting an accurate reconstruction.
Integrated Differential Phase Contrast (iDPC) imaging is a technique which has contrast proportional to atomic electrostatic potential captured using a segmented detector. iDPC provides a better signal-to-noise ratio than HAADF at similar electron doses due to use of the bright-field disk and allows for atomic-resolution imaging with lower electron doses. iDPC additionally enables simultaneous imaging of light and heavy atoms, due to its image contrast being proportional to Z rather than Z^2 as in HAADF (Lazić et al., 2016).
Atom and defect positions at the surface of nanoparticles are crucial to catalytic performance. Accurate characterisation of 3D structure can therefore explain trends in catalytic activity/selectivity and assist in the rational design of catalysts. iDPC provides an excellent technique to image light atoms and their vacancies, even alongside atoms of higher atomic number. This is particularly valuable in the imaging of metal oxides, where surface termination and surface defect density can greatly impact catalytic properties.
We aim to demonstrate that an iDPC atomic resolution ET reconstruction is able to provide the locations of oxygen atoms, in addition to metal atoms within a nanoparticle. To investigate this, we simulate tilt series of iDPC and HAADF images, and generate tomographic reconstructions of a CeO_2 nanoparticle. CeO_2 was chosen due to its prevalence in catalysis and its requirement of a flux lower than $7x10^5$ $e^-nm^{-2}s^{-1}$ to avoid beam damage (Johnston-Peck et al., 2016).
With these reconstructions, we assess the ability of iDPC tomography to distinguish between oxygen-terminated and cerium-terminated surfaces, and to detect surface oxygen vacancies. Additionally, we demonstrate that iDPC will produce accurate tomographic reconstructions when applied at lower doses, resulting in reduced beam damage, compared to HAADF tomography.
Method
Atomic models of octahedral ceria nanoparticles of lengths of 3 nm and 7 nm are built using the Python package Atomic Simulation Environment (ASE), using an additional Python package (Wulffpack) to adjust particle truncation based on surface energies.
iDPC-STEM and HAADF-STEM images of these models are simulated using the PRISM algorithm within the Python package abTEM (Madsen & Susi, 2020). We define set values of semiangle cutoff (17.5 mrad for iDPC, 30 mrad for HAADF), accelerating voltage (200 kV), PRISM interpolation factor (4) and collection angle (13-56 mrad for iDPC, 56-200 mrad for HAADF). A total of 151 images are simulated with tilt angles ranging from ±75°. The effects of finite electron dose (via Poisson noise) and partial spatial coherence (via Gaussian noise) are added in post-processing.

3D reconstruction is performed using the ASTRA toolbox, applying the ASTRA-SIRT algorithm. TVM and GENFIRE reconstruction algorithms are also compared when using reduced numbers of projections. Reconstructions are formed with 1, 3 or 5° increments between each image. Determination of atom intensities in the resulting reconstructions are performed through ImageJ.

Results

Oxygen atoms were clearly distinguishable in the tomographic reconstructions of the iDPC images (without the addition of noise). The SIRT iDPC reconstruction had a Ce:O intensity ratio of 170:60 compared to 135:5 for HAADF. The iDPC reconstruction additionally displayed a 177.6% intensity increase when comparing the locations of surface oxygens to vacancies, enabling clear differentiation between oxygen atoms and vacancies. This visible difference is demonstrated in the attached reconstruction slice graphic.

Partial spatial coherence (source size 0.2 – 0.4 eV), and finite electron doses (50 – 50000 e^{-} /Å²) were applied to successfully demonstrate the impact of these conditions on the quality of tomographic reconstructions. This has been quantified by measuring atom intensities in the reconstruction and assessed qualitatively by comparing the ability to visually distinguish individual oxygen atoms and vacancies without further processing. We plan to additionally assess aberrations (such as defocus).

The SIRT iDPC reconstruction with a dose per image of 5000 e^{-} /Å² and a source size of 0.3 eV had a 256.50% intensity increase of the locations of surface oxygens compared to vacancies, showing vacancy detection is still feasible under low-dose experimental conditions. This reconstruction also displayed a Ce:O intensity ratio of 104:44, compared to 23:5 for a HAADF reconstruction under the same conditions. This HAADF reconstruction contained no visible oxygens, as expected.

These simulations confirm the resolution limits of different acquisition conditions for iDPC tomography, enabling experimental application of optimum conditions, and a known error margin to operate within.

Conclusions

Simulating iDPC and HAADF-STEM tomography has successfully confirmed parameters and requirements for atomic resolution iDPC tomography, enabling future experimental applications. By confirming the lower dose requirement for iDPC tomography, we have demonstrated the ability to create tomographic reconstructions of beam-sensitive samples which could not be captured with HAADF tomography.

We have additionally confirmed the ability of iDPC-STEM tomography to distinguish between vacancies and oxygen and cerium atoms within a 3D reconstruction of a CeO_2 nanoparticle. This demonstrates the potential of iDPC-STEM tomography as a technique for analysis of the surface termination of metal oxides, detection of oxygen vacancies and support-nanoparticle interface analysis.

Poster Group 2

Background and aim: Reduced oxygen availability is prevalent in several conditions affecting the brain including Alzheimer's disease [1, 2]. The mitochondria are main consumers of oxygen for ATP production, and the mitochondrial network adapts to changes in substrate availability and metabolic needs of the cell with dynamic shape transitions. Fusion of mitochondria enables transfer/sharing of organelle components, thereby improving energy conversion efficiency, and fission makes removal of damaged mitochondria possible. The cristae of the inner mitochondrial membrane, where oxidative phosphorylation takes place, are also remodelled in adaptation to energy substrate availability. The close relation between mitochondria morphology and function makes analyses of this organelle valuable in the search of an improved understanding of the subcellular effects of decreased tissue oxygenation in vivo. This is central in the elucidation of Alzheimer's disease pathogenesis and identification of novel therapeutic targets. We aim to investigate the effect of insufficient oxygen availability on the structure and function of mitochondria in a mouse model of Alzheimer's disease.
Methods: At the microscale, brains undergo MR scanning to examine the correlation between non-invasive detection of structural modelling and subsequent histological observations. Capillaries from the hippocampal strata oriens, -radiatum, and -lacunosum moleculare in CA1 are analysed using stereology to assess vascular changes. Based on these findings, a specific stratum is chosen for nanoscale analysis of mitochondria using vEM. The total volume and volume distribution of mitochondria are acquired, and crista related parameters evaluated in 3D applying our newly developed method [3]. Mitochondrial respiration is assessed with Seahorse assays on tissue punches and isolated mitochondria obtained from the hippocampus.
Results and Conclusion: Analyses are ongoing and hopefully results can be presented at EMC2024.

Cryo-EM Reveals RECQ5's Regulatory Role in RNAPII-Mediated Transcription

Karel Skubnik[1], Marek Sebesta[1], Jana Moravcova[1], Jiri Novacek[1], Richard Stefl[1,2]
[1]CEITEC–Central European Institute of Technology, Masaryk University, Brno, Czech Republic ,
[2]National Centre for Biomolecular Research, Masaryk University, Brno, Czech Republic

Poster Group 1

Background

In eukaryotic nuclei, the synthesis of mRNA is carried out by RNA polymerase II (RNAPII), a crucial enzyme in transcriptional processes. RECQ5 helicase, a general elongation factor, associates with RNAPII and controls its movement along genes. Despite its significance, the precise mechanism through which RECQ5 regulates RNAPII movement remained unknown.

Methods

We employed a combination of cryo-electron microscopy methods to investigate the interaction between RNAPII and RECQ5. These methods included single-particle analysis (SPA), correlative light-electron microscopy (CLEM), and subtomogram averaging (STA).

Results

Here, we present the details of the interaction between RECQ5 and RNAPII determined by cryo-electron microscopy. SPA reconstruction with a resolution of 3 Å revealed near-atomic level details of the interaction between the RECQ5 helix and RNAPII DNA. Additionally, cryo-EM imaging showed that the RNAPII with RECQ5 complex formed large, spherical objects resembling condensates. CLEM confirmed the presence of both fluorescently labeled RNAPII and RECQ5 within these objects. STA revealed the organization of condensates, further enhancing our understanding of their functional assembly. The subtomogram averaging model of RNAPII with RECQ5 reached a resolution of 7 Å, confirming the observed interaction between the RECQ5 helix and RNAPII DNA across analytical methods.

Conclusions

Our study emphasizes RECQ5's crucial role in modulating transcriptional processes by using the brake-helix to regulate RNAPII movement along genes. Additionally, we discovered that condensates contain tens to hundreds of RNAPII molecules with RECQ5. The study provides valuable insights into how transcriptional machinery functions in eukaryotic nuclei.

Poster Group 2

Droplets are held together by the surface tension, which is the force from the surface molecules attracting each other. It is not only the phenomenon explaining droplet formation, but it is also an important factor, when studying vapor-liquid-solid growth, which is a commonly used growth mechanism for nanowires. Today however, growth models and predictions are based on approximate values of the surface tension, lacking in reports of empirical values e.g., for Au-catalyzed GaAs-nanowires.
An external electric field has previously been used to deform the catalyst droplet on AuSi eutectic droplets on silicon nanowires and the balance of field and surface tension can be used to measure the surface tension. Here, we use a similar procedure growing Au-catalyzed GaAs nanowires on microfabricated Si-cantilevers, which opens up for many types of in-situ experiments, deforming the catalyst in an arsine atmosphere using a unique ETEM with a purpose-built gas injection system. Image analysis and 3D simulations (Fig. 1a) using COMSOL Multiphysics are used to compare the droplet shape e.g., the aspect ratio of the droplet at various fields and temperatures (Fig. 1b) reporting an empirical value of the surface tension for the first time and with improved analysis also an updated value on the AuSi surface tension reported earlier.
In conclusion, an empirical value of the surface tension of the AuGa eutectic of GaAs nanowires is reported using locally heated Si-cantilevers in an ETEM. This will be compared with theoretical predictions.

Poster Group 2

Background incl. aims
Gallium nitride becomes increasingly utilized in power electronics and currently competes with silicon carbide for the lead in many power applications. Each of the two materials faces different challenges. In GaN, for example, the effect of threading dislocations in GaN-on-Si epitaxial layers is still an open issue. Despite great effort in research of this material, it is questionable whether the high concentrations of dislocations deteriorate device operation [1]. Additionally, dislocation motion at elevated temperature, under local electric field or passing current could be significant in delayed device failure. Localization, identification and operando observation of dislocations is a highly complex task, requiring a correlative multimodal approach [2]. Here, we present initial attempts which include operando TEM observations of threading dislocations.

Methods
We localize and identify dislocations by means of electron channeling contrast in SEM, conductive AFM and wet etching. Subsequently, dislocation dynamics is observed by TEM on FIB-prepared cross-sectional lamellae on MEMS chips.

Results
We inspect the effect of heat, electrical current and electric field on the dislocation motion. The dislocations are stable at elevated temperatures, and they start to move/unpin if extreme current densities over tens of kA/cm2 are passing through (i.e. much higher than common current densities in GaN devices,). We will also present our first attempts to observe the motion initiated by an extreme electric field, generated by a sharp tip close to the lamella surface.

Conclusion
In this contribution, we demonstrate a correlative approach to dislocation identification, combining SEM, TEM, wet etching and probe microscopy. We show the results of our TEM observations of dislocation motion under external stimuli (heat, electric current and large electric field). The dislocations seem to be immobile until only very extreme conditions are met.

IM-13 (2), Lecture Theater 5, august 27, 2024, 14:00 - 16:00

Background
Correlative microscopy involves using multiple imaging techniques on the same sample to enhance the overall understanding of the data by correlating the information gathered from each method. [1] While Correlative Light and Electron Microscopy (CLEM) is an established method in life sciences, its application in materials science remains underutilized yet equally crucial. [2] The primary challenge in materials science correlative microscopy lies in co-localizing and registering (aligning) microstructure images, a task complicated by possible microstructure complexity compared to cellular images. In our previous work, we described a method developed to generate a large dataset of light optical microscope (LOM) and scanning electron microscopy (SEM) images for training a deep learning (DL) model aimed at microstructure image enhancement. [3] To achieve automatic alignment of distinct images, we found it necessary to include Confocal Laser Scanning Microscope (CLSM) images, which serve as a visual intermediary. Despite the Keyence VK-X1100 CLSM being fully automated, software limitations precluded the use of its automation features. This resulted in a bottleneck, as the raw images from mapping could not be saved, forcing reliance on semi-automatic imaging. In addition, too small and unalterable overlap between images hindering further processing. Initially, we trained a deep learning model built on Generative Adversarial Networks (GAN) to enhance LOM images. However, improving this model requires additional data, which is time-consuming to obtain. Therefore, we suggest using the trained model as a style transfer filter to eliminate the need for CLSM images. This approach enables the simulation of SEM appearance from LOM images, thereby assisting the elastic image transformation tool (bUnwarpJ [4]) in identifying common features across images, facilitating their alignment.

Methods
We used pre-aligned images from the aforementioned dataset to effectively demonstrate the success ratio of image registration with the bUnwarpJ ImageJ tool, comparing its performance on both the original and style transferred images. This dataset consists of LOM and SEM-CBS micrographs of TRIP steel (512x512 px, 20x20 µm field of view), which were initially aligned using a workflow detailed in our previous work.[3] We employed 252 image pairs to evaluate our hypothesis. The investigation began with elastic registration on the original LOM (source) and SEM-CBS (target) images, establishing a baseline success rate. Subsequently, a GAN model was introduced to transform LOM images into CBS-like counterparts. This transformation aimed to narrow the visual disparity between LOM and CBS images, facilitating improved registration accuracy by the bUnwarpJ tool. The transformations devised for the predicted images were then applied to the original LOM images to achieve the desired alignment. Given the absence of a robust metric for registration (aligning) quality, evaluations were subjectively categorized into four tiers: poor, bad, decent, good.

Results

Elastic registration from raw LOM to CBS images was notably unsuccessful across the majority of cases (poor: 160, bad: 90, decent: 1, good: 1). This failure is immediately apparent, with the algorithm causing significant distortion and deformation of the source LOM images. In contrast, the application of GAN to transform LOM into CBS-like images resulted in a marked improvement in registration convergence across all examined instances (poor: 0, bad: 0, decent: 8, good: 244), as evidenced by the provided examples. However, the overall quality of this image registration remains a matter of contention. The inherent low quality of LOM images limits the fidelity of their transformation into CBS-like counterparts, leading to inaccuracies particularly in the depiction of grain boundaries. These inaccuracies result in mismatches when aligning to the target CBS image boundaries. Conversely, while CLSM serves as a comparable intermediary and faces similar challenges, it benefits from a precise physics-based acquisition method, which mitigates issues associated with generative model-induced artifacts. However, this approach requires a two-step alignment process: first from LOM to CLSM and then from SEM-CBS to CLSM. This sequential alignment process inherently doubles the potential for error. Furthermore, as previously highlighted, CLSM mapping represents a significant time-consuming bottleneck.

Conclusion

This study demonstrates the value of style transfer in facilitating the alignment of a large volume of corresponding images from different microscopy techniques. Utilizing LOM and SEM microstructure images of TRIP steel (20×20 µm field of view) as a case study, we illustrate the method's potential to bridge the visual modality gap between disparate imaging techniques. Initially, this approach requires the manual creation or clever generation of a dataset of aligned image pairs to train a deep learning model. Once established, this model significantly simplifies the alignment challenges for subsequent and future datasets of a similar nature. Although, utilization of a less complex U-Net model—typically employed for segmentation—could reduce the size of the required training dataset, our work leveraged a more sophisticated GAN model, necessitating a larger dataset. This work underscores the potential for enhancing image registration through preprocessing with GAN-based transformations, effectively addressing modality differences in correlative microscopy.

IM-13 (1), Lecture Theater 5, august 27, 2024, 10:30 - 12:30

Background and Purpose:
Volume correlative light and electron microscopy (vCLEM) has the potential to provide both function and ultrastructure of biological specimens by combining light and electron microscopy. One attractive approach for vCLEM is to prepare samples for electron microscopy (EM) in a way that preserves fluorescence even after they've been embedded in resin (in-resin fluorescence preservation). This allows for navigation to a ROI using fluorescence and EM images acquired at various points through the imaging workflow, including the final ultrathin sections used for transmission electron microscopy (TEM) imaging.
Image registration of light microscopy (LM) and EM images at various scales is required throughout this process. Current trends in image registration rely on methods that warp one image based on user-defined corresponding landmarks. While these methods yield high accuracy, they require significant user time and effort in selecting corresponding landmarks. Recent advancements have introduced automated methods that leverage Laplacian-of-Gaussian filtering or point cloud mapping. While these methods enhance both efficiency and reproducibility, their applications have primarily been limited to cell CLEM, leaving their efficacy in the realm of tissue CLEM unverified. Moreover, achieving ROI navigation through image registration across multiple scales remains a challenge, as existing tools lack the capability to visualize this process effectively.
Here, we aim to bridge this gap by proposing an efficient ROI navigation workflow that leverages new image registration techniques.

Methods:
We use image datasets encompassing mouse brain tissues. The mice are labelled with intrabodies specifically targeting inhibitory synapses, alongside cytoplasmic markers that comprehensively labelled the entire neurons. They are anesthetized, perfused, and brain vibratome sections are collected. Then, cell nuclei are labelled with DAPI and blood vessels with tomato lectin LEL. Next, the tissues are high-pressure frozen, freeze-substituted, and resin embedded. Following the acquisition of a confocal image of the resin block, it is sectioned into ultrathin slices (200 nm) using an ultramicrotome, and fluorescence images collected of some of those sections. Finally, TEM images of these ultrathin sections are obtained.
Our workflow facilitates the acquisition of EM images corresponding to ROIs identified using LM images. It encompasses two key components:

1. Semi-automated image registration algorithm: This algorithm aims to achieve the registration of images acquired through diverse microscopy techniques. Its core functionality consists of two primary processes: (a) object segmentation and (b) image registration. In (a) object segmentation, the objects that appear commonly in both images are segmented either automatically or with a degree of user interaction. During (b) image registration, images are warped to match objects in (a)

across imaging modalities. Image registration metrics such as mutual information are calculated to assess the quality of the warping. Arranged in descending order of value, a user is presented with the overlayed images corresponding to the warping yielding the highest metric value. With the help of the user, the successful registration parameters are determined. In scenarios where one image has greater dimensions than the other, the larger image undergoes a raster scan. During this process, the image value registration metric is computed at each scan position. Notably, if the input consists of an image stack, additional scanning additionally occurs along the depth axis.

2. ROI navigation viewer: This viewer facilitates the visualization of image stack and section image registration results, ultimately guiding navigation towards ROI acquisition via high-resolution EM. The viewer leverages the Napari framework for its implementation and has multiple advantages.

(a) Three-dimensional visualization
This function accepts the image stack and warping parameters to display the three-dimensional positioning of the ROI and ultrathin section fluorescence (and TEM) images relative to the entire low-magnification confocal microscopy image stack. This comprehensive view allows for at-a-glance comprehension of the spatial relationships between multiple images and datasets. Additionally, the depth information from the ROI surface serves as a guide for selecting ultrathin sections.

(b) Overlaying an ROI on an ultramicrotome stereomicroscope image
This function accepts an ultramicrotome stereomicroscope image, a transmitted DIC image, and a confocal microscope image of a tissue block and overlays the ROI location onto the ultramicrotome image to facilitate the precise trimming of the tissue block containing the ROI.
Notably, the transmitted DIC image serves as an intermediary to achieve accurate superposition onto the ultramicrotome image.

(c) Overlaying ROI on low-magnification EM image
This function accepts block confocal microscopy image of a tissue block and its ultrathin section EM image, and displays the location of the ROI overlayed on the low-magnification ultrathin section EM image to facilitate acquisition of high-magnification EM images of the ROI.

Results:
We assessed the efficacy of the proposed workflow using image datasets encompassing brain tissues from two mice. The image acquisition procedure is detailed within the background section. The key distinction between the two datasets is the presence or absence of blood vessel staining (Datasets 1 and 2, respectively).

For the Dataset 1, we succeeded in navigation of the entire block image (2 mm x 2 mm x 0.1 mm, pixel size 0.57 µm in the X and Y, 1 µm in Z) to the single nuclei (roughly size of 5 x 5 µm2, pixel size: 7 nm x 7 nm). For the Dataset 2, we applied Functions 1 through 3 sequentially and succeeded in navigation of the entire block image (600 x 600 x 35 μm^3, pixel size: 0.63 µm in X and Y, 1 µm in Z) to the single axon (roughly size of 1 x 20 µm2, pixel size: 3.4 nm x 3.4 nm).

Conclusion:
While vCLEM offers unparalleled access to three-dimensional information regarding both cellular function and ultrastructure, navigating the ROI for EM image acquisition has been laborious. Our segmentation-based image registration algorithm facilitates seamless navigation across modalities

and scales. Coupled with our interactive viewer capable of visualizing registration results and guiding ROI navigation from LM to EM imaging, this integrated approach enables efficient ROI navigation.

Poster Group 2

Background incl. aims
Eutectic high-entropy alloys (EHEAs) have been around for a decade but only recently has become a hot topic in a field of metal alloys . As a subclass of high-entropy alloys (HEAs) enriched with a variety of advantages of eutectic alloys, EHEAs possess superior mechanical properties opening a broad spectrum of possible applications in industry [1]. These alloys are best characterized by the absence of the conventional „strength ductility trade-off“ and remarkable stability over a wide temperature range due to their high-entropy state. Combined with excellent castability, mitigating segregation and shrinkage, they appear to be an ideal candidate for demanding design scenarios such as exposure to elevated temperatures or mechanical stresses commonly encountered in the energy industry [2]. Therefore, they can be seen as a possible competitor for austenitic stainless steels, which possess high ductility with lower tensile strength values and are used for such applications nowadays [3,4]. In this regard , examining the behavior of these specific materials when welded together is prudent, as it can provide valuable insights into their compatibility and suitability for coexistence in industrial applications or utilization in tandem within various industrial sectors. Motivated by the imperative to harness the full potential of advanced materials, our study focuses on the characterization of heterogeneous weld joints between AlCoCrFeNi2.1 EHEA and austenitic steel EN 1.4571, achieved through electron beam welding. The primary objectives of this study are to conduct a comprehensive investigation into the microstructural characteristics of the weld interface and constituent materials. Through a multifaceted approach encompassing various analytical techniques, tests, and image analysis methodologies, our aim is to elucidate as much information as possible, thereby enhancing our understanding of the welding process and the resultant material properties.
Methods
The electron beam welding process was employed to fabricate weld joints between EHEA (AlCoCrFeNi2.1) and austenitic stainless steel (EN 1.4571). Three sets of samples were prepared, each subjected to different welding parameters: beam currents of 13 mA, 17 mA, and 25 mA, with corresponding welding speeds of 10 mm/s, 20 mm/s, 30 mm/s respectively. Prior to welding, samples underwent traditional metallographic procedure. The final preparation step involved electro polishing with parameters meticulously adjusted for optimal results. The microstructure of the weld joints and base materials was examined using multiple microscopy techniques. Light optical microscopy provided a macroscopic view of the weld interface, while confocal scanning laser microscopy offered high-resolution imaging of surface features. Additionally, scanning electron microscopy (SEM) was employed to investigate microstructural details at higher magnifications. On the SEM, Energy Dispersive X-ray Spectroscopy (EDS) was employed for elemental analysis of the weld zones. EDS mapping was conducted to assess the spatial distribution of alloying elements and identify any potential elemental segregation. Furthermore, Electron Backscatter Diffraction (EBSD) was utilized for phase identification and crystallographic analysis of the welds and base materials. Apart from microscopic analysis, mechanical properties of the weld joints were assessed through

tensile testing and nanoindentation for hardness evaluation. Tensile tests were conducted to measure the mechanical strength and ductility of the weld joints. On top of that, convolutional neural networks (CNNs) were employed for image analysis to estimate the fractions of BCC and FCC phases present in the microstructure.

Results

All observations were conducted in the same manner to achieve comparable results. The fusion area was examined at three levels: top, middle, and bottom. The top area was defined as 1 mm below the surface of the weld, while the bottom area was 1 mm above the root of the weld, with the middle area positioned equidistantly between these top and bottom regions. Summarizing the results, in all scenarios, EDX line scans along the axis of the weld showed minimal fluctuations in chemical composition. Conversely, significant chemical composition changes were observed when examining lines across the weld, particularly at the fusion zone boundaries, while the elemental levels remained stable after the transition. This phenomenon was consistent at every level of observation, with increasing fluctuations in the middle and bottom areas. It is also noteworthy that carbon nitrides from EN 1.4571 were observed across various regions of the fusion zone, contributing to the complexity of the microstructure and hindering the diffusion of chromium due to carbon and nitrogen binding. From a phase perspective, the entire fusion area exhibited a face-centered cubic (FCC) dendritic structure with interdendritic space formed by body-centered cubic (BCC) precipitates, resembling the EHEA-like phase map, which consists of FCC and BCC lamellas, while EN 1.4571, consistent with its inherent properties, maintained an FCC phase. Moreover, BCC stripes were predominantly observed at the interface between EHEA and the fusion zone, likely as a product of segregation. Conversely, the transition between EN 1.4571 and the fusion zone primarily consisted of an FCC phase with smaller BCC precipitates appearing deeper into the fusion zone. This observation is further supported by the grain orientation map, where grains adjacent to EN 1.4571 maintained larger sizes comparable to the base material matrix on this side of the weld, while also exhibiting almost identical orientation to the nearest grains of the base material.

As one delves deeper into the fusion zone, the relative grain size diminishes, and their orientation becomes more random, coinciding with the appearance of precipitates. These precipitates, besides exhibiting a BCC phase, displayed an inner structure that was analyzed, albeit yielding no further discoveries.

Conclusion

Optimal parameters for welding EHEA together with EN1.4571, as well as metallographic preparation of such welds, were established. The microstructure was subsequently observed and analyzed using a spectrum of different techniques, offering profound insights into both the welding process and the resultant structure. Our observations unveiled a finely nuanced and complex microstructure within the fusion zone, adorned with small BCC precipitates ranging from a few to tens of micrometres. Additionally, EBSD analysis underscored the pivotal role of the weld interface in shaping the evolution of the microstructure. Continued analysis, including the exploration of AI-powered image analysis techniques for fusion zone estimation, is warranted to deepen our understanding and uncover further intricacies.

Poster Group 1

Microglia, the main immunocompetent cells in the central nervous system, rapidly respond to disturbances in their microenvironment, largely relying on purinergic (ATP, ADP) signaling through P2Y12 receptors. However, while the effects of exogenous ATP on microglial activity have been extensively tested in previous studies, the mechanisms involved in microglial response to endogenous, focal ATP events in the brain tissue are unclear. To visualize changes in the extracellular ATP levels, we introduced a sensitive fluorescent ATP sensor (GRAB-ATP) to cultured neurons and astrocytes and prepared acute brain slices from mice expressing the sensor in VGlut1+ neurons. We observed both spontaneous and injury-related ATP events in astrocytes and neurons in vitro, and detected significant extracellular ATP increase after slice preparation or secondary injury, even hours after slice cutting. ATP accumulation due to blockade of ecto-ATPase activity indicated an ongoing ATP release from the damaged tissue. Interestingly, we also observed a highly dynamic, focal, flashing ATP activity, persisting for hours ex vivo. Importantly, microglia processes were recruited to complex, nano- and micromolar ATP events in a P2Y12R and CX3CR1 dependent way, leading to marked morphological transformation of the cells. Microglial response to spontaneous- and injury-related ATP signals also occurs in vivo as revealed by in vivo two-photon microscopy. We suggest that focal, submilimolar ATP events represent a major modulator of microglial states and are likely to alter inflammatory responses in different CNS disorders.

Complementary vEM approaches for ultrastructural changes during the development of D. melanogaster germline intercellular bridges

Dr Irina Kolotuev[1], Abigayle Elsbury[2], Caroline Kizilyaprak[1], Stephanie Pellegrino[2], Dr Lindsay Lewellyn[2]
[1]Faculté de Biologie et de Médecine, Université de Lausanne, Lausanne, Switzerland, [2]Department of Biological Sciences, Butler University, Indianapolis, USA

Poster Group 1

Background and aims
The fruit fly Drosophila melanogaster is an excellent model for studying biological processes, and many questions in cell and developmental biology have been answered using this system. Incomplete cytokinesis is an essential process studied in many cell types which allows cells to form stable intercellular bridges that connect them to each other. Although intercellular bridges are found in somatic and germ cells throughout the animal kingdom, the most well-studied are those within the developing egg chamber. Many essential pathways and processes are required to allow the egg chamber to develop into a mature fly egg. The egg chamber consists of a cluster of 16 interconnected germ cells surrounded by a layer of somatic cells. Following each of the four germ cell divisions that create the germ cell cluster, the midbody is re-organized to form a stable intercellular bridge or ring canal. These ring canals undergo significant growth, which allows cytoplasmatic contents and nutrients to be transferred from supporting nurse cells to the growing oocyte. Although fluorescence and electron microscopy-based studies have been used to study the role of ring canal proteins during oogenesis, a complete ultrastructural characterization of these structures is lacking.
Methods
Electron Microscopy is a powerful tool for imaging cellular structures at the nanoscale, providing valuable insight into the ultrastructure of many cell and tissue types. Volume microscopy techniques such as Focused Ion Beam, Scanning Block Face, and Array Tomography have considerably advanced the potential applications of SEM-based approaches. To learn more about ultrastructural changes in the ring canals throughout oogenesis, we have used a combination of complementary vEM approaches – FIB-SEM to monitor the early stages of oogenesis and AT-SEM to follow the structures in later stages of oogenesis. We have aligned and segmented the stacks of images to analyze the structure of the ring canals during the development of the egg chamber.
Results
By using a complementary set of vEM-based approaches, we were able to visualize ultrastructural changes in the germline ring canals throughout oogenesis. We segmented the large data set collected using Focused Ion Beam SEM to generate a complete 3D model of the germarium and an early-stage egg chamber. The combination of AT-SEM and FIB-SEM allowed us to gain insight into previously unappreciated aspects of ring canal structure and function. In addition, we have characterized the microvilli meshwork surrounding the ring canal structures (Figure). These structures have been proposed to be essential to anchor the ring canals within the nurse cell membranes, but such a detailed three-dimensional view of their orientation has not been produced.
Conclusions
This combination of complementary vEM approaches allowed us to capitalize on the strengths and overcome the limitations of each individual approach. This modern framework could be used to answer biological questions in other tissues or organisms that face similar technical challenges; for example, in older egg chambers, the ring canals are very small structures within a large sample

volume. Our work illustrates the potential scientific insight that can be provided by a high-content dataset, which could potentially become a valuable resource for further analysis by additional groups in this field. Although the focus was on ultrastructural changes in the germline RCs, our dataset contains valuable details of additional cell types and structures.

Poster Group 1

Background incl. aims
With the growing environmental deterioration and ever-increasing energy demand, exploring a renewable and clean energy for human development has been regarded as a promising research subject. Hydrogen is one of the most desirable energy carriers. Fujishima and Honda discovered that hydrogen can be generated from water splitting on a TiO_2 photoelectrode under UV light illumination.[1] TiO_2 is considered to be stable since its redox potential has been calculated to be more positive/negative relative to the water oxidation/reduction potential. This means that photogenerated charge carriers would participate in driving the desired water splitting reactions rather than oxidizing or reducing semiconductor photoelectrodes.[2] Nevertheless, it is reported that there is degradation of performance and alterations in surface morphology of TiO_2 under UV light irradiation. Understanding the dynamic catalyst behaviour during electrochemical application plays a key role in developing improved catalysts.
Methods
We applied scanning electron microscopy (SEM), aberration-corrected transmission electron microscopy (TEM), X-ray diffraction (XRD), x-ray photoelectron spectroscopy (XPS) and Raman spectroscopy together with operando inductively coupled plasma mass spectrometry (ICP-MS) coupled with illuminated scanning flow cell to investigate photoelectrochemical (PEC) corrosion pathways of TiO_2 semiconductor photoelectrodes. TiO_2 nanotube array was utilized as our model system to conduct the quantitative study in understanding the effect of the PEC conditions on its photostability. PEC measurements were performed on a Reference600 potentiostat (Gamry) with a three-electrode PEC cell in 0.1 M of $HClO_4$ solution as the electrolyte. The electrolyte was pumped through the PEC cell into ICP-MS for time-resolved analysis of the amount of dissolved titanium ions.
Results
The XRD pattern indicates that all peaks agree well with the tetragonal rutile phase (SG, $P4_2/mnm$; JCPDS No. 21-1276) which is further confirmed by Raman spectrum. X-ray photoelectron spectroscopy (XPS) analysis was performed to study the chemical components and the states of Ti and O in the TiO_2 nanocomposites. The XPS spectra reveal that the dominant elements are Ti, O of the TiO_2 composites. The peaks located at about 458 and 464 eV are corresponding to Ti 2p3/2 and Ti 2p1/2, respectively. SEM (Figure a, b) show that the prepared TiO_2 exhibits nanotube morphology with a thickness of 2.1 µm and an average diameter of 150 ± 20 nm. TiO_2 nanotube grows along with the direction [001] as demonstrated from TEM images (Figure c,d) and high-resolution TEM (HRTEM) image confirms that the surface is (110) facet. From operando ICP-MS setup (Figure f), we can measure the dissolution of TiO_2 during PEC process. Through this method, the operation parameters of PEC on photoelectrodes can be controlled to elucidate sufficiently by quantifying dissolved metal ions of photoelectrode surface in the electrolyte during the whole PEC process in real time.
Conclusions
In summary, our work demonstrates that electron microscopy characterization together with operando ICP-MS plays an important role in investigating the intrinsic mechanism of the improved

PEC performance and photostability of TiO_2. The technique will be strongly needed in our future research and offers significant guidance in (photo)electrochemistry field.

Background
Determining the exquisite features of flexible biological assemblies remains a challenge in field. Although it is often neglected in high-resolution interpretations, dynamic information holds the secret to how molecules perform their essential duties. For small polymers, NMR studies paired with molecular dynamic (MD) simulations are a powerful combination. Microfluidic imaging techniques based on liquid-electron microscopy (liquid-EM) principles can fill this gap for larger macromolecules and soft polymer assemblies, pushing us closer to seeing live events in the sub-nanometer range.

Methods
Liquid-EM experiments were performed using a Thermo Fisher Scientific Talos F200C transmission electron microscope (TEM), operating at 200 kV under low-dose conditions. Non-infectious and de-identified SARS CoV-2 sub-viral assemblies were examined using a variety of specimen enclosures including ultra-thin Silicon Nitride (SiN) and carbon-based enclosures. Multi-framed movies and images were recorded over different timeframes and magnification ranges, and the output data was analyzed.

Results
Non-infectious SARS CoV-2 components were enriched from de-identified COVID patient serum and verified using SDS-PAGE and Western blot analysis. The enriched samples showed that Spike protein, Spike protein fragments, and Nucleocapsid (N) protein were present. Protein fractions were prepared in HEPES buffer solution (pH, 7.5) and placed in microchip enclosures using the thin-film hybrid approach. Liquid specimens were hermetically sealed using autoloader clips employed for automated cryo-EM preparation. Images of enriched SARS CoV-2 proteins and RNA in solution showed self-assembly processes happening within 72-hours at room temperature. The small black components in the background of the images were N proteins along with Spike proteins and other unidentified fragments. These individual items (~5 nm) were smaller in comparison to the larger sub-viral particles (~100 nm or greater) that assembled over time. The final complexes formed at the 72-hour time point are consistent in size and shape with full RNA-nucleocapsid particles that comprised the SARS CoV-2 virus. We posit these particles have high contrast with respect to the surrounding liquid due to their RNA content. Slices through a putative 8.25-Å structure of the larger assemblies showed internal features of the protein and RNA subunits. Formed particles were also be treated with over-the-counter substances to visualize disassembly steps (DiCecco et al, J. Vis. Exp, 2022).

Conclusion
The testing of alternative substrates and enclosures helped improve knowledge of biological processes in liquid droplets. We visualized processes involving sub-viral particles having features consistent nascent SARS-CoV-2 assemblies. Spike remnants on the particle surfaces were often visibly

although some particles lacked these features. White bubbling in the samples ensured the presence of the liquid layer and samples could be preserved up to 6 months. Chemical mapping experiments confirmed the presence of phosphate in the particles that were also coated with calcium. While these experiments are an excellent start to monitoring assembly pathways, additional work is needed to understand how building blocks form larger units, and to test how chemical reagents may affect these processes.

Poster Group 1

Background
Stress is accepted as an important risk factor for Alzheimer's disease (AD) (1,2).High levels of cortisol, which is the stress hormone, in the cerebrospinal fluid (CSF), plasma and serum of Alzheimer's patients and the decrease in hippocampus volume and declarative memory disorders in patients with major depression and chronic corticosteroid treatment give rise to thought for a possible relationship between AD and stress (2,3,4). This suggests that the increase in glucocorticoid levels, which occurs as a result of stress, may participate in the formation of pathological mechanisms seen in AD, and raises the question of whether stress triggers the pathways that cause neurodegeneration or not.
Methods
In the study; in organotypic brain slice cultures, which allows to obtain results closest to in vivo models by protecting tissue architecture and microenvironment, circadian rhythm and stress models with corticosterone application and Alzheimer-like model with amyloid beta 1-42 (Aβ1-42) peptide application were generated. The effects of these treatments on glucocorticoid receptor (GR) and mineralocorticoid receptor (MR) expressions, which are corticosteroid receptors, were investigated at both mRNA and protein levels. Regional localizations of these proteins in the brain were also examined by immunofluorescence method.
Results
As a result of our study, we found that GR and MR expression levels and their localizations in the hippocampus region changed both in circadian rhythm and stress models created by corticosterone applications and in AD-like models created by amyloid beta 1-42 application, and we determined that these changes differ depending on the dose. When we evaluate the findings of corticosterone and Aβ1- 42 applications we obtained in our study together, we observed that GR protein level, and GR localization in the hippocampus, especially in the stratum pyramidalis region, were similarly affected.
Conclusion:
Our findings point out that the increase in corticosterone caused by stress may be involved in the formation of pathological mechanisms seen in AD.

Morphological investigation of periodic structures created by focused ion gallium beam

Márk Windisch[1,2], Dániel Selmeczi[3], Ádám Vida[2], Zoltán Dankházi[1]
[1]Eötvös Loránd University Department of Materials Physics, Budapest, Hungary, [2]Bay Zoltán Nonprofit Ltd. for Applied Research, Budapest, Hungary, [3]Semilab Semiconductor Physics Laboratory Co. Ltd., Budapest, Hungary

Poster Group 2

Background incl. aims
Surface periodic structures on solids by ion-beam irradiation were first observed in the early second half of the 20th century. The initial observation, in parallel with the investigation of ion techniques, was followed by several other experimental works and theoretical descriptions based on ion-material interaction. Some developed models in this field can predict the morphological properties of the periodic structures as a function of some parameters of the ionic irradiation. In our experimental work, periodic structures were created on silicon surface by a low-energy focused ion beam at different incidence angles. The created morphology of periodic structures was compared to the predictions of the most cited Bradley-Harper (BH) model. Based on the experimental work, one of our goals is to explain the deviation from the BH model. In addition, the material structural and optical properties of the periodic patterns were also investigated by some spectroscopic measurement techniques. These measurements were used to determine the amorphization of the structured surface layer. Moreover, the reflectances of the structured surfaces were determined as a function of the applied ion incidence angle. Another goal of our work was to achieve a controlled modification of the reflection on Si surfaces by low-energy ion irradiation.

Methods
Ion irradiation was performed on polished Si (111) by focused 2 keV gallium ion beam (FIB) at incident angles between 60° and 80°. The morphology of the irradiated Si surfaces was investigated by scanning electron microscopy (SEM) and atomic force microscopy (AFM). To determine the wavelength of the structured periodic patterns, the power spectral density (PSD) function calculated from a 2-dimensional Fast Fourier Transformation was used. The position of the first peak of the PSD function was used to determine the characteristic periodicity of the structured surface. Spectroscopic elllipsometer (SE) and reflectometer were used to study the material structure of the structured Si layers.

Results
Regular ripple formation was created at ion incident angles between 60° and 72.5°. The wavelength of the ripple patterns was measured between 38 nm and 60 nm. The trend of the measured wavelengths showed exponential growth in the mentioned range. The regular periodic structure broke up above 72.5° ion incidence angle and turned into a smooth surface up to 80°. The wave vector of the ripple formation was parallel to the incident ion beam. The rotation of ripples did not appear in the range of 60° and 80° ion incidence. This observation is not consistent with the predictions of the BH model. The amorphised layer thicknesses of the strutured surface were determined between 3.8 and 7.9 nm in the range of 60° and 80° ion incidence by SE. Furthermore, the reflectances of structured surface was measured in the range of 300 nm and 900 nm wavelength

of light. According to the measured results, a linear connection was observed between the reflectance and ion incident angle for 460 nm wavelength of light.

Conclusion
Periodic structures were created by low-energy focused ion beam on Si (111) in the range of given angles. The characteristic sizes of the formed structures could be controlled within a few of tens of nm by changing the ion incident angles. Based on the meaured morphology results, explaination was given for deviation from the prediction of the BH modell. The amorphization of irradiated surfaces was modified with different ion incidence angles. Furthermore, the reflectances of Si surfaces was fine-tuned in 460 nm wavelength of light by low-energy ion irraidation.

Poster Group 2

Background including aims: Cellulose, an abundant and renewable natural polymer, offers extensive opportunities for diverse applications in materials science due to its favorable properties [1,2]. In this context, nanocomposite materials combining cellulose or its derivatives with nanoparticles such as Fe_3O_4, Au, Ag, and TiO_2, emerge as versatile platforms for sensor development. For instance, the characteristics of nanocellulose-water interactions can be exploited for the fabrication of flexible humidity sensors [3]. This study aims to create nanocomposite sensors specialized for detecting humidity and volatile organic compounds (VOCs) exploiting the synergistic effects of nanoparticles within the fibrillated nanocellulose or cellulose acetate matrix. Additionally, we investigate the potential of these nanocomposites for UV photodetection in flexible sensor systems.
Methods: We utilize different approaches for synthesizing fibrillated nanocellulose, cellulose acetate, nanoparticles of Fe_3O_4, Au, Ag, or TiO_2, as well as the related nanocomposites, aiming to integrate nanoparticles into flexible cellulose matrices [4]. Advanced electron microscopy techniques including conventional and low-dose Transmission Electron Microscopy (TEM), high- and low-vacuum Scanning Electron Microscopy (SEM), Focused Ion Beam (FIB) sectioning and Energy-Dispersive X-ray Spectroscopy (EDX) mapping are employed for precise characterization of nanocomposite morphology, structure and nanoparticle distribution. Humidity and VOC sensing experiments, along with UV photodetection tests, are conducted in the custom-built sensing system to evaluate sensor performance.
Results: TEM analysis reveals the precise morphology and dispersion of nanoparticles within the cellulose matrix at the nanoscale, highlighting the homogeneity crucial for sensor efficiency. SEM results, including cross-sectional profiling, provide detailed microstructural insights and, in combination with EDX, elucidate the spatial distribution of nanoparticles. Our nanocomposite-based sensors demonstrate notable sensitivity, selectivity, and response time towards varying humidity levels and diverse VOCs, as well as promising UV detection capabilities [5].
Conclusion: This study advances nanocomposite-based sensor technology by exploring the complex relationship between nanoparticle composition, nanoparticle distribution within cellulose matrix, and sensor performance. The findings underscore the potential of these multifunctional nanocomposites for diverse sensor applications, including humidity, VOC, and UV detection in flexible sensor platforms, thus paving the way for next-generation sensing technologies.

Poster Group 2

Background incl. aims
Surface functionalization of 1D and 2D nanomaterials is a perfect way for controlling their properties [1-5]. Very detailed structural and chemical composition analyses, at the atomic scale, of such surface modifications are required in order to determine their impact on the electronic/optoelectronic properties. Transmission electron microscopy (TEM) and in particular, spatially-resolved electron energy loss spectroscopy (SR-EELS) developed in an aberration-corrected TEM, is the most powerful technique to get this information. Indeed, having access to a close to 1 angstrom electron probe, the atomic configuration and concentration of the different species of these functionalized nanomaterials can be obtained [1-5]. In this contribution, we report an in-depth study of the atomic configuration of covalent and non-covalent functionalized (pi-stacked and endohedral) single-walled (SW) C-NTs via SR-EELS [5].

Methods
These studies have been developed via spatially-resolved EELS performed using a liquid-nitrogen holder (−170 °C) and Thermo Fisher Scientific Titan Low-Base microscope, working at 80 kV. This microscope is equipped with a Cs probe corrector, a monochromator and an ultra-bright XFEG electron source. The HRTEM studies have been carried out in a Thermo Fisher Scientific Titan Cubed microscope (equipped with a Cs image corrector), under the same cryogenic conditions (−170 °C) and at 80kV.

Results
We have investigated different systems of functionalized NTs (covalent and non-covalent (endohedral and pi-stacked)), for getting local information about these different hybrid configurations, studying the chemical environment and bonding of the NTs and the organic moieties [2-5]. Figure 1 illustrates some of these results, in particular the case of endohedral functionalization: iron-phthalocyanine (Fe-Pc) moieties in single-walled nanotubes [5]. Figure 1 (a) corresponds to a HRTEM image of one of these individual filled single-walled C-NTs. Figure 1 (b) displays an atomic-sketch, showing the supramolecular order of the Fe-Pc within a SWNT and Fig. 1 (c) shows an atomic-sketch of one of these Fe-Pc molecules (a Fe atom is surrounded by 4 pyrrolic-like subunits). As it is well known, these NTs tend to be organized in bundles. Figures 1 (d) and (e), which correspond to of STEM (BF and HAADF) micrographs, show one these bundles of SW-CNTs. A 24x12 EELS spectrum-image (SPIM) has been recorded in the green marked area on one of these NT. (f) EEL spectra extracted from the squared regions marked in Fig. 1(e). They correspond to four EEL spectra each of them. C-K, N-K and Fe-$L_{2,3}$ edges are clearly seen. From these spectra, nitrogen and iron elemental maps can be obtained, see Fig. 1 (g) and (h). These studies reveal the supramolecular organization of

the organic moieties (in this present case showed in this figure, iron-phthalocyanines) used for the functionalization of the NTs [5].

Conclusion
In summary, these works provide very rich information about these hybrid and complex nanomaterials, opening fascinating perspectives for optoelectronic applications of such nano-systems. All these aspects will be discussed in this contribution.

Electron beam manipulation with auto-ponderomotive potentials for interaction-free measurements

Msc. Franz Schmidt-Kaler[1], Mr. Michael Seidling[1], Mr. Robert Zimmermann[1], Mr. Nils Bode[1], Mr. Fabian Bammes[1], Mr. Lars Radtke[1], Mr. Peter Hommelhoff[1]
[1]AG Laserphysik, Friedrich-Alexander Universität Erlangen-Nürnberg, Germany

Poster Group 1

Background incl. aims

In many electron microscopy applications, beam damage is a serious issue, often preventing true single particle imaging with atomic resolution to date. When one and the same electron interacts with the sample multiple times, the extracted information can be increased for the same amount of damage [1, 2, 3]. This is at the core of what is known in quantum mechanics as interaction-lean or also interaction-free or measurement (IFM). This concept has been demonstrated to work well with light [6]. We aim at realizing this approach with electrons.

The IFM concept was introduced by Elitzur and Vaidman [1]. Recently, a first demonstration experiment with electrons in an interferometer scheme but without multipassing was reported [4]. To increase the scheme's efficiency substantially, a resonator structure is needed to enable repeated electron-sample interrogation [5]. A quantum electron microscope can be set up in different ways [5], all of which are technically highly demanding. We focus on auto-ponderomotive structures acting as electron guide, beam splitter and resonator. We demonstrated electron beam guiding and splitting [6, 7], as well as 7 round trips in an auto-ponderomotive electron resonator [8]. The current state of the experiment will be reported.

Methods

Auto-ponderomotive structures rely on electrodes applied with alternating DC voltages. In the frame of the swift electrons, an oscillatory potential results forming transverse guiding and beam splitting potentials. We experimentally demonstrated electron beam guiding as well as electron beam splitting in a conventional Philips XL30 SEM at energies up to 9.5 keV and 1.7 eV respectively. Our auto-ponderomotive structures were aligned towards the electron beam with a 5D stage. The electron distribution after the auto-ponderomotive structures (guiding and splitting) was imaged with a micro-channel plate detector via fluorescence detected by a camera (Fig. 1).

Furthermore, we designed a 87.95 mm long resonator, consisting of a central auto-ponderomotive guiding structure [6] and two switchable electron mirrors acting as "barn doors" at the entrance and exit of the resonator. We laser-triggered electron bunches of a nanometric tungsten tip and used deflectors and electron optical elements to steer them into our resonator. The electron barn doors could be opened and closed within nanoseconds at a variable delay towards the laser triggering event. Varying the delay of the outcoupling mirror towards the delay-line detector resulted in detection of up to 7 round trips (Fig.2).

Results

We show successful electron beam guiding as well as electron beam splitting of up to 1.7 keV. In a separate setup, we could demonstrate up to 7 round trips in our auto-ponderomotive resonator. All three modalities create new possibilities for enhanced electron beam control needed for an interaction-free measurement with electrons in a future quantum electron microscope.

Conclusion

We demonstrated controlled electron beam guiding and resonated 50 eV electrons for up to 7 round trips. In addition, we show an electron beam splitting auto-ponderomotive layout for 1.7 keV electrons and electron guiding up to 9.5 keV.

Microstructure and mechanical properties of AlCu thin films in a wide range of composition

Dániel Olasz[1,2], György Sáfrán[2], Noémi Szász[2], Tamás Kolonits[2], Nguyen Quang Chinh[1]
[1]Department of Materials Physics, Eötvös Loránd University, Budapest, Hungary, [2]Institute for Technical Physics and Materials Science, HUN-REN Centre for Energy Research, Budapest, Hungary

Poster Group 2

Background incl. aims
Copper is a common additive in bulk aluminum alloys, where its effect on phase composition and strength of the alloys is well documented. Thin films, however, often contain non-equilibrium phases, which may change significantly the mechanical properties of the material. AlCu thin films in a wide range of composition have been less discussed in the literature, as the existing papers are mainly concentrating on the cases of small alloying concentration. In this work, we aimed to study systematically the microstructure and mechanical properties, as well as to understand their correlations in the case of AlCu thin films having compositions widely changing.
Methods
Thin films were deposited by dual DC magnetron sputtering of Al and Cu targets. Applying the micro-combinatorial technique [1] 15 Al1-xCux films with different compositions ($0 \leq x \leq 1$) were deposited within a single experiment (under the same vacuum conditions) on a single Si substrate. Depth sensing indentation (DSI) measurements were conducted to reveal the hardness and the deformation mechanism of the layers. Cross-sectional lamellas were prepared from each layer by the focused ion beam (FIB) technique, and then investigated by transmission electron microscopy (TEM) techniques, including: bright field, dark field and HRTEM imaging, selected area electron diffraction (SAED), TEM energy dispersive spectroscopy (EDS), scanning TEM (STEM).
Results
Layers near to the equiatomic compositions (Al59Cu41, Al48Cu52, Al39Cu61) are built up from crystalline columns of ~30-40 nm in diameter. At these compositions the SAED measurements show the presence of the Al4Cu9 crystalline phase, which differs from that predicted by the equilibrium phase diagram. Lamellas prepared from the indentation imprints also indicate the presence of deformation bands, suggesting an amorphous like deformation behavior. This is coupled with an exceptional hardness of ~ 16 GPa [2] and a step-like indentation curve during the loading stage of the indentation.
The pure Al and Cu layers also possess small grain-size (~300-400 nm) structure, coupled with an increased hardness compared to their bulk counterparts. Furthermore, indentation process taken on these ultrafine-grained thin film do not show the size effect often observed in the case of bulk materials. The absence of the indentation size effect may be the consequence of the deformation mechanism as intensive grain boundary sliding (GBS) is revealed in these layers by both surface SEM and cross-sectional TEM images.
Conclusion
Composition-dependent mechanical and structural properties of AlCu alloy thin films were determined over the entire alloying concentration range. The decreasing grain size and the appearance of non-equilibrium phases are in good agreement with the increasing alloying concentration - increasing hardness trend. The presence of GBS suggests a mitigation of the classical dislocation-driven plastic deformation mechanism, which is compatible with the absence of an indentation size effect.

Poster Group 2

Background incl. aims
Industrial development contributes significantly to environmental pollution, especially from organic pollutants, which underlines the urgent need for global wastewater recycling. Over the last two decades, extensive research has been conducted on the photocatalytic degradation of pollutants in wastewater [1]. This process begins with the absorption of light in the semiconductor. This generates free electrons and holes that react with oxygen and water on the semiconductor surface to produce chemically reactive products capable of degrading pollutant molecules into less harmful compounds [2].
ZnO, a wide bandgap semiconductor photocatalyst, facilitates photocatalysis under UV light exposure. Current research focuses on tailoring the energy bandgap and improving visible light absorption, which is often achieved by doping the semiconductor with transition metal atoms [3]. Copper is a promising candidate for doping ZnO as it is able to replace Zn in the matrix, creating native point defects such as oxygen vacancies, which significantly affect the material properties [4]. The effectiveness of photocatalysis is closely linked to the active surface area of the catalyst, which has led to a strong interest in the use of powders or colloidal suspensions of nanoparticles. This interest stems from their remarkable surface area-to-volume ratio, which enhances the availability of surface states that serve as reaction sites. However, the separation of nanoparticles from solution poses a major challenge. The development of highly efficient photocatalytic materials for water treatment must therefore be optimized to achieve practical benefits.
Both high surface area and high optical efficiency are essential to achieve increased photocatalytic activity in metal oxide films. Polycrystalline thin films deposited on porous substrates are promising candidates in this context, as they serve as effective photocatalysts without the need for post-treatment. They also facilitate complete recovery after the experiments. In order to take advantage of Cu-doped thin ZnO films for visible-light photocatalysis, different fabrication techniques have been used. In addition, atomic layer deposition (ALD) proves to be a promising technique for the growth of semiconductors or insulating thin films as it allows precise control over the film thickness and deposition on different substrates. [5].
Our goal is to find a photocatalyst that exhibits enhanced photocatalytic activity under UV and simulated sunlight irradiation. We achieve this by manipulating two parameters: the band gap of the ZnO films by doping with Cu atoms and the active surface area of the sample.

Methods
In this study, we have used the ALD technique to synthesize thin ZnO films and Cu-doped ZnO films on flat or porous silicon wafers. All pure ZnO samples were grown in a Beneq TSF 200 system at 180 °C using diethylzinc (DEZ, $Zn(C_2H_5)_2$) and distilled water (H_2O) as zinc and oxygen precursors, respectively. The source of copper in the ALD-grown ZnO samples doped with Cu was copper (II)

acetate ($Cu(OAc)_2$), evaporated at 180 °C from a hot source into the reaction chamber with nitrogen as carrier gas. The influence of the Cu dopants on the surface morphology and topology of the samples was investigated by scanning electron microscopy (SEM), the penetration depth of the ALD films into the pores was determined with focused ion beam (FIB), the crystallinity was investigated by grazing incidence x-ray diffraction (GIXRD). In addition, x-ray photoelectron spectroscopy (XPS) was used to analyze the chemical state of the Cu atoms and secondary ion mass spectrometry (SIMS) to determine the distribution of Cu atoms in the films. Finally, the photocatalytic activity was investigated by measuring the degradation rate of methylene blue (MB) in an aqueous solution under a UV and simulated sunlight irradiation.

Results

The ALD synthesis of ZnO, in which diethylzinc (DEZ) and water (H_2O) are used as precursors, usually leads to polycrystalline films. Size, shape and crystal orientation of the ZnO grains are influenced by deposition parameters such as temperature, pulsing and purging times of the precursors and substrate type. Our analysis starts with microscopic SEM images of undoped and Cu-doped ZnO samples on flat and porous substrates. The different surface morphologies observed in our samples correspond to variations in grain orientations within the films, as shown by the XRD patterns of the ALD-grown films. The penetration depth of pure ZnO and Cu-doped ZnO films on porous substrates was determined by examining the cross-section of the film profile within the pores using FIB.
The oxidation state of the copper was determined by XPS analysis around the Cu 2p core levels. The XPS analysis revealed two sharp and symmetrical peaks without satellite lines, demonstrating the presence of Cu+ states in the Cu-doped sample. In addition, the SIMS measurements determine the in-depth distribution of Cu dopants. The concentrations of Zn and Cu appear to be consistent throughout the film, with a sharp drop at the interface between the ZnO film and the Si substrate. Finally, we investigated the photocatalytic activity of pure and Cu-doped ZnO films grown on flat and porous substrates under UV light and simulated sunlight. For this purpose, we immersed the samples in an aqueous solution of methylene blue (MB) and monitored the degradation rate of MB. First, we investigated the photocatalytic activity of pure ZnO films grown on both flat and porous substrates under UV light. The porous sample showed many times higher photocatalytic activity than the flat sample. We then investigated the photocatalytic activity of Cu-doped ZnO films on flat and porous substrates under simulated sunlight irradiation. The increased surface-to-volume ratio improves the availability of surface sites, which significantly enhances the photocatalytic activity of the porous sample.

Conclusion

In summary, we have investigated the structural and photocatalytic properties of flat and porous ZnO films doped in situ with Cu during the ALD process. Our results shows that ZnO films synthesized on porous substrates exhibit better photocatalytic performance under UV light than those grown on flat substrates. In addition, the Cu-doped compared to the Cu-doped films on flat substrates. By doping the ZnO ALD films with Cu atoms, we successfully shifted the photocatalytic activity from UV to visible light. In addition, by increasing the surface-to-volume ratio, we have significantly increased the photocatalytic activity.

Poster Group 1

Background

Thanks to its high electrical conductivity and exceptional thermal and chemical stability, rutile ruthenium dioxide (RuO2) has attracted significant attention across a range of applications in energy storage and microelectronics [1]. Research indicates that RuO2 behaves as a Dirac nodal line semi-metal with flat band surface states, and it theoretically demonstrates a novel crystal Hall effect [2], thus reasserting itself as a quantum material [3]. Particularly intriguing is the rutile phase of ruthenium dioxide (RuO2), which epitaxially oriented along the (110) direction on rutile titanium dioxide (TiO2) substrates, displays remarkable anisotropic behavior, possibly originating from a 2.2% tensile strain along the [1$\bar{1}$0] direction and a 4.9% compressive strain along the [001] direction. This anisotropy, stemming from the interaction between crystallographic orientations and epitaxial strain, provides fertile ground for both fundamental research and technological exploration [4,5].
Transmission electron microscopy (TEM) researchers to probe the atomic-scale structure and defects at interfaces with unprecedented precision. In this context, the interface between RuO2 and TiO2 in (110)-oriented films has garnered considerable attention.
In this work, we characterize (110)-oriented RuO2 films on TiO2 substrates using TEM techniques. Specifically, we focus on the detection and analysis of dislocations and stacking faults within the RuO2 film, as well as the variations in defect density along different in-plane directions.

Methods
An 11 nm Hybrid MBE-grown rutile film of RuO2 oriented along (110) on rutile TiO2 (110) substrate was used in this research. Transmission electron microscopy (TEM) samples were prepared using a Focused Ion Beam Scanning Electron Microscope (FIB-SEM) equipped with a Ga ion gun (Thermo FEI Helios 5 FIB). A tungsten (W) and carbon (C) film were deposited on the area of interest before FIB milling to protect the surface from ion damage. A double-corrected TFS Spectra Ultra HRTEM/STEM (operated at 300 keV) is used to acquire high annular angle dark field (HAADF) micrographs and Energy-dispersive X-ray spectroscopy (EDS).

Results
Figure 1 displays High-Angle Annular Dark Field (HAADF) micrographs across the RuO2/TiO2(110) interface along [001] and [1$\bar{1}$0] zone axes. The accompanying EDS elemental maps in Fig. 1 revealed the presence of a Ru-oxide film on the surface of TiO2. Inverse FFT techniques were used to unveil defects during atomic-scale investigations. Interestingly, it can be observed from Fig. 1(b) and (c) that there are no defects at the RuO2/TiO2(110) interface along the [001] zone axis. However, various defects become apparent at the interface when changing the zone axis from [001] to [1$\bar{1}$0].
Severe lattice distortions were observed at the interface between RuO2/TiO2 (110) along [1$\bar{1}$0] zone axis. In the corresponding enlarged lattice, dislocation loop, stacking faults, and dense dislocation

arrays were observed. All were caused by strain induced lattice distortion in [1$\bar{1}$0] direction. An exploration as the origin on these defects and their confinement to the tensile strain zone axis is underway.

Conclusion

Aberration-corrected scanning transmission electron microscopy (STEM) operating at 300 keV was employed to analyze the atomic-scale interface of RuO_2 and TiO_2 (110) along both the [001] and [1$\bar{1}$0] zone axes. Utilizing the inverse FFT method, various dislocations and defects were identified. Specifically, dislocation arrays and dislocation loops were observed within the RuO_2 film along the [1$\bar{1}$0] zone axis. Furthermore, stacking faults were observed near the RuO_2/TiO_2 interface along the [1$\bar{1}$0] zone axis, potentially attributed to strain effects.

Background
The study of prevalent defects and their impact on functional properties is a critical issue for the successful implementation of 2D materials in next generation devices. However, the direct quantitative characterization of a specific defect is a challenging task, requiring atomic resolution measurements that are sensitive to the electronic structure of the material. The use of differential phase contrast (DPC) in scanning transmission electron microscopy (STEM) is particularly promising for this purpose, leveraging the natural coupling between the electron probe and the atomic-scale electric fields within a sample, which leads to a redistribution of intensity at the diffraction plane. For thin specimens, the centre of mass (CoM) of the diffraction disc is then directly related to the phase gradient, allowing for the mapping of electrostatic forces between atoms of the material structure, a capability which has already been demonstrated in the study of several 2D materials [1–4].

CoM-based measurements can be performed with pixelated detectors, capable of recording the entire diffraction disc, or with segmented detectors that integrate the intensity of the disk over independent quadrants. Pixelated detectors offer the greatest accuracy, but the faster processing times associated with segmented detectors allow for the generation of DPC-STEM images in real time, making it easier to identify interesting features and to correct electron lens aberrations. Additionally, series acquisitions and larger fields of view become more manageable, greatly aiding in the observation of easily damaged 2D materials. These benefits, along with the fact that segmented detectors are still the most accessible option, make it worthwhile to explore methodologies to manage their reduced accuracy. For this reason, it is essential to understand the precise effect of instrumental parameters on segmented-detector DPC STEM observations, such that their influence may be accounted for when analysing the results.

Methods
In this work, the influence of key instrumental parameters – probe convergence angle, defocus and detector orientation – on the retrieval of atomic-scale electrostatic field and potential configurations obtained from COM-based images is analysed, by determining the qualitative and quantitative changes induced by each of the parameters. This analysis is based on extensive multislice simulations of DPC- and COM-STEM images, in which the impact of each parameter under study is evaluated independently. Due to the complications of directly interpreting and comparing the vectorial electrostatic field images, these are analysed by representing the vector field in scattergrams [5] – polar graphs where the COM vectors associated with the pixels of the original image are plotted as points (Figure 1). This representation allows us to readily evaluate and compare the maximum magnitude of the measured field configurations in every direction, as well as to more easily detect qualitative changes. The scalar electrostatic potential images are directly compared through relative

difference maps that show the increase or decrease in magnitude at every pixel of the imaged region, allowing for a more spatially detailed analysis.

Results
Analysis of the influence of convergence semi-angle shows how an increased angle leads to higher susceptibility to the aberrations studied, despite the improved resolution. In the case of defocus, a maximum relative change above 30% is determined in the electrostatic field images for an angle of 30 mrad, at the limit of image interpretability, whereas the impact grows at a slower rate with increasing defocus for angle of 21 mrad. Additionally, overfocus primarily affects quantification, while underfocus results in more qualitative changes to the electrostatic configurations, albeit with a reduced quantitative impact. Two-fold astigmatism has a more pronounced impact in the field configurations, with maximum relative magnitude changes higher than 60% and stronger qualitative effects. The influence of this asymmetric aberration is shown to have a resonance effect with the orientation of the segmented detector, varying the identified magnitude of quantitative and qualitative impacts.
The electrostatic potential images show the same trend as that identified in the field configurations; however, the average relative changes identified are much lower, demonstrating an improvement in image quality due to the integration applied.

Conclusions
Following the procedure described, the relative quantitative and qualitative changes in electrostatic field and potential images due to the influence of key experimental parameters are identified. Differences in impact between imaging at over- and underfocus are determined and the more complex impact of asymmetric aberrations is analysed by considering the influence of two-fold astigmatism, identifiying a resonance effect with the orientation of the segmented detector.

Analysis of photon bunching in coherent cathodoluminescence

Mr Sotatsu Yanagimoto[1], Dr Naoki Yamamoto[1], Dr Takumi Sannomiya[1], Dr Keiichirou Akiba[1,2]

Background
Cathodoluminescence (CL) microscopy, utilizing an electron beam of an electron microscope, is a powerful approach for accessing nanoscale optical information of materials and devices. Furthermore, the time correlation measurement of CL by the Hanbury-Brown=Twiss (HBT) interferometer enables lifetime analysis without pulsing the electron beam by utilizing the photon bunching features [1]. This CL-HBT microscopy has been applied in various ways, such as lifetime measurements of semiconductors and dielectrics [2] and evaluations of the Purcell effect [3]. The origin of the bunching in CL has been investigated through a semiclassical description [4] and descriptions starting from quantum master equation [5] and is understood to be due to the random time modulation of excitation event by the fast electrons. The CL process can be classified into two classes depending on their excitation mechanisms, namely coherent CL (CCL) and incoherent CL (ICL). In the CCL process, fast electrons directly generate photons, e.g., transition radiation or Cherenkov radiation. On the other hand, in the ICL, photons are indirectly excited through mediator particles, such as bulk plasmons or secondary electrons, thus involving relaxation processes. Examples of the ICL are emission from defects and semiconductors. It is theoretically expected that the photon bunching can be observed even in CCL as far as emission events of two or more photons are included. However, most discussions on photon bunching using CL-HBT focused on ICL, and few studies have been reported regarding CCL. In this study, we experimentally confirmed the bunching phenomenon in CCL. By formulating the correlation function, we propose a method to extract the photon statistics in individual excitation events, excluding the bunching enhancement effect due to the excitation timing modulation.
Methods
Considering the semiclassical model, where n-photons are excited by a single electron, split by a half-beam splitter, and then detected by two single-photon detectors, the correlation function can be formulated. The analytical formula includes the parameters of electron beam current, correlation time and inherent correlation factor which reflects the fluctuation of the number of photons excited by a single electron. In CCL, it is expected that the photon statistics follow the Poisson distribution, and the inherent correlation factor should equal to unity. We performed this statistical analysis for localized surface plasmon (LSP) radiation, which is one of the typical examples of CCL, using a silver nanosphere with a diameter of approximately 200 nm, as schematically shown in Fig.1 (a).
We utilized a scanning transmission electron microscope (STEM) equipped with a CL detection unit and an HBT interferometer [3]. The light emitted from the sample was guided out of the STEM column by a parabolic mirror to the HBT measurement system. We performed the measurement at room temperature at an accelerating voltage of 160 kV.
Results
From the HBT measurement of the LSP radiation, we observed photon bunching, as shown in Fig. 1(b). The correlation time is approximately 400 ps, which reflects only the temporal resolution of our instrument, indicating that the lifetime of LSP is extremely short and cannot be resolved. We can observe a trend where the bunching height decreases with an increase in the electron beam current.

Figure 1(c) shows an inversely proportional dependence of the correlation function on the electron beam current; such a tendency is described from our analytical formula. On the other hand, from Fig.1 (d), the values of the inherent correlation factors are approximately 1 for all the beam currents. This suggests that the photon statistics of LSP radiation follow the Poisson distribution, which is consistent with the theoretical predictions. Additionally, the independence of the inherent correlation factor on the electron beam current indicates that the pure photon statistics by a single electron excitation is effectively extracted by removing the effect of the time modulation of the excitation event by fast electrons.

Conclusions

Through the analysis of the correlation function obtained from the HBT measurement of CL, we successfully extracted the coefficient which reflects the fluctuation of the number of photons excited by a single electron. We believe that this method is useful to investigate the elementary processes of photon generation by fast electrons.

The structural basis for energy extraction from air by Mycobacterium smegmatis

Ashleigh Kropp[1], Hari Venugopal[2], Chris Greening[1], Rhys Grinter[3]
[1]Department of Microbiology, Monash Biomedicine Discovery Institute, Monash University, Clayton, Australia, [2]Ramaciotti Centre for Cryo-Electron Microscopy, Monash University, Clayton, Australia, [3]Department of Biochemistry and Pharmacology, Bio21 Molecular Science and Biotechnology Institute, The University of Melbourne, Parkville, Australia

LS-09, Lecture Theater 4, august 27, 2024, 14:00 - 16:00

Background
Mycobacterium smegmatis is a heterotrophic, obligately aerobic soil-dwelling bacterium that requires organic carbon for growth. Due to fierce competition for resources in the soil, the bacterium often experiences deprivation of both oxygen and organic carbon sources. To cope with this, M. smegmatis has evolved to persist through metabolic flexibility, upregulating enzymes, such as the high-affinity [NiFe] hydrogenase Huc, that enable it to utilise electron donors and acceptors other than organic carbon and molecular oxygen. Huc provides electrons from H_2 to the cytochrome bcc-aa3 oxidase super complex via the quinone pool, which results in the generation of the proton motive force. The molecular details underpinning hydrogen oxidation in M. smegmatis were unknown. We aimed to characterise how Huc oxidises hydrogen and how the electrons liberated from this process are transferred to the respiratory chain.
Methods
In this work, we purified Huc natively from an M. smegmatis strain and visualised it by cryo-electron microscopy (cryo-EM). We used a wide range of techniques to characterise the enzymatic capabilities of this unique enzyme. Utilising an H_2 sensing electrode and gas chromatography, we quantitated the kinetics of hydrogen oxidation by Huc and the specificity of Huc to different electron acceptor molecules. Further molecular dynamics simulations and mass spectrometry enabled us to identify the specific electron acceptor substrate of Huc. To characterise how this enzyme differs from other low-affinity hydrogenases, we employed spectroscopic and electrochemical techniques.
Results
Our cryo-EM maps of Huc revealed an impressive enzymatic structure with electron density maps at a maximum resolution of 1.52 Å. Uniquely, Huc is an octamer of the large and small enzymatic subunits, with an additional novel membrane-associated central stalk. We showed that this stalk, called HucM, is critical for transporting the electron acceptor molecule menaquinone directly from the bacterial membrane to the enzyme. This long-range quinone transport is a unique feature of Huc. Further, we demonstrated for the first time a very high-affinity purified enzyme capable of oxidising atmospheric H_2 in isolation from the respiratory chain. In addition, we demonstrated that, unlike many other [NiFe] hydrogenases, Huc is insensitive to inhibition by oxygen.
Conclusions
This work represents the first molecular characterisation of a member of a novel family of hydrogenases capable of scavenging H_2 at atmospheric concentrations. This discovery will provide insights for the investigation and development of hydrogenase-based fuel cells that can operate at atmospheric levels of oxygen and use very small amounts of hydrogen to produce energy.

Simple and efficient three-dimensional reconstruction method of plant cells using transmission electron microscope

Ms. Haruka Aoki[1], Ms. Mizuki Matsuzaki[1], Mr. Hideo Nishioka[1], Ms. Chieko Hamamoto[1]
[1]JEOL Ltd., Akishima, Japan

Poster Group 2

Serial section transmission electron microscopy (ssTEM) is a vital technique in Volume Electron Microscopy (vEM) for unveiling fine structures of cells and tissues in three dimensions (3D). While the ssTEM provides superior X and Y resolution compared to other vEM, it is a challenge to acquire wide field of view images. Conventional mesh grids, for instance, often obscure the desired field of view with mesh bars. Even single-hole grids without bars, the support membrane remains susceptible to tearing and wrinkling, risking the loss of information. To address these challenges, we employed SiN Window Chip [1] for ssTEM. SiN Window Chip has no bars, ensuring uninterrupted observation without any missing information. In addition, its support membrane, made of high-strength silicon nitride film, minimizes the risk of tearing, distinguishing it from single-hole grids. We collected approximately 50 sections, each 70 nm in thickness, onto each of the five SiN Window Chips, resulting in a total of about 250 serial sections. The serial section images of a carrot leaf cell were obtained with a sample holder capable of simultaneously mounting multiple SiN Window Chips. For data acquisition, we used a new 120-kV transmission electron microscope (JEM-120i) equipped with a pole piece that provides high contrast. We attempted to undertake a segmentation analysis of organelles from the 177 TEM images.
Segmentation for annotating regions of interest continues to rely largely on manual methods. This task requires extensive time and effort, a challenge commonly encountered in other vEM as well. To streamline this task, we used convolutional neural networks (CNN) [2], a subtype of deep learning. Only a small number of images were required as training data; chloroplasts were manually segmented from just five images of 512x512 pixels (18.4 nm/pixel). Subsequently, a model was trained using deep learning based on these training data, and chloroplasts were inferred from all TEM images. The entire process, from model training to inference, took only an hour. In contrast, if performed manually, this process would take several weeks. As a result of 3D reconstruction of a cell body and chloroplasts, we gained insights into their shape, distribution, and volume.
Performing 3D reconstruction based on the inference results obtained through deep learning enables streamlined analysis of the shape and distribution of the target tissue. Additionally, the trained model can be applied to different serial section data. We successfully employed the model to other fields of view obtained from the same specimen. Therefore, we anticipate that this method can also reduce the time required for training data creation.

Poster Group 1

Time-resolved high speed TEM imaging technique is of great importance for in-situ observations such as heating/cooling, biasing, stressing, and liquid-cell experiments. Recently camera's frame rate is getting faster, but to dynamically visualize a structural change process of materials happen at a high speed, it is necessary to record TEM micrographs with a higher frame rate in the order of sub-millisecond.
Electrostatic type deflector can deflect the electron beam in tens of nanoseconds to microseconds. To using this property, there is a possibility to realize a high-speed imaging technique. In this study, we demonstrate a result of feasibility test for this system, electrostatic sub-flaming system developed by IDES Inc. This method improves temporal resolution by effectively increasing the frame rate while maintaining the same performance of the existing camera.
Fig. 1 shows schematic illustration of experimental setup. Electrostatic electron beam deflectors were installed beneath a projector lens cross-over in TEM column with a CMOS camera. The deflector itself acts as an aperture, limiting the area of the camera's sensor to which the electron beam is exposed, thus producing a small TEM image (sub-framed TEM image). By electrostatically deflecting the sub-framed TEM image at high speed in front of the camera sensor during exposure time, the images are laid out like 5x5 or 7x7 tiles. By doing this, each sub-framed image having a different time stamp. The difference between the timestamps of each sub-frame image is the time resolution.
Using this system, we observed time-series changes in (111) surface facet structure of CeO2 nanoparticles [1]. The data was recorded in 7x7 sub-frames. Since 49 sub-frames are recorded in one frame (CMOS Camera's exposure time is set to 40 ms), the exposure time per single sub-frame image is ~0.82 ms. The frame rate increased 25 fps to 1,225 fps. The 1st (0 ms) and 6th (4.08 ms) sub-frame TEM images are shown in Fig. 2. The atomic columns indicated by the arrows can be clearly seen in the 1st image, but are obscured in the 6th image. Motion of the atomic column of CeO2 (111) surface ware successfully observed in atomic level with a time scale of 4 ms by enhancing an effective frame rate of camera acquisition.

IM-04 (2), Lecture Theater 1, august 27, 2024, 14:00 - 16:00

Background incl. aims
Cryogenic transmission electron microscopy (cryo-TEM) has been significantly advanced in the past decade for imaging macromolecular protein complexes and cellular structures with close-to-atomic resolution in three dimensions [1]. Beyond life sciences, cryo-TEM has also enabled observation of otherwise inaccessible information in weakly bonded and reactive materials that typically degrade under electron irradiation or environmental exposure [2]. Furthermore, many of the exotic properties in quantum materials, such as, superconductivity, charge density waves, quantum hall effect, and topological behaviours, only manifest at extremely low temperatures [3]. Historically, a few top-entry TEM stages were developed allowing specimen temperature cooled down to even 1.5 K [4]. Those designs were seldom followed up because of the preference towards more flexible and versatile side-entry specimen holders, especially to introduce different kinds of external stimuli for in situ and operando studies. On the other hand, currently existed liquid helium (LHe) cooling side-entry holders are usually very difficult, if not impossible, to reach and maintain a long-time stability of the ultimately low temperature (close to LHe temperature, 4.2 K). This is firstly limited by their considerable mechanical and thermal instability, and, in addition, their base temperature hold time is typically short because of the low latent heat of LHe and the limited cryogen capacity of the dewar attached to the back end of the holder.
Methods
In this context, a new miniaturized continuous-flow LHe cryostat was designed for in situ cryo-TEM applications. This was initially created for X-ray diffraction experiments in pulsed magnetic fields and later adapted to TEM side-entry holders by condenZero, a spin-off company from the University of Zurich, with further test and optimization in cooperation with the Ernst Ruska-Centre (ER-C) in Research Centre Juelich. The full setup is illustrated in the enclosed figure. A purpose-designed vibration damping stage, consisting of a few active and passive damping units, is of vital importance to this system. It suppresses significantly the external vibrations from the floor and environment as well as from the boiling of cryogen during transfer. The LHe transfer line is developed to maximise its flexibility and thermal efficiency, which further minimises the vibration as well as the cooling loss during transfer. A gas He outlet port is spared on the transfer line to support He recovery in order to save the consumption of the valuable He resource. The transfer line, at its end, is docked to the specimen holder with a bellow connected in between for the final stage vibration isolation. The holder can host either standard 3mm TEM grids or MEMS chips for in situ and operando cryogenic measurements. At least 10 electrical feedthrough is integrated to this holder, with 4 for the built-in Cernox temperature sensor and 6 for electrical biasing or heating. The tip of the holder, where the specimen sits, is fully surrounded (except two holes of 3 mm in the top and bottom for electron beam transmission) by a thermal shield cooled at the same temperature as the specimen to avoid contamination build-up when the sample is cooled but also to suppress the heat radiation from the objective pole piece and other components that are at room temperature. This system is currently

installed on one of our image Cs-corrected microscopes, Titan HOLO, which is optimised for off-axis electron holography imaging (double biprisms with additional transfer lenses) as well as in situ and operando measurements (ultrawide pole piece gap). This microscope is recently upgraded with an ultrafast beam chopper and an event-driven delay-line detector, which would eventually allow time-resolved cryogenic biasing measurements.

Results

A typical cool-down curve is shown in the enclosed figure. Starting from room temperature, a base temperature of 5.2 K, measured by the Cernox sensor very close to the specimen position, was reached within one minute and kept stable with temperature fluctuation of +/- 2.5 mK over hours. Because of the continuous flow design as well as the highly efficient cryogenics that currently consumes only 2-3 liter LHe per hour, the ultimately low temperature can easily last for more than 24 hours with the 100 liter LHe dewar. We have tested this system with a few applications, including magnetic solitons, superconductors, dielectrics and soft matters, by measuring their defocused Lorentz imaging, off-axis electron holography or electron diffraction. As an example, which is shown in the enclosed figure, the high stability of this system at ultimately low temperature allows us to quantitatively map the magnetic states of Bloch skyrmions in B20-FeGe at 5.2 K with 200 mT out-of-plane magnetic fields using off-axis electron holography. Furthermore, we also tested the in situ biasing and heating capabilities based on different MEMS chips on this holder. With four-probe measurements, we can measure the electrical resistivity drop of superconducting structure across its transition temperature and can also heat up very locally the specimen from cryogenic to elevated temperature (above room temperature).

Conclusion

We have developed a new continuous-flow LHe-cooling holder for in situ and operando cryogenic TEM applications. It is featured by very swift cool-down and ultra-long cryo-hold time at ultimately low temperature with minimal thermal fluctuation as well as in situ electrical biasing and local heating functions. Further optimisation on this system will also be discussed during the presentation.

Revealing the origin of green light emission in Cs4PbBr6 by cathodoluminescence

Tetsuya Kubota[1], Mr. Sotatsu Yanagimoto[1], Prof. Hikaru Saito[1,2], Dr. Keiichirou Akiba[1,3], Prof. Ayumi Ishii[4], Prof. Takumi Sannomiya[1]

PS-11, Lecture Theater 2, august 28, 2024, 14:00 - 16:00

Background
Metal halide perovskite is expected as next-generation material for the application for solar cells and light-emitting devices due to their excellent optical properties. Among them, Cs_4PbBr_6 has obtained significant attention as a luminescent material for its high-efficiency green emission and ease of synthesis. However, the mechanism of this green luminescence from Cs_4PbBr_6 has not been understood so far since the bandgap energy of Cs_4PbBr_6 lies in the ultraviolet range, which suggests that the green emission originates from intermediate states formed by impurities or defects within the host phase [1].
Previous discussions have proposed that $CsPbBr_3$ nanocrystals embedded in the Cs_4PbBr_6 host phase are the primary candidates for the green light source [1]. However, conventional photoluminescence measurements cannot spatially resolve such nanocrystals, and thus definitive evidence has been lacking. Recently, cathodoluminescence (CL) studies taking advantage of nanoscale spatial resolution achievable by electron excitation have reported the presence of microcrystals dispersed within the host phase [2]. However, detailed information of these microcrystals as well as their luminescence mechanism remains unclear, necessitating further elucidation of local optical properties.
In this study, we evaluated the nano-scale optical properties of Cs_4PbBr_6 powder samples using CL with scanning transmission electron microscopy (STEM). CL spectral and lifetime mapping analysis with a temperature dependence validated the inclusion of $CsPbBr_3$ nanoparticles within the Cs_4PbBr_6 host phase.

Methods
CL Measurement: Light emitted from the sample by electron irradiation was collimated by a parabolic mirror inside the microscope and directed toward the spectrometer for the CL spectrum measurement and a Hanbury Brown-Twiss (HBT) interferometer for the emission lifetime measurement. By the HBT measurement, one can measure emission lifetime without pulsing the electron beam. In these measurements, the light detection and electron beam scanning were synchronized, enabling CL spectral and lifetime mapping.
Sample Preparation: Cs_4PbBr_6 powder samples, were synthesized via a solution method. CsBr and $PbBr_2$ precursors were prepared and held in dimethyl sulfoxide (DMSO) for one hour. The precipitate, grown by the anti-solvent method, was washed with DMSO to obtain a powdered sample. X-ray diffraction (XRD) analysis confirmed only peaks corresponding to Cs_4PbBr_6 in the crystal structure.

Results
The secondary electron (SE) image of the measured powder is presented in Fig.(a). The CL image revealed the existence of bright spots with high luminescence intensity within the particle (Fig.(b)). Furthermore, the area-integrated spectrum showed peaks at emission wavelengths of 375nm,

520nm, and 700nm (referred to as Peak1, Peak2, and Broad Peak, respectively). According to previous studies, Peak1 is attributed to the optical transition of Pb ions originating from Cs_4PbBr_6 [3]. Broad peak can be attributed to emission derived from some other defects according to a radio-luminescence study by X-ray [4]. Peak2 is the green emission that we discuss in this study.
In the CL spectral mapping on the same measurement area that was conducted at low temperature (120K), the emission intensity of Peak1 exhibited a homogeneous distribution across the entire area, whereas Peak2 showed high intensity specifically in the bright spot regions (Fig.(c-d)). CL spectra were extracted from the region with single bright spot (Spot1), and regions without bright spots (Matrix), shown in Fig.(e). In all regions, the intensities of Peak1 and Broad Peak remained approximately the same, while the intensity of Peak2 changed depending on the presence of spots inside the signal extraction area in CL mapping (Fig.(d)). Particularly noteworthy is the significantly lower intensity of Peak2 in the Matrix region. On the basis of these findings, it is considered that nanoparticles forming the bright spots emit green light within the host phase of Cs_4PbBr_6.
To further investigate the optical properties of the green light emission, CL measurements were both performed at room temperature and low temperature (120K). It revealed that the emission wavelength is longer and the emission lifetime shorter at 120K than at room temperature. These trends are opposite to typical semiconductor materials but are consistent with $CsPbBr_3$ nanoparticles without a bulk host material [5]. This suggests that $CsPbBr_3$ nanoparticles surrounded by Cs_4PbBr_6 host phase are the origin of the highly effective green light emission.

Conclusions
In this study, we conducted nanoscale evaluation of the optical properties of Cs_4PbBr_6 using STEM-CL. By the spectral mapping, the presence of nanoparticles emitting green light within the Cs_4PbBr_6 host phase was observed. Furthermore, by measuring the spectra and lifetime under varying temperatures, it was confirmed that the characteristics of the green emission have the same tendency as bare $CsPbBr_3$ nanoparticles without a matrix. Thus, it is suggested that the highly effective green emission originates from $CsPbBr_3$ nanocrystals precipitated within the host Cs_4PbBr_6 material.

In-situ HAADF-STEM observation of phase transformation in microencapsulated Al-Cu-Si alloy

Dr Melbert Jeem[1], Dr Norihito Sakaguchi[1], Dr Takahiro Nomura[1]
[1]Faculty of Engineering, Hokkaido University, Sapporo, Japan

Poster Group 1

Background incl. aims
The increasing relevance of latent heat storage through phase change materials (PCMs) in advanced thermal energy storage technologies is underscored by challenges such as deformation during thermal cycling. This issue is typically mitigated by encapsulating PCMs to create microencapsulated PCMs (MEPCMs) with high thermal conductivity, rigid structures, and improved durability.1 Despite these enhancements, hysteresis during solidification remains a concern. Recent innovations include a core-shell structure of Sn@α-Al2O3 MEPCM that lowers the energy barrier for nucleation, effectively reducing hysteresis through the formation of localized Sn nanoparticles on an α-Al2O3 nanoparticle.2 Expanding on this, we used an Al-Cu-Si alloy for a similar MEPCM structure, achieving notable hysteresis suppression. Unlike Sn, Al-Cu-Si does not volatilize, avoiding the formation of oxide byproducts over repeated thermal cycles. These MEPCMs were calcined at 1000°C in an O2 atmosphere, developing a dense α-Al2O3 shell. However, no localized nanoparticles were detected, prompting further in-situ HAADF-STEM studies to explore hysteresis mechanisms in Al-Cu-Si@α-Al2O3 MEPCM.
Methods
Al-Cu-Si alloy (m.p. = 529 °C, ϕ ≈ 38 µm, 99.95% purity, Hikari Materials Industry Co., Ltd, Japan) was encapsulated with α-Al2O3 nanoparticles (ϕ ≈ 100-200 nm, 99.99% purity, Kojundo Chemical Laboratory Co., Ltd., Japan) using a dry synthesis method, as described in our previous study.2 The encapsulation was facilitated by a rapidly spinning rotor equipped with blades, which promoted the adherence of α-Al2O3 nanoparticles to the Al-Cu-Si microparticles. Sintering at 1000°C for 6 hours in an O2 atmosphere helped form a dense α-Al2O3 shell. For in-situ S/TEM sample preparation, a 6 × 6 µm lamella of the MEPCM was processed using FIB milling (JEM-9320 FIB, JEOL) followed by a standard lift-off procedure. A lamella of the raw Al-Cu-Si alloy was also prepared for comparative analysis. The lamella was placed on a MEMS-based microheater (FEI) with a silicon nitride heating element capable of reaching temperatures up to 1000 °C (Fig. 1). The lamella was positioned over the electron-transmissible window, and the holey film was removed by FIB milling to eliminate non-sample-derived Si X-rays. To secure and enable heating of the lamella, a 300 nm thick tungsten (W) film was deposited at the contact area between the lamella and the heating pad using FIB. S/TEM observations were performed using a Titan3 G2 60-300 (FEI) double aberration-corrected microscope, operated at 300 kV. In-situ heating observation involved acquiring a series of HAADF images with a convergence angle of 17.9 mrad. The camera length was set to 115 mm for a HAADF collection range of 51–200 mrad. The series were taken with a pixel size of 512 × 512 and a dwell time of 2 µs/pixel, resulting in an image frame rate of 787 ms/frame. The probe current was set to 44 pA. The MEMS microheater's temperature was controlled using a closed-loop feedback system to prevent temperature undershoot or overshoot, starting from room temperature and increasing to a maximum of 500 °C at a rate of 5 °C min-1, similar to the heating rates used in differential scanning calorimetry (DSC) for latent heat measurements. A series of HAADF images were taken during each temperature ramp. The temperature was maintained at each 100 °C increment until no further changes were observed, and EDX analyses were performed at each stage. The FEI heating holder's

slight curvature over the microheater's window slightly compromised EDX signal counts for the 4-quadrant Super-X windowless detectors. EDX maps were acquired with a resolution of 256 × 256 pixels, a dwell time of 20 µs, and a total of 250 – 350 frames per map.

Results

The target observation area focused on the core-shell interface structure consisting of α-Al2O3 and the Al-Cu-Si alloy. Compared to the raw Al-Cu-Si, the calcined MEPCM exhibits coarsening of intermetallic Cu2Al and Si. In-situ heating observation of the raw substrate revealed initial dendritic Si structures becoming denser and increasingly aligned with the Cu2Al structure during heating from 100 to 500 °C. This suggests a possible higher melting temperature for Cu-Si formations, which remain solid even at the eutectic melting point of 529 °C. This compound is confirmed in the MEPCM calcined at 1000 °C, where it appears as dispersed nanoparticles in the primary Al matrix. During the temperature ramp from 100 to 300 °C, the applied voltage increased linearly while a notable increase in current is observed, likely due to the thermal lattice expansion of Cu2Al, which leads to fluctuations in electrical conductivity. This was validated by rigid registration of the acquired frames, confirming an approximate size increase of 100 nm in Cu2Al.

This behavior persists until 300 °C. Thereafter, during the ramp to 400 °C, the current value nearly stabilizes, indicating that the Cu2Al phase is reaching its thermal stability limit and beginning to dissolve into the Al matrix. A continued ramp to 500 °C results in complete phase dissolution. This dissolution involves the diffusion of Cu and Al atoms out of the Cu2Al phase and into the surrounding matrix, driven by the gradient in chemical potential caused by temperature changes and the concentration gradients of Cu and Al in the different phases. Interestingly, during the complete phase dissolution, some phases from the Cu2Al adhere to the α-Al2O3 surface. Although α-Al2O3 acts as an inert barrier, surface defects and partial charges may provide sites for adsorption or chemical interactions. If the lattice constants of the dissolute phases are close enough to those of the α-Al2O3, epitaxial growth or nucleation could occur. Atomic resolution HAADF observations in the area where adhesion occurred confirm the presence of seed crystals.

Conclusions

The in-situ HAADF-STEM observations have provided valuable insights into the thermal expansion and dissolution behaviors of Cu2Al within Al-Cu-Si@α-Al2O3 MEPCM during heating. A critical observation from this study is the adhesion of dissolute phases from Cu2Al to the α-Al2O3 surface during phase transformation. This adhesion suggests a potential for epitaxial growth or nucleation at the interface, which could effectively induce nucleation in the Al-Cu-Si alloy during solidification, thereby suppressing hysteresis.

Microstructural characterization of Zr/ZrN and ZrN/ZrCN hard coatings using TEM

Dr. ANWAR UL HAMID[1]
[1]Core Research Facilities, King Fahd University of Petroleum & Minerals, Dhahran, Saudi Arabia

The nitride, carbide, and carbonitride of transition metal elements like Zr, W, Ti, and so on are commonly used to create hard coatings. Zirconium-based hard coatings are ideally suited for use in tribology, biomedical, and electronics applications due to their superior resistance to wear, corrosion, and erosion, as well as their high thermal stability, hardness, and biocompatibility.

We produced homogenous, robust, and mechanically well-performing Zr-based nanostructured hard coatings. Zr/ZrN and ZrN/ZrCN multilayers were deposited onto stainless steel 316L substrates by means of magnetron sputter deposition technique. Each individual layer's thickness ranged from 250 to 500 nm based on the coating's composition. The deposition parameters were adjusted to create two unique coating thicknesses of 2 and 3 µm.

Cross-sectional TEM lamellae were prepared and examined with a transmission electron microscope. To clarify the differences in phase and elemental constitution at the microscale, x-ray mapping data and selected area diffraction data was obtained from multilayers. The adherence was also evaluated by taking images and energy dispersive spectroscopy was used to examine the coating-substrate and layer-to-layer interfaces.

There was uniform, compact, and dense columnar growth of all the coating grains at the substrate/coatings interface, and no evidence of decohesion was seen. The ZrN/ZrCN coatings were found to have denser, finer, and more compact grains than the Zr/ZrN coatings. ZrN/ZrCN coatings outperformed Zr/ZrN coatings in terms of hardness, modulus, and H/E values. This suggests that ZrN/ZrCN coatings may be able to achieve better wear resistance and fracture toughness. The study's developed coatings are anticipated to be used in tribology due to their superior hardness and H/E properties.

SEM Insights: Sample Temperature Evolution during EBSD

Christina Koenig[1], Yi-Chieh Yang[1], Senior Researcher Alice Bastos S. Fanta[1], Professor Joerg Jinschek[1]
[1]National Center for Nanofabrication and Characterisation (DTU Nanolab), Kgs. Lyngby, Denmark

Poster Group 2

Background incl. aims
Electron Backscatter Diffraction (EBSD), with application in geology, ceramics, semiconductor, and metals research, enables a comprehensive analysis of the microstructure in materials. By mapping crystallographic orientation it aids in understanding phenomena, such as character of grain boundaries, etc., for the investigation of crystal/grain growth, phase transformations, as well as the detailed analysis of material deformations and strain.
Despite its widespread use, still many challenges remain, such as the effect of sample surface roughness, sample preparation artifacts, sample drift during data acquisition, image distortions due to the sample positioning and drift, effect of surface contaminations, as well as simply the complexities in EBSD data interpretation. This is stimulating ongoing research and requests further improvements.
Furthermore, potential effects of the electron beam itself, particularly beam-induced heating, remain an unexplored concern . Such effects could affect the microstructure of examined samples or lead to inaccuracies in assumed temperature conditions during experiments, in particular in in-situ heating experiments. Here, we aim to investigate these effects to better understand their impact on samples and discuss potential associated drawbacks.
Methods
In-situ heating holders based on micro-electro-mechanical systems (MEMS) were initially developed for stable and accurate transmission electron microscopy (TEM) investigations, but have since also found application in in-situ SEM experiments. Equipped with a four-point measurement system on their heating spiral, these holders provide real-time temperature feedback based on the measured resistivity of the heating spiral material, enabling precise temperature control during experiments as well as a direct feedback on additional sample heating effects.
With this approach, in our study we want to investigate the effects of beam exposure on sample temperature of various materials, as well as significant data acquisition parameters (i.e. SEM acceleration voltage, beam current, dwell times) as they occur during EBSD measurements of bulk-like samples. By utilizing COMSOL, a finite element analysis tool, we simulate the Joule Heating of the MEMS device to predict the temperature distribution in our sample caused by the Electron Beam, thereby improving our understanding of the complex electron beam-sample interaction.
Results
Our study provides insights into the evolution of sample temperature under EBSD-relevant microscope conditions. We observed an increase in the sample temperature of approximately 40K in dependency of the acceleration voltage used for an Iron Sample. These findings we compare with our COMSOL modeling results.
Thereby, we will emphasize the significance of temperature effects, particularly in critical cases like beam-sensitive samples, where beam-induced sample heating could affect interpretation of microstructural analysis results.
Additionally, we highlight the effects of beam-induced heat during in-situ heating experiments in SEM as well as the importance of incorporating an active temperature control feedback loop in such setups.

Conclusion
Here we present a novel approach to real-time temperature monitoring of samples, particularly under EBSD-relevant measurement conditions. This will provide important insights into the dynamic thermal behavior of specimens during examination in a scanning electron microscope

Development of chopped scan control for beam blanking

Dr Grigore Moldovan[1]
[1]point electronic GmbH, Halle (Saale), Germany

Poster Group 1

Beam blanking is a technique in electron microscopy whereby the electron beam is interrupted from reaching the sample at high speeds or frequencies. This is required for a range of experiments, including lock-in amplification of minute signals, close control of electron dose/fluence, or capture of fast events with high temporal resolution or in synchronization with external clocks. Beam blanking is typically achieved by deflecting the beam from the optical axis with added blanking plates into a purposely designed blanking aperture. However, this approach requires installation of additional hardware into the microscope column. Development of an alternative approach is presented here, where the beam is deflected using the normal scan control coils into a vacuum or sacrificial point in the sample plane. This removes the need of additional components in the microscope column and places the added complexity of beam blanking into the scan controller only.

Whilst blanking with the scan coils can be thought of as adding a second blanking pattern on top of the regular scan pattern, such a hardware configuration does not provide means to choose the position of the vacuum or sacrificial beam position, or to synchronize the two patterns, therefore the normal scan controller must take on the task of beam blanking in addition to beam scanning. This enables the user to freely define a position for blanking, which may be from a pre-scanned image, or from preplanned coordinates. Generation of both patterns from the same controller also enables the freedom to choose if blanking and scanning are synchronised to the same clock or are free running. Use of the scan controller in this fashion requires complex scan algorithms, as established scan patterns in electron microscopy already include advanced flyback strategies at end of line and end of frame.

Attached Figure presents such a scan pattern with blanking – a very small 3x3 pixel scan is shown here to simplify presentation, but resolution in this scan mode is only limited by the scan resolution of 16-bit corresponding to 65,536 x 65,536 pixels. A 1 µs acquisition time was used, with a line start wait of 10 ns, a beam return time of 320 ns, without any pre-scan, pixel settling or additional holding time. Digital frame, line and pixel trigger outputs typically used for detector or camera synchronization are shown here to guide the presentation and were set to a duration of 200 ns. A blanking reference frequency of 10MHz was selected for this example in order to give a visible blanking duration comparable to the pixel acquisition time. The blanking position was set to 0,0 (top left) and the image scan was set to begin at 32768,32768 (middle) of the scan space. Note in the analog scan outputs for column and row signals how the beam is encoded to jump between the blanking pixel and the image pixels, which gives a chopped appearance to the analog traces.

Practical application of this chopped scan mode for beam blanking will be shown in TEM and SEM, including the limitations to be expected from using the scan coils for such fast beam motion. It will be shown that hysteresis and amplifier bandwidth limitations restrict the maximum blanking speed possible to a range of approximatively 100kHz, which could be overcome with further development of distortion removal algorithms, however all this is achieved without modifications to the microscope column.

Analysis of the cause of imperfect adhesion of cataphoretic coating using SEM and EDS method

Ph.D. Zuzana Koutova[1], Ing. Marie Novotna[1]
[1]MemBrain s.r.o., Stráž pod Ralskem, Czechia

Poster Group 2

The automotive industry is one of the most overloaded and stressed in the point of view materials selection, characterization, application and their corrosion prevention and surface protection. Cataphoretic coating is one of the used and technologically most advanced method of anticorrosive surface treatment processes and it is usually used as surface treatment of metal products. The process itself is a set of several steps of pre-treatment, paint application and curing and although each sub-process is rigorously controlled (including production of parts and their storage), it can occur that the final product of the cataphoretic coating process are parts with a defective coating. Consequently, the anti-corrosion protection can be reduced even due to relatively small defects and thereby increasing, among other things, the safety risk. In this contribution, case study of the cause analysis of a non-conforming cross-cut test of cataphoretic coating surface on metal part is shown, where it is necessary to use the methods of scanning electron microscopy (SEM) and scanning electron microscopy with energy dispersed X-ray spectroscopy (EDS).

The metal part with a non-conforming cross-cut test of cataphoretic coating surface were examined by the SEM and EDS method. SEM analyses were taken with scanning electron microscope Quanta FEG 250 (FEI) at the regime pressure of the low vacuum mode and high vacuum mode. Further, EDS analysis were measured with TEAM™ Software Suite, coupled with the Octane Plus System, as well at the regime pressure of the low vacuum mode and high vacuum mode.

A metal part with a cataphoretic coating on the surface was examined in a place with a non-conforming cross-cut test. In this place (of the peeled coating on the metal part), elements that may originate from the zinc-phosphate layer were locally detected. Therefore, the peeled off coating from its underside was further analysed. Differently sized crystals were found here, and their composition may correspond to the zinc-phosphate layer.

Analyzing a metal part with a cataphoretic coating on the surface with with a non-conforming cross-cut test by using SEM and EDS methods, it was proven that the zinc-phosphate layer in the pre-treatment was applied, but did not adhere to the surface of the part as it should have. It is necessary to further focus on the individual steps of pre-treatment. There may have been insufficient degreasing at the beginning of the pre-treatment process. Or the cause is the poor quality of the zinc-phosphate solution.

TEM investigation of the defect structure in epitaxial corundum thin films

Claudio Bellani[1], Alberto Binetti[2], Wei-Fan Hsu[2], Simon Mellaerts[2], Koen Schouteden[2], Prof. Jean-Pierre Locquet[2], Prof. Jin Won Seo[1]
[1]Department of Materials Engineering, KU Leuven, Leuven, Belgium, [2]Department of Physics and Astronomy, KU Leuven, Leuven, Belgium

Poster Group 2

Metal oxides M_2O_3 thin films have extensively been studied as they offer a broad range of functionalities. Sapphire Al_2O_3 is the most common substrate for the epitaxial growth of several M_2O_3 since it shares the same corundum lattice (R-3c) with several M_2O_3 systems. Examples include Cr_2O_3, a magnetoelectric antiferromagnet with applications in memory devices, and V_2O_3, a popular material to study strong electron correlations. α-Fe2O3 and α-Ga2O3 also present the same corundum structure and have potential applications in catalysis and magnetic devices as well as power electronics, respectively.
A good understanding of the defect formed during the film epitaxial growth is crucial for both fundamental studies and devices. Examples of such defects present in M_2O_3 thin films grown on c-cut sapphire include twinning, columnar growth, misfit dislocations, screw dislocations and oxygen vacancies. In this work, the microstructure of Cr_2O_3 and V_2O_3 thin films are studied systematically. Our results indicate for these two M_2O_3 systems significantly different defect mechanisms.

All the thin films are grown by oxygen-assisted molecular beam epitaxy (MBE) on c-cut sapphire substrates at high temperature. V_2O_3 samples are grown at 700°C and Cr_2O_3 samples at 800°C. Base pressure of the system is 10E-10 Torr, while during the deposition the O_2 partial pressure is measured with a residual gas analyzer and kept constant at 2E-6 Torr. Bilayer structures have also been grown with V_2O_3 on a Cr_2O_3 buffer layer. The epitaxial growth is monitored in-situ in the MBE chamber by reflection high-energy electron diffraction (RHEED). X-ray diffraction (XRD) ϕ-scans are performed ex-situ after growth, and the twinned fraction of the film was estimated.
For transmission electron microscopy (TEM), cross-sectional lamellae are prepared by focused ion beam using DualBeam Nova 600 NanoLab and imaged by means of a cold-FEG JEOL ARM200F microscope equipped with a STEM-Cs corrector, operated at 200kV. Geometric phase analysis (GPA) of STEM images is also performed using the Digital Micrograph plugin developed by Du (Ernst Ruska-Center for Microscopy).

TEM images confirm the epitaxial growth of all the thin films. GPA strain maps highlight the strong lattice deformation at the interface linked to the presence of misfit dislocations, which appear periodically with an average distance of 9.5±1.5 nm at the V_2O_3/Al_2O_3 interface, when imaged along the <-2110> zone axis. This is comparable to the value expected when the lattice mismatch is fully compensated by incorporation of misfit dislocations, i.e. 10.2 nm for a 4.2% in-plane lattice mismatch. In contrast, strain maps of Cr_2O_3/Al_2O_3 films present strong deformations across the entire thickness of the film, despite having a very similar in-plane mismatch with the substrate (4.4%). In addition to misfit dislocations, the sample contains columnar domains and twinning. Columnar domains are best imaged with HRTEM and bright field STEM, although the grain boundary is not visible in the high-resolution STEM images. A similar bright field contrast is present in the V_2O_3 thin films as well, albeit less dense and with irregular shape. The presence of columnar domains in Cr_2O_3 thin films has been reported previously, and their origin was explained by an additional strain

relaxation mechanism beside the incorporation of dislocations. Secondly, twinning can be observed in the XRD ϕ-scan of the planes {10-110}, as a second set of 3 peaks appears while rotating the sample by 360° introducing an apparent sixfold symmetry instead of the trigonal symmetry of the corundum structure. However, XRD is unable to detect small, twinned fractions of the film which can be observed by TEM and are always present. Increased twinning is observed for samples grown with a higher Cr-flux rate, indicating that the precise growth parameters affect the formation of the twins. On the other hand, V_2O_3 does not present any twinning when grown directly on sapphire. Grown on a twinned Cr_2O_3 buffer, V_2O_3 shows the ability to recover to the untwinned structure despite the underlying twinned structure. This result is in contrast with other works where twinning in V_2O_3 and Cr_2O_3 appeared to be comparable. The absence of columnar and twinned domains in V_2O_3 thin films indicates a different strain relaxation mechanism in both M_2O_3 thin films.

Cross sectional TEM analysis of corundum M_2O_3 thin films grown on sapphire substrates indicates an intrinsic difference in the defect structure formed in Cr_2O_3 and V_2O_3 thin films. The former present misfit dislocations, columnar and twinned domains in agreement with previous studies, while the latter does not present any twinning and compensates the lattice mismatch only by incorporation of misfit dislocations.

Automated Alignment Strategies for Integrating Cryo 3D-SIM and SXT Data

Dr Joaquín Otón[1], Dr Josué Gómez-Blanco[1], Dr Johannes Groen[1], Dr Ana Joaquina Pérez-Berná[1], Dr Eva Pereiro[1]
[1]ALBA Synchrotron - CELLS, Cerdanyola del Vallés, Spain

IM-13 (1), Lecture Theater 5, august 27, 2024, 10:30 - 12:30

Background incl. aims
The correlation between Cryo 3D Structured Illumination Microscopy (3D-SIM) and Soft X-ray Tomography (SXT) has become a complementary tool for the comprehensive exploration of complex biological systems. The challenge in this correlative microscopy lies in aligning datasets acquired through different imaging modalities and reconstruction procedures. Cryo 3D-SIM and SXT data, while offering complementary insights into cellular structures, present inherent discrepancies due to their distinct imaging techniques. To address this challenge, our study aims to develop novel algorithms for automated alignment, with the goal of improving the integration of cryo 3D-SIM and SXT data. We aim to enhance the accuracy and efficiency of the correlative process by overcoming imaging and reconstruction differences, thereby facilitating comprehensive investigations into intricate cellular structures and their function.

Methods
Our study employs a multi-faceted approach to address the challenge of aligning datasets acquired through different imaging modalities and reconstruction procedures. Firstly, we utilize feature-based matching, leveraging distinctive features within both cryo 3D-SIM and SXT datasets. This involves conducting feature size range-based matching to establish correspondences between images, ensuring accurate alignment by identifying common structural landmarks present in both datasets. Subsequently, our alignment strategy is divided into two sequential processes. Initially, we perform a coarse 2D alignment, aligning a Soft X-ray mosaic view with a 2D projection of the 3D fluorescence data. Following this, we refine the alignment further through a fine iterative 3D angular and shift search, ensuring optimal spatial correspondence between the two 3D datasets. Additionally, considering the sparsity of SXT 3D data in the Fourier domain, we implement a novel 3D correlation process. This involves tomographic 3D-correlation based on 2D-correlation backprojection, focusing solely on effective data through tomographic backprojection reconstruction of 2D projection correlations. These methods collectively constitute our approach to automated alignment, aimed at enhancing the integration of cryo 3D-SIM and SXT data for cellular structures.

Results
We conducted extensive testing using experimental data to evaluate both 2D and 3D alignment approaches. For the 2D alignment approach, we utilized samples from the Huh-7.5 Human Hepatocellular Carcinoma Cell Line, where the signal emitted by mitotracker green was employed for alignment purposes. Despite the low resolution of the fluorescent signal, our approach consistently demonstrated good alignment across all cases. In contrast, for both 2D and 3D alignment approaches, we utilized experimental data from the work of Groen et al. [Groen21], which involved primary cardiac mouse fibroblasts and NIH-3T3 cells treated with TPR-Hsp90-AuNC with green emission (alexa-488). The manually aligned performed in [Groen21] has served as the benchmark for comparison with our automated results. Our findings reveal that the automated alignment results

exhibit a high degree of agreement with the manually aligned data, highlighting the reliability and accuracy of our methodology.

Conclusion
These results underscore the effectiveness of our approach in achieving precise alignment of both 2D and 3D datasets. The success of this automated alignment process relies on size range filters rather than specific landmarks, allowing for the effective fiducialization of various cellular structures, such as lipid droplets or mithochondrias. Additionally, our utilization of a 3D correlation process based on 2D correlations effectively addresses Fourier artifacts arising from the tomographic reconstruction process. Furthermore, the agreement between automated and manual alignment results further validates the robustness of our methodology, showcasing its potential for advancing correlative microscopy techniques.

Reconstruction of Angstrom resolution exit-waves by the application of drift-corrected phase-shifting off-axis electron holography

Jonas Lindner[1], Ulrich Ross[2], Tobias Meyer[1], Victor Boureau[3], Michael Seibt[2], Christian Jooss[1,4]
[1]1 Institute of Materials Physics, University Goettingen, Goettingen, Germany, [2]2, 4th Institute of Physics – Solids and Nanostructures, University of Goettingen, Germany, [3]Interdisciplinary Center for Electron Microscopy, École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland, [4]4 International Center for Advanced Studies of Energy Conversion (ICASEC), University of Goettingen, Goettingen, Germany

Poster Group 2

Background

Off-axis electron holography is a phase retrieval technique which enables access to the full complex-valued exit-wave of thin samples. The potential distribution at interfaces obtained from the measured phase information is highly relevant for in-situ experiments. Combining off-axis holography with the capabilities of an environmental TEM offers the ability for exit-wave reconstruction under external bias and in catalysis relevant gases and material systems. However, the conventional holography Fourier-reconstruction suffers from a trade-off between spatial and phase resolution caused by the fringe spacing and visibility. To tackle the open fundamentally questions in catalysis research, e.g. the atomic structure of the electrolyte-solid interface, the identification of active reaction sites and the influence of surface faceting, atomic resolution is highly desired. Therefore, state-of-the-art phase retrieval techniques must be adapted to the particular requirements of in-situ studies. Phase-shifting electron holography bypasses the spatial resolution limit by real-space evaluation of hologram series. However, to reach atomic resolution in reconstructed hologram-series, special care is needed to correct sample and biprism drift.

Methods

Phase-shifting holography acquires a series of holograms formed by tilted incident waves. This results in a shift of the hologram fringes, that are modulated by the potential of the specimen. If specimen and biprism drift are carefully corrected, the cosine intensity dependency of the hologram series can be used for linear fits of the local amplitude and phase of the exit wave. This obviates the use of the low-pass aperture which is necessary for the conventional reconstruction of off-axis holograms in the Fourier domain. The upper bound of the spatial resolution is thus only limited by the performance characteristics of the instrument, while the low-frequency information is also retained.

Results

Previous implementations of phase-shifting holography have been limited by the independent drift of biprism and sample and allowing for medium spatial resolution. We improve the reconstruction process by introducing a drift correction scheme and demonstrate exit wave reconstruction on platinum. The reconstructed exit-waves show reliable phase information at the 1 Å information limit of the used Titan 80-300 kV environmental transmission electron microscope. Simultaneously, the omission of the trade-off between fringe spacing and visibility leads to phase resolutions up to $2\pi/452$ rad at moderate birpism voltages of 250 V (fringe spacing 1 Å). The obtained phase and

amplitude information is validated at a thin Pt sample due to the excellent matching to frozen-lattice multi-slice image simulations.

Conclusions

In conclusion, we demonstrate the successful method improvement of the phase-shifting holography reconstruction process by introducing novel drift correction of the mixed signals of biprism and sample drifts. The reconstructed exit-waves of a thin platinum sample show spatial resolution up to the 1 Å information limit of the microscope simultaneously with a phase resolution up to 2π/452 rad. The exit-waves are in excellent agreement with multi-slice frozen lattice image simulations and preserve the high- and low-frequency information. The published method is applicable in any TEM equipped with a single electron biprism and thus allows to achieve high resolution off-axis holography in various instruments including those for in-situ applications. A software implementation for the acquisition, calibration and reconstruction is provided. The combination of environmental TEM and high-resolution phase-shifting electron holography grants access to the platinum-water interface at the atomic scale in ongoing studies.

The effects of TiC network microstructure on the mechanical properties of spark plasma sintered Al2O3

Umut Savaci[1], Salih Cagri Ozer[1], Eren Can[1], Yiğit Berkcan Harmankaya[1], Servet Turan[1,2]
[1]Eskisehir Technical University, Department of Materials Science and Engineering, Eskisehir, Turkey, [2]Ceramic Research Center, Eskisehir, Turkey

Poster Group 1

Background incl. aims
Al_2O_3-based composite materials are widely used for cutting tool applications due to their high strength, hardness and wear resistance. Despite these ideal mechanical properties, having low fracture toughness values and brittleness present problems during application. This study aimed to improve both the hardness and fracture toughness of Al_2O_3 simultaneously by taking advantage of different mechanisms with TiC network structures. Hardness was aimed to be increased by introducing the TiC secondary phase with high hardness throughout the Al_2O_3 matrix. On the other hand, fracture toughness was aimed to be improved by promoting crack deflection mechanisms by the formed network structure.
Methods
Al_2O_3 ceramics with TiC network microstructures were produced by the spark plasma sintering (SPS) technique by coating the Al_2O_3granules with 2-10 vol.% TiC powders, utilizing a simple dry coating method. The sintering process was carried out at a minimum of 1400°C dependent on the TiC content. The effects of various amounts of TiC addition and differing sintering temperatures on the microstructural and mechanical properties of Al_2O_3 were observed by scanning electron microscopy techniques as well as mechanical testing.
Results
Network structures of TiC were formed successfully around the Al2O3 matrix during the SPS process, resulting in simultaneous improvement of hardness and fracture toughness. Present TiC and Al2O3 phases were confirmed by the X-ray diffraction analysis. The fracture toughness of Al2O3 was improved by crack deflection and bridging mechanisms induced by the introduction of the network structure, as observed by the microstructural investigations. In addition, Vickers microhardness values of the samples were found to be increased with increasing volume fraction of TiC.
Conclusion
As a conclusion, in this study, mechanical properties of the Al2O3 ceramics were successfully improved by the formation of TiC network around Al2O3 granules. Electron microscopy studies revealed the formation of the continuous network around the matrix and microstructural features such as grain size, and porosity as well as toughening mechanisms.

VitroJet: ice thickness control and measurement for time-efficient single particle structure determination3052

Rene Henderikx[1,2], Prof. Peter Peters[2], Dr. Bart Beulen[1]
[1]CryoSol-World, Weert, The Netherlands, [2]Maastricht University, Maastricht, The Netherlands

Poster Group 2

Background incl. aims
Single particle cryo-electron microscopy (cryo-EM has emerged as a prevalent technique for structural biology due to its capacity to visualize of individual macromolecules, which is applied across a variety of diverse projects. However, the current practice of thickness screening and hole selection for data acquisition within the electron microscope consumes significant beam time. We aim to control and measure ice thickness during sample preparation, to predictably achieve high resolution.
Methods
The VitroJet is utilized for cryo-EM sample preparation, leveraging its automation to enhance productivity and increase accessibility for novice users. Pin-print sample deposition and jet vitrification combined provide a reproducible framework for generating high-quality grids.
Results
Multiple case studies employing the VitroJet showcase its benefits across various sample categories: membrane proteins, nucleosomes, fatty acid synthase, tick-borne virus, lipid nanoparticles, tobacco mosaic virus, and bacteriophages. By adjusting pin-printing velocity and standoff distance from pin to grid, we effectively regulated the median ice thickness, achieving a standard deviation below ± 11 nm for thicknesses up to 75 nm. The integrated optical camera enables precise measurement of ice thickness in individual holes with an accuracy below ± 20 nm within the 0 - 70 nm range. Data collection at 30 nm to 70 nm ice confirms the importance of ice thickness for time-efficient structure determination, with 3.7 times fewer particles needed to attain a resolution 3 Å.
Conclusion
Users in several labs worldwide have validated the versatility of the VitroJet across various sample types and workflows. The capability to control and measure ice thickness empowers users to optimize layer thickness on-the-fly during grid preparation, without the need of cryo-EM. Furthermore, the estimation of ice thickness facilitates targeted selection of holes for data collection based on optical imaging. This underscores how the VitroJet accelerates the entire workflow and enhances the efficiency of utilizing microscope infrastructure for data collection.

Direct observation of charge modulation in nanoprecipitates by 4D STEM

Dr. Juhyun Oh[1], Prof. Young-Woon Kim[1], Prof. Cheol-Woong Yang[2], Prof. Cheol-Hee Ahn[1], Prof Miyoung Kim[1]
[1]Department of Materials Science and Engineering, Seoul National University, Seoul, Korea,
[2]Department of Materials Science and Engineering, Sungkyunkwan University, Suwon, Korea

Poster Group 2

Background incl. aims
Charge modulations induced by structural, compositional and electronic variation in a solid can be investigated using various analytical techniques, including scanning tunnelling microscopy/spectroscopy, Raman spectroscopy, and recently available four-dimensional scanning transmission electron microscopy (4D-STEM), depending on the nature of the modulation. We explore the interplay between charge density modulation and structural distortion in nanoscale moiré structures, $MgZn_2$ nanoprecipitates imbedded in Al matrix using 4D-STEM.
Methods
A series of diffraction patterns by 4D-STEM offers a wide range of information, which includes local electric fields and charge density, in addition to atomic configurations. We integrated intensities at different scattering angles and directions to extract various types of images. Template matching was employed to the real space, depth-sectioned STEM images to locate the accurate atomic positions, which facilitated the mapping of local strain distributions within the imbedded nanostructures. Density functional theory (DFT) calculations are performed to find the origin of the charge modulation and multislice simulations are further employed to compare the experimental results with the theoretical prediction.
Results
We present center of mass (COM) images derived from the in-plane diffraction patterns of the MgZn2/Al heterostructure. Interestingly, the images clearly reveal charge density modulations which are highly dependent on the depth of the probe position in the specimen. Moreover, strain mapping within the Al matrix is intricately linked to charge modulation, suggesting the potential influence of structural distortion on the charge modulation. The periodicity and the location of the modulation are further analyzed to determine the correlation with the moiré supercell structures.
Conclusions
A series of multislice simulations generated numerous COM images, encompassing single atoms to stacks of multi-layers, at different probe depths. We propose that the primary contribution to the modulated charge distribution originates predominantly from the interface area between the $MgZn_2$/Al heterostructure. Furthermore, we demonstrate how manipulation of COM images provides more detailed insights into the structural and compositional variations within materials.

In-situ TEM annealing of vanadium oxide thin films

Claudio Bellani[1], Simon Mellaerts[2], Koen Schouteden[2], Alberto Binetti[2], Wei-Fan Hsu[2], Prof. Jean-Pierre Locquet[2], Prof. Jin Won Seo[1]
[1]Department of Materials Engineering, KU Leuven, Leuven, Belgium, [2]Department of Physics and Astronomy, KU Leuven, Leuven, Belgium

Poster Group 2

The multitude of vanadium oxide phases are traditionally grouped into two families: Magnéli phases (VnO2n-1 where 3 ≤ n ≤ 9) and Wadsley phases (VnO2n+1 where 1 ≤ n ≤ 6). These groups are characterized by the oxidation states V3+/V4+ and V4+/V5+, respectively, separated by the purely V4+ phase, i.e. VO_2.
Many of these vanadium oxides present a metal-to-insulator transition (MIT) upon cooling coupled with structural and occasionally magnetic transitions. Of all the VOx phases, VO_2 has attracted the greatest attention in terms of technological applications, because the electrical transition occurs close to room temperature at 68°C. The semiconducting monoclinic phase (P21/c) is most stable at room temperature and transitions into the metallic rutile phase (P42/mnm) above the transition temperature. The transition is accompanied by a change in resistivity up to 5 orders of magnitude in single crystals as well as in optical properties. This abrupt change has triggered a broad range of applications: e.g. thermal sensors, electrical switches, smart windows, optical limiting, modulators, bolometers, and Mott field-effect transistors.
The growth of VO_2 thin films requires a higher oxygen partial pressure than what is typical for the growth by means of MBE. Therefore, crystalline VO_2 thin films have been obtained by growing amorphous VOx and to convert to VO_2 through a subsequent annealing process. Very little is known about the structural transition from the amorphous to the crystalline phase, especially how the VO_2 phase is established, as well as the structural transition underwent during the MIT.
However, an in-situ transmission electron microscopy (TEM) experiment using an environmental cell experiment provides the possibility to live monitoring of the oxidation and crystallization process of the film by mimicking the annealing process in a furnace-like environment. The structural and chemical information collected during the in-situ annealing can shed light on the complicated mechanism involved in VO_2 films as a function of the temperature and the annealing environment.

VOx thin films are deposited directly on the MEMS chips of a closed-cell gas reaction system (Atmosphere, Protochips) by oxygen-assisted molecular beam epitaxy (MBE) at room temperature. The film is directly in contact with the electron transparent membrane of the chip which consists of 30 nm of amorphous Si_3N_4. The vanadium flux in the MBE is calibrated to 0.1 Å/s with a quartz crystal microbalance, and the total thickness of the sample is estimated to around 40 nm. Base pressure of the system is 1E-10 Torr, while during the deposition O_2 partial pressure is measured with a residual gas analyzer and kept constant at 2E-6 Torr. The sample is then mounted on the TEM sample holder and inserted into a cold-FEG JEOL ARM200F microscope equipped with a STEM-Cs corrector. The MEMS chip is heated up to 500°C in Ar or Ar/H_2 mixtures at 760 Torr with a 0.1 sccm flow. Base pressure of the closed-cell is 1 Torr. The sample is imaged both in TEM and STEM mode, with bright field (BF) and high-angle annular dark field (HAADF) detectors. Electron energy loss spectroscopy (EELS) is performed with a Gatan Tridiem detector in STEM mode to evaluate the local oxidation state with the V L edges and O K edge.

The as-grown sample is amorphous and dominated by the V3+ stoichiometry. As temperature increases in the closed cell, the first transformation occurs between 290-310°C for both Ar and Ar/H_2 mixtures. Several grains of a few hundred nanometers in size form, with irregular shape and areas showing different HAADF contrast. Grain boundaries are decorated with dark regions linked to V-deficiency. These areas gradually disappear as the temperature approaches 420°C, where the main crystallization takes place. The morphology of the annealed film shows a great variability with the different gas mixtures applied, while the EELS spectra generally confirm the oxidation of V3+ to V4+ and/or V5+. The residual O_2 in the closed-cell gas reaction system is expected to be responsible of the oxidation of the film, and the H_2 insertion is intended to counterbalance and to avoid the sample being further oxidized to V_2O_5. The fully polycrystalline film is stable until about 500°C when it transforms into V_2O_5, which very often forms elongated grains and leaves holes behind between these grains. Electron beam can additionally influence the annealing as it induces local heating of the film, with consequences on the final morphology and oxidation state.

The annealing of vanadium oxide thin films on amorphous substrates has been investigated in several reported works, with the goal of obtaining VO_2 polycrystalline films. The outcome is often complex, as the films frequently include additional phases alongside the desired monoclinic VO_2 phase, due to under or over-oxidation. The presence of multiple crystalline and amorphous phases, which has a detrimental effect on the electrical transition, complicates the thin film characterization by the most common techniques (e.g. x-ray diffraction, scanning probe microscopies, and x-ray photoemission). A closed-cell experiment in the TEM provides the possibility to mimic the annealing environment and to observe the structural changes as a function of the temperature and the environment. These results can enhance the understanding of the annealing process by combining structural and chemical information at the nanometric scale. In particular, a detailed nano-scale understanding of the oxidation/reduction routes in vanadium oxide films on amorphous substrates can be gained.

Annular silicon drift detector for advanced EDS on SEM applications

Dr. Igor Németh[1], Dr. Yang Yang
[1]Bruker Nano GmbH, Berlin, Germany

Poster Group 1

Background incl. aims
Energy dispersive X-ray spectroscopy in an SEM can be challenging in certain cases: if no sample preparation (cutting, polishing) is possible or allowed to generate a flat sample surface (which would be ideal for analysis). Furthermore, samples having low electrical conductivity or high electron beam sensitivity can only be investigated using low beam currents, which in turn results in a low X-ray signal. Under such conditions, trace elements cannot be analyzed using EDS within reasonable measurement times.
Methods
We present a solution for maximizing X-ray signal collection: an annular EDS detector, inserted between the pole-piece and the sample. High count rates can be reached even at low beam currents as the four separate X-ray detector segments cover a large solid angle (up to 1.1sr). Due to the high count rates, element distribution mapping (including trace elements) is orders or magnitudes faster than using conventional EDS detection geometry. This configuration is also ideal for the analysis of samples with high topography as shadowing effects are minimized by X-ray detection from all spatial directions.
Results
We present various examples benefiting from the annular acquisition geometry. Li-ion battery components (anode and cathode particles) or black mass material can be mapped with high spatial resolution without the need of any meticulous sample preparation. Contaminants and inhomogeneities in the submicron range can be visualized within the micrometer-sized particles. We will demonstrate that the annular EDS detector is capable of identifying and mapping contaminants in the range of only a few tens of ppm within a few minutes of measurement time. These findings will be compared to a classic trace element detection method (X-ray fluorescence).
Conclusion
The annular EDS detector in an SEM is a proven tool for challenging elemental analysis, such as unprepared samples with high topography and low conductivity (for example battery components: anode, cathode particles, black mass). Due to its maximized collection solid angle, this type of detector yields significantly higher count rates compared to conventional EDS detectors and thus considerably reduces the necessary electron dose or measurement time. EDS using annular detectors is an analytical method capable of detecting and mapping contaminants in the sensitivity range of X-ray fluorescence methods but with the advantage of having high spatial resolution.

Poster Group 2

Localised Surface Plasmon Resonance (LSPR) is a non-propagating electron-density wave that is confined at the surface of a metallic nanoparticle. They can enhance the electromagnetic radiation, concentrating it into sub-wavelength volumes. Its resonance can be tuned by changing the surrounding medium and its geometry. This unique property opens a wide range of applications across various fields of applied research.
Electron Energy Loss Spectroscopy (EELS) within a Scanning Transmission Electron Microscope (STEM) has revealed remarkable capabilities in the analysis of plasmons at nanometric scale, as this technique achieves sub-angstrom spatial resolution and can excite the complete range of LSPR modes supported by the nanostructure. By employing EELS, the plasmonic properties can be correlated with geometric or structural characteristics, enabling a more comprehensive understanding of the plasmonic response.
In this study, based on the analysis of Silicon/Gold nanopillars samples, we demonstrate that clustering techniques can be used for detecting LSPRs in EELS. We propose a novel combination of unsupervised machine learning strategies that detect LSPRs in EELS spectrum images. To demonstrate the effectivity of this methodology, we studied Si/Au nanopillars. The detection of LSPRs is done by reducing the dimensionality of the data, clustering this low-dimensional space, and recuperate the spatial space. We demonstrate that using this methodology, it is possible to recover the LSPRs, among distinct spectra in a large EELS dataset, and easily make a plasmonic spatial map without the need for prior knowledge or labelling of the data.

Is iron a hidden culprit in Alzheimer's disease?

PhD Sowmya Sunkara[1], Dr Marlene Leoni[2], Dr Johannes Haybäck[2,3], Assoc. Prof. Dr Gerd Leitinger[1]
[1]Division of Cell Biology, Histology and Embryology, Gottfried Schatz Research Center, Medical University of Graz, Graz, Austria, [2]Diagnostics & Research Institute for Pathology, Medical University of Graz, Graz, Austria, [3]Tyrolpath Obrist Brunhuber GmbH, Zams, Austria

Poster Group 1

Background incl. aims
Up to 80% of dementia cases globally are down to Alzheimer's disease (AD), a major neurodegenerative disorder[1]. The disease was discovered in 1906 by Alois Alzheimer[2], and in spite of great research efforts, therapeutic progress has been slow. This is probably because AD is characterized by several factors, namely amyloid beta (Aβ) deposits, neurofibrillary tangles (NFTs), and neuronal inflammation, with an unclear connection between these factors. It has been shown previously that iron is dysregulated in AD pathology [3]. Here we used an organotypic tissue culture model for studying the contribution of iron overload to the disease.
Methods
We established an organotypic tissue culture model of AD, for which we cultivate either human or porcine brain tissue and inject Aβ monomers into the tissue, which triggers aggregation of Aβ and the deposition of the aggregates in the tissue. In order to study the contribution of excess iron in this model we injected ferric citrate into the tissue.
Results
A careful analysis of the shape of the deposits in vitro showed that iron changes the shape of the deposits. Furthermore, we reveal that combined iron overload and Aβ injection exacerbated neuronal loss, enhancing the toxicity of Aβ on its own.
Conclusion
The advantage of our organotypic brain tissue culture model is that the natural organization of the cells within the tissue is preserved. This technique will eventually also open the possibility of reducing animal experiments. This integrated approach will elucidate the complex mechanisms underlying neuronal degeneration in AD, paving the way for targeted therapeutic interventions.

Cryo-FIB milling and Cryo-electron tomography of tissue biopsies: BBQ method

Dr Gediminas Gervinskas[1], Viola Oorschot[1], Hari Venugopal[1], Sylvain Trepout[1], A/prof Georg Ramm[1]
[1]Monash Ramaciotti Centre for Cryo EM, Clayton, Austalia

LS-08, Lecture Theater 4, august 28, 2024, 10:30 - 11:30

Cryo-electron tomography (CET) allows for unique insights into molecular structures in situ down to near atomic resolution. To access thicker cellular areas, thin samples of less than 250nm thickness are required and cryo-lamellae can be obtained by cryo-focused ion beam (cryo-FIB) milling. Specialized cells in tissue display unique molecular architectures that are not easily reproduced in isolated cell culture. While cryo-lamellae can be routinely prepared for cells in culture, there are only a few published examples of tissue CET due to the technical challenges associated with obtaining cryo-lamellae of tissue samples. To explore the full potential of CET for cell and developmental biology, better methods for cryo-lamellae preparation of tissues are required. Here we show a new workflow for cryo-FIB milling specifically for tissue samples. The workflow uses standard sample preparation equipment and on grid milling on a Gallium FIB and allows to routinely obtain cryo-lamellae on high-pressure frozen samples. The technique can be combined with automation and allows for the generation of tissue cryo-lamellae in a timely manner. Examples for several tissues obtained from mice and zebrafish are presented.

Investigation of the effects of production conditions and additives on the microstructure of PVDF-HFP membranes

Umut Savaci[1], Onur Ozgur Erkarslan[1]
[1]Department of Materials Science and Engineering, Eskisehir Technical University, Eskisehir, Turkey

Poster Group 1

Background incl. Aims
The Intergovernmental Panel on Climate Change (IPCC) reports on the global increase in average temperature and the escalating levels of CO2 emissions underscore the urgent need for sustainable energy solutions. Therefore, lithium-ion batteries (LIBs) have emerged as a key technology for energy storage, renewable energy systems and particularly in electric vehicles to reduce CO2 emissions. LIBs consist of a cell with a electrolyte containing membrane between anode and cathode. Besides the improvement of electrodes, membranes are key and active components that strongly affect battery performance due to its essential role to modulate both the ionic conductivity and effective lithium migration across the membrane's polymeric barrier PVDF's polymeric and chemical structure ensures the long-term durability of membranes compared to conventional PP and PE membranes; however, its limited adjustability of surface chemistry and micro-porosity restrict wettability and lithium-ion mobility. In the literature, it was shown that different processing conditions and inorganic particle additives may help to overcome these limitations. Metal-organic framework (MOF) particles, formed by metal ions surrounded by organic ligands, can be a promising additive for PVDF-HFP matrix due to its high surface area, adjustable pore size, and high thermal and chemical stability properties. This study aims to determine the effects of processing conditions as well as MOF addition on the microstructure and properties of the PVDF-HFP membranes.
Methods
The thermal-induced phase separation (TIPS) method was chosen to produce porous membranes. In this method, PVDF-HFP polymer, either with or without additives, was mixed with Dimethylformamide (DMF) solvent using a heated magnetic stirrer to obtain a homogeneous mixture. Then the final solution was subjected to degassing under vacuum to remove air bubbles. Subsequently, the solution was poured into a smooth glass surface and casted using a Dr. Blade equipment with three different polymer solid ratios and three different casting thicknesses, then subjected to heat treatment to remove the DMF solvent from the casted mixture. Produced membranes were analyzed by using SEM, XRD, TGA, DSC and FTIR analysis methods.
Results
Qualitative X-Ray diffraction analysis (XRD) of the samples revealed that they consisted of α and β PVDF phases. Fourier Transform Infrared Spectroscopy (FTIR) analysis was conducted to determine the quantitative phase ratios, and the effects of solid ratio and casting thickness on the beta phase ratio were examined. The calculations from the obtained analyses showed that the β phase ratio changes slightly depending on the solid ratio and casting thickness, consistent with the XRD results. Differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA) were also performed to calculate the crystallinity and estimate thermal stability. When the surface and cross-sectional microstructures of the produced samples were examined by scanning electron microscopy-secondary electron (SEM-SE) images, it was determined homogeneously distributed spongelike porous structure were successfully obtained. In the light of SEM images, the average pore diameter and average dry thickness of the samples were measured. Also, porosity and electrolyte uptake values were also measured depending on the processing parameters as well as additive ratios. With the addition of

MOF to the membranes' phase ratio remains similar, but DSC results showed an increase in the melting temperature. According to TGA results, changes in the decomposition temperature depending on the percentage of the additive were also observed.

Conclusions

This study shows that PVDF-HFP stable membranes can be successfully produced via TIPS methodology and reveals the effects of processing conditions and MOF additives on the properties important for the lithium-ion battery applications such as thickness, pore morphology, present phases and their amounts, crystallinity, porosity and electrolyte uptake.

This Study was supported by Eskisehir Technical University Scientific Research Commission under grant no 22ADP416.

In-situ observation and analysis of Ni-based catalysts for dry reforming of methane

Dr. Ayako Hashimoto[1,2], Mr. Yutain Han[1,2]
[1]National Institute for Materials Science, Tsukuba, Japan, [2]University of Tsukuba, Tsukuba, Japan

Poster Group 2

Background incl. aims

Global warming is getting a tremendous issue because of the large release of greenhouse gases such as carbon dioxide (CO_2), methane (CH_4) and so forth. Catalyst is one of promising solutions for global warming to reduce the greenhouse gases. Dry reforming of methane (DRM, $CH_4 + CO_2 \rightarrow 2H_2 + 2CO$) is a powerful reaction utilizing the two greenhouse gases. Ni-based catalysts are useful owing to their high catalytic activities and lower cost compared with noble metals. However, they are easily deactivated via carbon formation during RDM reactions, which is referred to as coking by generation from side reactions. While improvements in catalytic activities have been reported so far [1-3], coking and catalytic deactivation have been not fully studied yet. In this work, structural and chemical changes of Ni nanoparticles during DRM process were investigated using in-situ scanning transmission electron microscopy (STEM) with electron energy-loss spectroscopy (EELS) analysis.

Methods

Ni nanoparticles supported Al_2O_3 catalyst (Ni/Al_2O_3) powders were prepared with different mass ratios of 5 and 10 wt% through the impregnation method. Al_2O_3 powders were dissolved with $Ni(NO_3)_2{\cdot}6H_2O$ into ethanol. After the remaining ethanol was evaporated at 80 °C, the powders were heated in H_2 gas at 600 °C for 6 h to reduce the oxidized Ni. The prepared Ni/Al_2O_3 catalysts were observed in the DRM mixture gas conditions (50% CO_2 and 50% CH_4) with pressure of 0.3 ~ 10 Pa and then, were gradually heated at 150 - 450 °C. In comparison, they were also observed in pure CH_4 gas.

For in-situ observations, our previously developed gas environment heating specimen holder system was used [4]. The Ni/Al_2O_3 powders were dispersed on a Si-based heater chip (E-chip, Protochips, USA), which was arranged in the specimen room at the tip of the specimen holder connecting to the heater controller outside of an electron microscope column. The chip was sandwiched between the two orifice plates to create a differential pumping effect leading to a higher environmental pressure in the specimen room. The powders were observed through a double aberration-corrected electron microscope (JEM-ARM200F, JEOL, Japan) operating at an accelerating voltage of 200 kV. In addition, ex-situ experiments were conducted compared with in-situ ones to examine electron irradiation damages.

Results

The TEM and STEM observations of the prepared Ni/Al_2O_3 powders show the Ni nanoparticles with the size of 5 to 50 nm were uniformly dispersed on the Al_2O_3 support powders. After the ex-situ experiment in the DRM gas (10 Pa) at 450°C for 6 h, the powders were covered with thick carbon films due to coking. During in-situ observation at 550°C after ~15 min of elevating temperature, the similar carbon films were also observed on the Ni nanoparticles. This comparison demonstrated that the in-situ observation had little electron irradiation effects on the structures and reaction phenomena. The carbon deposition was observed even at 350°C in the DRM gas, although the amount of carbon was much less than that in the pure CH_4 gas condition.

Next, the chemical bonding and valence state of the Ni nanoparticles on the Al_2O_3 supports were measured under the DRM conditions by in-situ EELS. Before the DRM gas flowing, the Ni nanoparticles were mainly metallic Ni. But after the gas flowing, most of the nanoparticles changed

from Ni to oxidated Ni depending on temperature. Some Ni nanoparticles were oxidized at over 450°C and then reduced at over 550°C in the DRM gas. In addition, structural changes of the Ni nanoparticles were also observed with the oxidation and reduction reactions.

Conclusions

We observed the Ni nanoparticles on the Al_2O_3 supports through in-situ STEM and EELS to elucidate actual phenomena occurring on the Ni/Al_2O_3 catalysts under the DRM conditions. Carbon deposition on the Ni nanoparticles was observed even the in-situ observations. Furthermore, the change in the chemical bonding and valence state of the Ni nanoparticles were also measured on some Al_2O_3 supports depending on elevating temperature through in-situ EELS.

Combining synchrotron-based microCT with plasma FIB-SEM for targeted Volume EM

Dr Rachel Templin[1], Dr Denis Korneev[1], Dr Sergey Gorelick[1], Minyu Chan[1], A/prof Georg Ramm[1]
[1]Monash Ramaciotti Centre for Cryo EM, Clayton, Australia

IM-12, Lecture Theater 5, august 26, 2024, 10:30 - 12:30

Background
Although offering the highest resolution for volume EM, conventional FIB-SEM imaging has a limited field of view, provides only surface-level information, and is unable to access information non-destructively from within the sample volume to pinpoint areas of interest. Hence, integrating an additional imaging modality capable of non-destructive volume imaging becomes necessary to accurately locate and target regions of interest within complex multilayered specimens. Micro-Computed Tomography (MicroCT) offers a larger 3D overview but at lower resolution lacks many subcellular details. For volume EM, the combination of the two methods offers precise targeting of regions of interest that can be pre-identified in the microCT volume.

Methods
We used the new microCT beamline on the 3 GeV Australian Synchrotron, which has an X-ray energy range from 8 to 40 keV. We imaged Epon resin embedded tissue blocks processed for slice and view imaging by FIB-SEM. We initially tested both monochromatic and white beams as well as different detector distances, but found no major differences, so choose to continue with the white beam to take advantage of the much shorter imaging times. Blocks were subsequently pre-trimmed by ultramicrotomy, transfer to a Helios Hydra plasma FIB-SEM and block cross-sections were aligned with the microCT volume. Final trimming was done using oxygen plasma milling on the plasma FIB before starting the slice and view run for volume EM.

Results
We here show examples where we targeted specific brain regions in zebrafish embryos by microCT and volume EM and the correlation of the two volumes.

Conclusion
Synchrotron based microCT is substantially faster than microCT on lab-based instruments. As plasma FIB allows milling of larger volumes more rapidly than conventional FIB-SEM it is possible to perform the final fine targeting on the FIB-SEM. In summary, the combination of synchrotron microCT and plasma FIB-SEM offers particular advantages for targeted volume EM.

Innovative Nanoanalytical Approaches for Lithium Metal Interface Analysis

Clementine Warres[1], Philipp Karl Albrecht[1], Dr. Tarek Lutz[1], Dr. Wilfried Nisch[1]
[1]NMI Natural and Medical Sciences Institute at the University of Tuebingen, Reutlingen, Germany

Poster Group 1

Background

Lithium metal anodes are important for next generation high-energy batteries, enhancing energy density in terms of both volume and mass while remaining cost effective. They are already implemented in lithium-sulfur batteries nowadays. However Interfacial instability reactions during operation still represent a challenge for the commercialization of solid-state batteries and require further research.

Challenges in Characterization
The analytical characterization of lithium metal interfaces with high lateral resolution is essential for understanding chemical reactions. These interfaces are highly reactive in ambient air and in particular sensitive to electron and ion beam interactions at room temperature. Employing an argon filled glove box prevents Lithium from reacting with moisture and oxygen. Nevertheless, the reaction with the residual nitrogen content in argon-flooded glove boxes is often overlooked. Additionally, conventional electron microscope air locks are typically vented with nitrogen and are therefore another nitrogen contamination source when samples were transferred between microscopes.

Methods

We deposited lithium layers and other thin test layers by thermal evaporation in a vacuum glove box and flooded afterwards with pure argon gas. With this approach we achieved an oxygen-, water- and nitrogen-free environment in the glove box. Our workflow also involves nitrogen free transfer between the scanning electron microscopes (SEM) and transmission electron microscopes (TEM) under argon atmosphere as well as cryogenic electron microscopy. Chemical characterization of the interfaces with high spatial resolution is achieved by focused ion beam secondary ion mass spectroscopy (FIB-SIMS), energy dispersive x-ray spectroscopy (EDS) and electron energy loss spectroscopy (EELS).

Results and Conclusion

We demonstrate the preservation of metallic lithium via the analysis chain. We also show the possibility of depositing additional thin test layers within the glove box. The methodology and workflows shown in this work give rise to an understanding of Li metal / coating interfaces and can be adapted to study other thin coatings or reaction products sensitive to ambient conditions.

Mapping of phase separation of supramolecular protein assemblies by live-cell holotomography microscopy

Dr Orlando Marin[1], Dr Arina Dalaloyan[1], Professor Michael Elbaum[1]
[1]Weizmann Institute of Science, Rehovot, Israel

Poster Group 1

Supramolecular protein assemblies (SMPAs) have demonstrated to be a great tool for studying the biophysical properties of human cells. Liquid-liquid phase separation is a driving mechanism in the assembly of various intracellular structures. An oligomerizing biomimetic system, known as Corelets, has helped to map phase separation within the cell subregions by means of protein condensation. Corelets are photosensitive phase-separating photoinduced oligomers of self-interacting proteins. Previous studies on protein condensation by localized oligomerization showed that sequestering protein ligands to slowly diffusing nucleation centers move the cell into different regions of the phase diagram, resulting in localized phase separation. The real-time oxidative-induced stress in human cells has also remained an enigma in cellular biology. A previous work on the redox state of the cell showed that supramolecular protein assemblies have a self-assembly interface sensitive to the exposure to a thiol-specific oxidizing reagent. We worked with a system of self-associating proteins built onto a ferritin core, genetically encoded for the expression of supramolecular protein assemblies based on a fusion construct between citrine, a yellow fluorescent protein variant and the heavy chain human ferritin. Here, we use a novel 3D label-free non-invasive fluorescent live-cell imaging method, which allows performing high-precision in-vivo holotomographic microscopy of subcellular structures, coupled with cryo-electronic tomography and image processing to evaluate real-space structure of solid and liquid localized phase separation and of SMPA oxidation within the cell nucleus; which allows us to use the refractive index as a method to map the emergence and prevalence of the Corelets in the cells. Our work has allowed the three-dimensional visualization of phase separating condensates in mammalian cells.

Differential axon terminal spread and synapse numbers amongst afferent neurons onto a locust's movement detector

Assoc. Prof. Dr Gerd Leitinger[1], Snjezana Radulovic[1], Dr Erin Cocks[3], Dr Claire Rind[3]
[1]Division of Cell Biology, Histology and Embryology, Gottfried Schatz Research Center, Medical University of Graz, Graz, Austria, [2]Electron Microscopy Research Services, Faculty of Medical Sciences, Newcastle University, Newcastle upon Tyne, UK, [3]Biosciences Institute, Faculty of Medical Sciences, Newcastle University, , Newcastle upon Tyne, UK

LS-07 (2), Lecture Theater 5, august 28, 2024, 14:00 - 16:00

Background incl. aims
The locust giant movement detector neurons, LGMD1 and LGMD2, faithfully signal impending collisions by summing up information about changes in light levels across the compound eye. These changes in light levels are transmitted by trans-medullary afferent neurons that correspond to the thousands of facets of the locust's eye. It is known that the afferent neurons preserve anatomy, so each afferent transmits signals from a defined facet and reaches a defined area on the LGMDs dendritic tree, but anatomical studies of afferent neurons are very rare, with the exception of two full length – reconstructions from a fourth larval instar (reference). In order to detect differences in afferent anatomy, spread of their terminal arbour along the LGMD, and synapse numbers between neighbouring afferents and between the LGMD1 and LGMD2, we are 3D - reconstructing the terminal arbours of afferents of both the LGMD1 and LGMD2.
Methods
Tissue taken from adult locusts is chemically fixed, contrasted and embedded and either one of two 3D Scanning electron microscope methods are employed : either the tissue is serially sectioned within the chamber of a scanning electron microscope and the block face scanned (serial block face SEM), or series of sections are produced using an automated tape collection ultramicrotome (ATUMTome SEM), which are later scanned using Zeiss Atlas software in a Zeiss Gemini SEM.
Results
Surprisingly, in the LGMD2, we found two types of trans-medullary afferent neurons: first, second, other neurons that were rarer had a significantly larger spread of neurites and significantly more synapses among. Retinotopy appeared to be preserved for both neuron types.
Conclusion
The fact that some afferent neurons exhibit larger spread of arbours and more synapses onto the LGMD2 is surprising and has consequences for signal transduction. We assume that for the larger neurons, signal strength is increased at the cost of resolution.

Advanced approaches for the analysis of micro- to nano-quartz particles using SEM, ESEM, FIB-SEM, SBF-SEM

Martin Olbert[1], Vilém Neděla[1], Josef Jirák[1], Jiří Hudec[1]
[1]Environmental electron microscopy group, Institute of Scientific Instruments of the CAS, v.v.i., Brno, Czech Republic

Poster Group 2

Background incl. aims
Quartz micro- to nano-particles are used in a wide variety of industries, especially in the semiconductor industry, optics, as a filler for epoxy resins, etc.. During the preparation of these particles, it is essential to know and control one of the crucial parameters - the particle size distribution (PSD). The production process itself significantly affects the PSD as well as other morphological characteristics. The shape, texture, and size distribution of the particles have a significant impact on the material's mechanical strength, density, electrical properties, and thermal properties. Various methods are used to evaluate PSD. This paper discusses laser diffraction (LD), and microscopy methods: Scanning Electron Microscopy (SEM), Environmental Scanning Electron Microscopy (ESEM), Focused Ion Beam Scanning Electron Microscopy (FIB-SEM) and Serial Block-Face Scanning Electron Microscopy (SBF-SEM). The applications, sample preparation requirements, advantages and accuracy of PSD analysis for the above methods are compared and discussed. The study focuses on ESEM as an interesting, useful and cost-effective technique with many advantages for the study of quartz micro- to nano-particles.

Methods
Quartz powder was first measured using LD. For SEM and ESEM imaging, a non-commercial ESEM AQUASEM II was used. The samples were observed in vacuum and in water vapor at 200 Pa, at 2 magnifications to cover all particle sizes, and using three different types of detectors to detect backscattered and secondary electrons. The particles embedded in the resin were observed using high-resolution ESEM QUANTA 650 FEG at a water vapor pressure of 200 Pa equipped with a Gaseous Secondary Electron Detector. Sub-nanometer particles were observed with high magnification and under pressure of 200 Pa. A procedure has been developed for particle analysis using the Mountains SEM 9 Expert software. Next, the particles embedded in the resin were analyzed by FIB-SEM Tescan Amber. From the resin cube, layers with a thickness of 100 nm were successively sputtered with a Ga+ beam. The last method was SBF-SEM, where layers were sequentially cut from a 1x1x1 mm resin cube using a ConnectomX ultramicrotome in a Tescan Clara UHR SEM microscope.

Results
The result of particle analysis by LD is a plot of the cumulative distribution function of particle sizes. The size parameter is the equivalent spherical diameter. Comparisons were made between SEM/ESEM analyses of the particles, as well as between the powders themselves and their embedding in resin. Our results confirm that the ESEM provides accurate shape and size characterization of quartz particles at vapor pressures in the order of hundreds of Pa and working distances in the low mm range, regardless of the type of detector used. These conclusions were confirmed by the analysis of smaller particles (0.5 - 2 µm). ESEM has also enabled the identification and analysis of particles tens of nm in size. Images acquired with FIB-SEM were processed with 2 software. ORS Dragonfly provided an advanced view of the incorporation of particles embedded in

resin. The second, IP-SDK, allowed precise distribution and annotation of individual particles, which allowed accurate statistical evaluation of their distribution, sphericity, volume, aspect ratio, etc. Images obtained using the SBF-SEM method showed that during the cutting of each layer, the particles were disintegrating, breaking off, and being pulled out, preventing proper particle analysis.

Conclusions
LD is very fast, efficient and widespread method of particle analysis over a large size range. Its disadvantage is the impossibility to know the real morphology of the particles. SEM and ESEM are able to image not only the powder particles but also the particles embedded in the resin, making it possible to fully control the production and use of these particles in other products, which is their great advantage. The ability of SEM and ESEM to image the real morphology and shape of the particles also allows quantification of other morphological parameters, and provide information on the exact shape of the particles. ESEM is a full-fledged and innovative particle analysis tool, and brings a number of advantages, such as a significant reduction in sample charging, thus avoiding the formation of image artifacts that distort the resulting statistics. The potential risk of microscope damage due to contamination of released particles is also significantly reduced. It allows imaging of non-conducting particles without prior modification, and another important advantage is the ability to reveal structural details of even sub-micrometer sized particles. FIB-SEM is one of the most modern, and very advanced tools that allows the measurement of 3D morphological properties of particles, in particular their spatial distribution. However, it is crucial to choose the correct particle labelling procedures, as the accuracy of the resulting distribution depends on this. ORS Dragonfly is a great imaging tool, while IP-SDK provides better statistical evaluation capabilities. SBF- SEM proved to be unsuitable for this type of sample due to the high hardness of the resin.

Enhanced sensitivity in label-free live-cell imaging using multi-pass stimulated Raman scattering microscopy

Joshua Reynolds[1], Dr. Shaun Burd[1], Tzu-Chieh (Jerry) Yen[1], Dr. Samsuzzoha Mondal[1,2], Dr. Soichi Wakatsuki[1,2], Dr. Mark Kasevich[1]
[1]Stanford University, Stanford, USA, [2]SLAC National Accelerator Laboratory, Menlo Park, USA

Poster Group 1

Background incl. aims
Stimulated Raman scattering (SRS) microscopy is a label-free imaging technique used for measuring chemical concentrations with high spatial resolution. The chemical sensitivity of SRS microscopy is limited by photostress or photodamage in sensitive specimens or by the timescales of fast dynamics. To increase the signal-to-noise and thus the sensitivity of SRS microscopy in live samples, we implement a multi-pass imaging protocol.

Methods
Two femtosecond near-infrared laser beams—a pump beam and a Stokes beam—are used to drive SRS. Pulses from both beams are chirped to gain spectral resolution in the measurements [1]. A Pockels cell is used to rotate the polarization of the Stokes pulses, first to initiate and then to end the multi-pass process. An intensity modulation on the pump beam results in a time-varying intensity gain in the multi-passed Stokes beam due to SRS, which is detected with a lock-in amplifier.

Results
We demonstrate an enhanced signal-to-noise ratio in SRS measurements at constant optical dose relative to equivalent single-pass measurements in both spectroscopy and imaging, with signal-to-noise increases currently of about 6 dB. We further characterize the performance of the microscope as a function of the number of interactions between the Stokes pulse and the sample and numerically study the tradeoffs and optimal operating conditions for multi-pass imaging. Using this microscope, we image live biological targets including plant roots and nematodes and use the chemical specificity of SRS to differentiate important biomolecules with subcellular spatial resolution.

Conclusion
Multi-pass protocols enable higher signal-to-noise measurements and thus increased sensitivity or imaging speed, as we demonstrate here for label-free live-cell imaging in an SRS microscope. Multi-pass techniques can be used to increase the sensitivity of many dose-limited measurements up to fundamental quantum limits [2, 3]. We show that multi-passing overcomes the shot-noise-limited signal-to-noise ratio of a standard single-pass experiment conducted with the same total optical dose. This increased sensitivity could enable new measurements of the spatial distribution of low-concentration or weakly scattering molecules in dose-sensitive biological specimens without the need for disruptive labels.

Poster Group 2

Background incl. aims:
Resonant inelastic light scattering (RILS) is a powerful technique to study collective charge excitations in semiconductor quantum nanostructures including quantum wells and nanowires [1]. The application of this technique to probe collective behavior of electrons and holes in novel two-dimensional (2D) materials has not been explored yet. The moiré superlattice potential in twisted 2D semiconductors, e.g. WSe_2, leads to carrier localization and emergence of (flat) moiré bands in the electronic band structure, which host interesting correlation physics [2]. Although the signatures of such flat bands have been shown in recent studies including scanning tunneling spectroscopy (STS) [3] and angle resolved photoemission spectroscopy (ARPES) [4] , the observation of electronic transitions between them proving the emergence of these bands, especially near the K-point of the electronic structure, have remained elusive. In this work, we used RILS micro-spectroscopy to probe the inter-moiré band excitations (IMBE) in twisted bilayers of WSe_2 with a twist angle of ~3° and ~8°.
Methods:
The twisted WSe_2 bilayers were mechanically exfoliated from bulk crystals of WSe_2 using a dry deterministic transfer technique based on viscoelastic stamps. The bilayers were also encapsulated in multilayers of hBN to protect them from environment and to provide atomically flat interfaces. The multilayer stack was built upon a ~300nm silicon dioxide layer thermally grown on p-doped silicon substrate. After preparation, the samples were annealed in vacuum and then mounted inside a refrigerator and cooled down to 4K using liquid Helium. Different regions of the sample were identified using a white LED source and Köhler illumination in combination with piezoelectric x-y-z stages and imaged using a CMOS camera. The twisted bilayer regions of the sample were optically excited using a laser beam from a frequency tunable Ti : Sa laser (linewidth = 50 KHz), cleaned up using a monochromator (1nm bandpass) and coupled to the sample through a large numerical aperture (NA = 0.82) objective lens which is compatible with low temperatures. The excitation energies were chosen near the direct optical bandgap at the K-point pre-determined using photoluminescence spectroscopy. The laser spot size on the sample was ~2µm. The emitted and scattered light from the sample was collected using the same objective and guided to a triple-spectrometer operated in a subtractive mode to reject any stray light. The RILS spectra were recorded using a liquid nitrogen cooled CCD camera.

Results:
Our results show the signatures of transitions between the 1st and 2nd moiré bands for the twist angle of ~8° and between the 1st moiré band and 2nd, 3rd and higher moiré bands for a twist of ~3° [5] We further compare our results with the RILS spectra of natural bilayers of WSe_2 where the absence of IMBE as a consequence of absence of a moiré superlattice further consolidates our results. The IMBE transition energies are in excellent agreement with those expected from theoretical ab-initio calculations in spite of broadening resulting from twist angle disorder and non-vertical transitions [5].
Conclusions:
Our results quantify the IMBE energies at the K-point of the electronic structure, where the states relevant for correlation physics are hosted. They further establish low temperature RILS as a powerful non-invasive technique for probing collective charge excitations in twisted 2D semiconductors [5].

Poster Group 2

Background incl. aims
Earth-abundant semiconductor material Zn_3P_2 is a promising alternative for photovoltaic applications. Unfortunately, there are not many suitable substrates for Zn_3P_2 nanostructure growth as it is difficult to find a lattice parameter and thermal expansion coefficient matching material. Therefore, growth of defect-free Zn_3P_2 nanostructures has been proven to be challenging as it tends to form defects during growth which results in poor crystal quality thus is detrimental for photovoltaic applications.[1][2] To minimize the number of defects, a new method of Zn_3P_2 growth is needed. Selected Area Epitaxy (SAE) and Vapour-Liquid-Solid (VLS) have been shown to be effective techniques in producing different morphologies of Zn_3P_2: nanowires, nanopyramids and thin films.[3] Both techniques reduce the interfacial area which is key in limiting defect formation. In both VLS and SAE indium has been utilized as a seed particle or the substrate (InP). By exchanging In for more earth-abundant Sn seed particles for VLS and InP substrate for Si, it would be possible to completely remove In from the growth process. It is also important to investigate high throughput methods of producing Zn_3P_2 nanostructures for possible future industrial scalability.
Methods
Metal organic vapour phase epitaxy (MOVPE) is an appealing method for growth of SAE and VLS Zn_3P_2. MOVPE is an epitaxy method that has a high through-put and is widely used in industry for manufacturing compound semiconductor devices. InP substrates have been used in our experiments with a silicon oxide (SiO_2) mask that was patterned by EBL to try and identify preliminary growth parameters for SAE growth. Growth times, temperature and precursor flows have been varied to try and find optimal conditions for Zn_3P_2 growth with minimal parasitic nucleation on the SiO_2 mask. For SAE patterning, displacement Talbot lithography (DTL) which is a lithography technique that uses collimated monochromatic light to create a periodic pattern on the substrate, was used. Moving away from EBL to DTL is a key step for scalability of Zn_3P_2 growth, as DTL can pattern much larger areas quicker. Si substrates were used for DTL dose and pattern testing. Sn seed particles on InP substrate for VLS growth were used. Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) were used to image and investigate the morphology and growth selectivity of the resulting Zn_3P_2 structures. Scanning TEM (STEM) together with x-ray energy dispersive spectroscopy (XEDS) was used to image and acquire compositional data of the nanowires.

Results
SAE Zn_3P_2 pyramidal structures by MOVPE on InP substrate were successfully grown (Fig.1a). By optimizing the precursor flows and temperature we were able to minimize most of the parasitic nucleation on the SiO_2 mask layer. DTL was used to pattern hexagonal pattern of holes on SiO_2 on Si substrates, which have diameter of 180nm-200nm and pitch of 500nm (Figure 1b). Sn seeded Zn_3P_2 nanowires were grown and then transferred to a TEM copper grid (Fig. 1 c-d). Additional compositional analysis of the nanowires was performed using XEDS coupled with STEM.

Conclusion
We have shown that growth of SAE Zn_3P_2 on InP substrate is possible using MOVPE. By optimizing the growth conditions parasitic growth is minimized on the mask. Si substrates were patterned by using DTL and desired size and pitch of the nanoholes was achieved. Nanowires were successfully grown by using Sn instead of In seed particles. We hope to exchange InP for Si thus removing any scarce elements from the production and enabling full scalability of Zn_3P_2 nanostructures. Future experiments will focus on realizing SAE Zn_3P_2 growth on the patterned Si substrates and exploring Si substrates for Sn seeded VLS nanowire growth.

Engineering electron-electron interaction for advanced quantum metrology in electron microscopy

Phd Caterina Chiari[1,2], Prof Marco Beleggia[2], Dr Vincenzo Grillo[1]
[1]Centro S3, CNR - Istituto di Nanoscienze, Modena, Italy, [2]Department of Physics, Informatics and Mathematics, University of Modena, Modena, Italy

Poster Group 2

Background incl. aims:
Electron microscopy (EM) is a fundamental instrument for our comprehension of nanoscale materials and biological samples, providing unparalleled resolution and structural information.
Standard electron microscopy uses beams where a single electron at a time forms the image. However, the recent demonstration of interacting electrons in Ultrafast TEM experiments [1,2] has opened up the possibility of a more complex electron beam characterized by strong electron-electron, mainly Coulomb, interaction.
In fact, electron-electron repulsion may significantly impact the spatial arrangement of beam electrons, leading to collective phenomena such as space charge, beam dispersion, and beam instability. While this is considered detrimental to image resolution and contrast, harnessing this new degree of freedom may be a new tool for electron microscopy and metrology.
In particular, electron-electron interactions can be represented as a non-linear Schrödinger equation and could bring quantum advantage in metrology.
This could be important in increasing the accuracy of measurements or reducing dose demand in imaging delicate matter (e.g., proteins). In fact, quantum discrimination theory [3] has helped us to ascertain the minimum number of electrons needed to discriminate between two particles, which depends on the superposition integral of the wave function corresponding to the imaging of the two particles. Unfortunately, unitary evolution of electrons in a microscope, even in the presence of beam shaping, cannot overcome such limitations. Conversely, the non-unitary wave evolution in multiple electron beams with "self-interaction" could potentially overcome this limitation.
Here, we aim to explore the feasibility of this new TEM metrology concept through quantitative wave simulations.

Methods:
We are using here a simplified mean field Hartree scheme [5] connected to multislice propagation of the electron wave function. We employ a modified multislice code [4], implemented in Python, to simulate the effects of electron-electron interactions alongside propagation. At each slice, the electron density is used to self-consistently calculate the self-interaction Coulomb potential.
In our simulation we used a Laguerre-Gauss (LG) multi-electron beam with an orbital angular momentum (OAM) of 10. The nm sized beam traverses here a cumulative distance of 280 nm.
For comparison we also investigated the behavior of a single-electron LG beam.

Results:
Our findings (as shown in the figures below) reveal that by increasing electron density (number of electrons per bunch) the gold atom becomes more visible, and that upon self interaction and

propagation the overlap integral [1], starts to decrease. This suggests that particle discrimination could be improved for interacting electron beam, if the electron density is sufficiently large.
In other words two initially identical multi-electron wave functions, where one of them is scattered by a single gold atom, progressively differentiate with propagation distance. The nontrivial evolution of the wave can be also interpreted in terms of vortex beam instability.

Conclusion:
In this preliminary study, we showcased with a relatively simple example how electron-electron interactions, generally considered detrimental to imaging and analysis, could potentially be exploited to enhance the discrimination between electron wave functions.

Figure Caption:
Fig.1 The amplitude (a,b) and phase (c,d) of the wavefront of a single electron LG beam (OAM=10) in the final () slice with and without gold, respectively. In e) the overlap integral as a function of propagation distance (slice number, with each slice comprising 14 nm) remains constant at a value of 1, denoting unitarian propagation.
The amplitude (f,g) and phase (h,i) of the wavefront of a multi-electron LG beam (OAM=10) in the final () slice with and without gold, respectively. In l) the overlap integral begins to exhibit a different trend, decreasing in value. This is attributed to the non-unitarity, arising from electron-electron interactions.

In recent years, bacteria have shown to be present of human tumors, but their role and advantageous to the tumors or to the bacteria themselves is still mostly unclear. Characterization of the tumor microbiome is challenging because of its low biomass. In order to confirm the presence of bacteria in human tumors, various methodologies were conducted including immunohistochemistry by using antibodies against bacterial lipopolysaccharide and lipoteichoic acid to detect Gram-negative and Gram-positive bacteria, respectively. However verifying the presence of bacteria inside cancer cells is challenging, due to the small size of the bacteria and its sparsity in the tumor tissue. We used Correlative Light-Electron Microscopy (CLEM) that localize specific cellular components using fluorescence labeling and microscopy and visualize in high resolution details the cell ultrastructure by electron microscopy. Fluorescent labeling has been used to identify bacteria over a large area of interest in a sample, and particularly beneficial in samples exhibiting a sparse number of targets or events. In this work we were able to validate the presence of bacteria inside cancer cells of human breast tumor. Combined fluorescence staining of bacteria and transmission electron microscopy imaging of the same cells clearly demonstrated the intracellular localization of bacteria in tumors [1].

Scientific Background
The mean inner potential (MIP) is an intrinsic material property describing the volume average of the atomic electrostatic potentials in a specimen. Accordingly, it depends on the atomic composition and structure and is sensitive to impurities. Typical values for the MIP lie on the order of 10-30V. However, literature values for common materials can vary by several volts, while values for less-common materials are often unavailable. Since the projected MIP across a homogeneous sample should be constant, the typically used off-axis holography approach involves reconstruction of the gradient of the projected MIP from a sample with a known wedge angle created by cleaving along lattice planes.
This approach has several limitations. Cleaving samples is only practical for single-crystalline, ideal samples. Alternatively, FIB-milling can be used to create the wedge profile, but this results in local deviations from the desired wedge angle as well as significant surface damage. Therefore, the reconstructed phase must be correlated to the local thickness of the material. It is imperative that the local thickness of the sample is known with a high spatial resolution, which then can be matched to the reconstructed phase at similar length-scale. The latter is particularly problematic, since the common Fourier sideband phase reconstruction introduces a low-pass envelope that degrades the spatial resolution of the phase map. We aim to improve the precision of the MIP measurement by correlating EFTEM thickness and off-axis holography phase with high fidelity using phase-shifting holography [1].
Methods
We have recently demonstrated the capability of phase-shifting holography with systematic beam tilt to reconstruct the complex exit-wave of a sample up to Angstrom resolution [2]. Here, we make use of the biprism drift in order to reconstruct the projected potential at lower magnifications, which allows us to reach a spatial resolution up to the pixel size of the camera device while still maintaining a large field of view. We demonstrate this method on a FIB-milled wedge from a lattice-matched heteroepitaxial AlAs-GaAs multilayer sample [3].
Wedge-shaped samples from AlAs-GaAs multiayers are prepared by Ga+ focused ion-beam milling and low-kV cleaning using stage and milling pattern rotations to optimize the wedge angle. The local thickness is mapped by EFTEM using the log-ratio technique. In order to reduce the uncertainty from the mean-free-path prediction, the crystalline part of the thickness wedge is measured by convergent beam electron diffraction (CBED). With the assumption that the FIB-damaged volume outside the sample edge is of homogeneous thickness, we thus calibrate the EFTEM thickness gradient at the sample tilt of the CBED two-beam condition. We then record series of off-axis holograms in Lorentz-TEM mode with a biprism voltage of 200V at zone-axis, two-beam and weakly diffracting tilt

conditions. The random drift of the biprism position is used in place of a systematic beam tilt, in order to generate a phase-shifting series. The holography data is then aligned and a narrow band of high visibility of the fringes in the vacuum region is selected in order to improve the cosine fit for phase-shifting reconstruction.

Results

Taking into account differences in magnification and lens rotation from the projection system, we are able to correlate local projected potential and local thickness with sub-nanometre precision (see Fig.1). Collecting all the data pairs and performing a linear regression results in an excellent fit to the linear phase prediction at kinematical conditions. However, results for different sample tilts also highlight the need for a dynamical scattering correction. The method thus is well-suited for homogeneous samples and uniform diffraction conditions.

Conclusions

Phase-shifting is a powerful tool to improve the correlation between off-axis holography and other TEM methods. Results at suitably large tilts off zone axis are in good argeement with literature, although MIP values appear to be systematically slightly larger than previously reported. Particular care must be taken in order to minimize or, barring that, account for the different influence of preparation damage and dynamical diffraction.

Poster Group 2

Background incl. aims
Copper-based chalcogenide materials exhibit distinct properties, making them promising candidates for a range of applications [1]. Among these materials, Cu-Te compounds have attracted significant interest due to their versatility in fields like thermoelectricity, memory technology, photothermal therapy, photovoltaics, and batteries. The properties of these alloys are closely linked to their local structure, making accurate description essential for optimizing device performance and advancing material development. The local structure of Cu-Te compounds remains a topic of ongoing discussion [2], especially concerning materials in their low-dimensional form, such as thin films.

This study addresses the controversial aspects of the local structure of Cu-Te phases prepared by thin-film solid-state reaction. Using Cs-corrected scanning transmission electron microscopy (STEM) and atomic-resolution electron energy loss spectroscopy (EELS), the atomic positions of metal and chalcogen atoms in Cu-Te structures are directly visualized. In addition, the investigation revealed the formation of new Cu-Te phase. A crystal structure model for this phase was proposed based on atomic-scale images.

Methods
Atomic-scale investigations are carried out via direct imaging in real space utilizing iDPC, ABF, HAADF and EELS methods. Cu-Te structures are synthesized from metal Cu layer and Sb_2Te_3 epitaxial thin films by thermal heating.

Results
The microstructural investigation of the Cu/Sb2Te3 system unveiled a reaction between the Cu layer and Sb2Te3 upon heating. This reaction led to the formation of van der Waals bonded layered Cu-Te structures, comprising double and triple layers of Te, as depicted in Fig 1. Contrary to existing literature, a detailed analysis of the atomic positions of Cu and quantification of interatomic distances revealed the crystallization of a Cu-rich trigonal Cu1.75Te phase (P-3m1) as the predominant double-layered Cu-Te structure.

Furthermore, a new metastable Cu-rich trigonal phase of Cu1.75Te (P3m1) was found, for which a structural model has been proposed. The phase features a triple-layered structure, resembling the Cu1.75Te double-layered phase. Notably, this metastable phase exhibits vacancies on Cu sites. A detailed analysis of the transition regions suggests that the triple-layered Cu1.75Te structure can easily transformed into the double-layer phase through rearrangements of Cu atoms. Crystal defects, including stacking faults and dislocations, were also observed within the crystal structures. Due to its resemblance to layered Sb_2Te_3 structure, a triple-layered structure was also fabricated as a thin film

through solid-state epitaxy of Cu and Sb_2Te_3 layers, using magnetron sputtering at room temperature.

Conclusion
The findings from this study offer valuable insights into the local structure and preferred phases of Cu-Te, which can be relevant during the cycling of Cu-based bulk thermoelectric materials [3]. This knowledge lays the groundwork for theoretical investigations into their properties and facilitates the design of novel layered materials.

Cryo-EM structure of the HD6 defensin helical assembly

Dr. Roman Kamyshinsky[1], Lev Khmelnitsky[2], Rishir Kalepu[2], Dr. Nadav Elad[1], Prof. Deborah Fass[2]
[1]Department of Chemical Research Support, Weizmann Institute of Science, Rehovot, Israel,

Poster Group 1

Defensins are small antimicrobial proteins produced by animals, plants, and fungi. HD6 is a human defensin secreted into the small intestine. Unlike other defensins, HD6 is not directly bactericidal but rather self assembles into «nanonets» [1] thought to physically trap bacteria and prevent them from penetrating the intestinal epithelium. The existing model for the nanonet filament structure, a spiral of HD6 dimers proposed based on an HD6 crystal structure, does not fully explain the long persistence length (microns) of HD6 filaments in vitro [2]. To resolve this apparent discrepancy, we determined structures of HD6 nanonet filaments using SPA cryo-EM.
HD6 filaments were produced in phosphate buffer according to a previous protocol [2]. The filaments demonstrated polymorphous behavior, so data were collected at different protein concentrations to favor different polymorphs. Specifically, low concentrations yielded predominantly thin filaments ~40 Å in diameter. Higher concentrations yielded thicker filaments ~80 Å in diameter. Cryo-EM data were collected on a Talos Arctica (Thermo Fisher Scientific) operated at 200 kV. EER movies were collected using EPU software in AFIS mode on a Falcon 4i direct detector at a nominal magnification of 190kx, corresponding to a physical pixel size of 0.73 Å. Image processing was performed using cryoSPARC v4 [3].
HD6 thin filaments were found to consist of stacked pairs of dimers spiraling along the helix axis with apparent D2 symmetry. Strong densities were observed along the axis and were interpreted as phosphate ions, each coordinated by multiple copies of a histidine, H5, in HD6. Mutation of H5 abolished filamentation. Once maps of sufficient resolution were obtained, a symmetry break became apparent: the two spirals of dimers in the thin filaments were found to be related by two-fold symmetry perpendicular to the helix axis, but not by true two-fold symmetry along the axis as would have been expected for D2. The repeating unit of the thin filament consists of two stacked HD6 dimers, with one protomer out of the four displaying a loop in a slightly different conformation than in the other three molecules. The thick filaments, in turn, formed by wrapping two additional HD6 dimer spirals around the thin filament without coordination of additional phosphate. The outer spirals adopt D2 symmetry and show helical rise and twist that differ from the inner filament.
The robust multiple micron length HD6 filaments are explained by the fact that two or more HD6 dimers constitute each level of the supramolecular assembly. Moreover, phosphate plays a structural role in stabilizing the filaments. HD6 helical polymorphs arise from an optional wrapping of additional stacked-dimer spirals around the phosphate-coordinating inner filament, and a symmetry mismatch exists between inner and outer spirals.

Temporal analysis of bone development in chick femur bone using label-free imaging

Miss Siddhi Chugh[1], Mr Jacob Kleboe[1,2], Dr Rahul S. Tare[3], Professor Richard OC Oreffo[2,3], Professor Sumeet Mahajan[1,2]
[1]School of Chemistry, Southampton, United Kingdom, [2]Institute of Life Sciences, Southampton, United Kingdom, [3]Human Development and Health, Southampton, United Kingdom

Poster Group 1

Background incl. aims:
Long bones such as femur develop via the process of endochondral ossification (EO). During EO, chondrocytes proliferate, undergo hypertrophy and subsequent cell death with the replacement of hyaline cartilage with bone. The constructed cartilaginous matrix is invaded by blood vessels, osteoblasts, osteoclasts, and bone marrow cells before it develops into bone. Currently, the gold standard techniques to study organ development are micro computed tomography, histochemical assays, or through fluorescence microscopy using dyes or endogenously expressed fluorescent proteins protein. However, all these approaches are invasive, and can require fixation or lysis of tissue, therefore are unsuitable for in-vivo studies on humans for monitoring disease progression or therapeutic benefit.
However, multiphoton microscopy utilising non-ionising, benign radiation (NIR light) offers non-invasive, label-free structural and chemical details, without damage in contrast to histological approaches and X-ray scans. Additionally, label-free microscopy facilitates high sensitivity and resolution. In this work, we report an application of multiphoton microscopy with the techniques of Second Harmonic Generation (SHG), Coherent Anti-Stokes Raman Scattering (CARS) and 2-Photon Excited Auto-Fluorescence (2PaF) to monitor bone development. We establish the methodology using the chick model to provide proof-of-concept of its capability for potential use with patients.
Methods:
The femurs of chick embryos were isolated at different growth phases, i.e., at day 11, 14, and 18. The bones were fixed, embedded in paraffin wax, and sectioned. The sectioned slices were imaged with histological methods to establish the ground truth. The parallel sections were imaged with SHG, CARS and 2PaF. SHG images collagen fibres while CARS is used to image distribution of lipids at their vibrational frequency of 2845cm-1 and 2PaF images autofluorescence at 520 nm (primarily FAD and NADH). CARS was obtained in both backward and forward scattering geometries. Subsequently, label-free imaging data was analysed using image analysis using Fiji software. SHG images were analysed using CT-FIRE software and statistical analysis were performed.
Results:
Histological staining (Alcian Blue and Sirius Red) revealed a clear demarcation between the early cartilaginous femur and the surrounding tissue. Proteoglycans were visible within the cartilage region and intense collagen staining in the tissue surrounding the femur.
SHG images of chick femur bones (n=6) at Day 11, 14 and 18 highlighting collagen fibres were analysed using “CT-FIRE” to extract collagen fibre details. It was observed that the length of collagen fibres steadily increased throughout the developmental process from Day 11 to Day 18, unlike the fibre width that remained similar for early developmental stages before sudden increase at day 18. However, there were no observed differences in fibre straightness throughout the developmental process. 2PaF images provided context for cells and tissue areas while CARS images showed the distribution of lipids and protein structures and provided a readout of changes on development from

Day 11 to 18. Further analysis is in progress to develop imaging based multimodal signatures for bone development.

Conclusions:

Our work shows that non-invasive and non-destructive, structurally, and chemically selective multiphoton label-free imaging techniques can be advantageous for monitoring bone formation and can track its development. Additionally, the label-free techniques explored here allow objective and quantitative analysis of the developing bone since signals are retrieved only from molecules and structures in their native state providing intrinsic contrast and are dependent on their amounts.

Background incl. aims
Since their first demonstration by Huang et al in 2001[1], semiconductor nanolasers have attracted a lot of interest especially for their application in optoelectronic devices. They have the advantages to be cost-effective, easy to fabricate and of a micron size. Since 2001, various semiconductors and geometries demonstrated lasing properties, for example ZnO[1] or GaN [2] nanowires act as nanolasers.
Lasing could be induced by optical pumping, usually it is characterized by a drastic reduction of the emission spectrum width, increase of the light coherence evidenced by interferences of laser diffracted light. The most significant lasing properties of nanolasers are the value of the lasing threshold, the emission wavelength (see Figure 1) and the reduction of the carrier lifetime. Moreover, nanolasers emission wavelength above the lasing threshold are linked to the laser cavity's resonance modes, which in our case is the nanowire itself. Thus, the shape of the nanowire and the laser characteristics are closely related. Due the nanoscale variation, electron microscopy is a suitable technique to examine its nanoscopic characteristics. Therefore, it is essential to link the lasing properties with the nanolaser shape and the local luminescence.
Methods
We particularly focused on the use of cathodoluminescence in a scanning electron microscope (SEM) and a scanning transmission electron microscope (STEM) to characterize the optical properties of GaN nanowires. In both microscopes, the focalised electron beam locally creates charge carriers in the semiconductor, in a pear of interaction of either hundreds of nanometers (SEM) or tens of nanometers (STEM). We studied the luminescence due to carriers recombination. Using a spectrometer, we can obtain a spectrally resolved map of the sample emission. In time-resolved electron microscopy, we are able to measure the charge carrier lifetime thank to the decay curve of the luminescence after an electron pulse (30 ps in SEM and 300 fs in STEM). . In this project we measure the lasing threshold and the cavity mode of single nanolasers and correlate the results to their nanoscale geometry and optical properties using cathodoluminescence and time-resolved cathodoluminescence measured both in STEM and SEM.
Results
We investigated the lasing properties using micro-photoluminescence UV[4] of several nanolasers and observed strong heterogeneity in the lasing mode and lasing threshold. As expected, we found that the side-pumped nanolaser had a lower energy threshold than the vertically pumped ones[5], and we observe strong variation with the nanolaser radius. We observe the same nanolaser in cathodoluminescence and obtain spectrally and spatially resolved intensity maps, that show strong intensity and spectral variation along the nanowire. Moreover, time-resolved cathodoluminescence showed that the CL decay time varies from 90 ps to 130 ps when the nanolaser radius varies from 200nm to 500nm.
Conclusion

Finally, one of the main actual challenge on the nanolaser is to link the nano-laser shape to the lasing luminescence. In this project, we combine electron microscopy to study the cavity properties with both photoluminescence and cathodoluminescence, permitting to study respectively the macroscopic and microscopic luminescence properties.

New strategies of TEM sample preparation for the mitigation of carbon contamination

Dr. Julia Menten[1], Dr. Daniela Ramermann[1], Prof. Dr. Robert Schlögl[1,2], Dr. Walid Hetaba[1]
[1]Max Planck Institute for Chemical Energy Conversion, Mülheim an der Ruhr, Germany, [2]Fritz Haber Institute of the Max Planck Society, Berlin, Germany

Poster Group 1

Transmission electron microscopy (TEM) measurements can be impaired by carbon contamination, which is caused by volatile organic components that get reduced by the electron probe and form a layer of amorphous carbon on the sample's surface. These contaminants often originate from the sample itself or are introduced during the TEM sample preparation process, e.g., when a sample is dispersed in a solvent for applying it to a TEM grid. In our work, we quantify the amount of accumulated contamination depending on the electron beam exposure time by electron energy loss spectroscopy (EELS) thickness measurements with a focus on different sample preparation parameters and mitigation strategies. A better understanding of the impact of these factors helps us to develop new sample pre-treatment strategies and thus drastically reduce carbon contamination in order to acquire clean TEM data.
TEM analysis was performed with a Thermo Scientific Talos F200X transmission electron microscope and a Gatan Continuum S spectrometer. Accumulated contamination was quantified by EELS thickness measurements by applying the log-ratio method [1]. The approach of contaminant removal in a self-built heatable vacuum sample cleaning station was compared regarding its efficiency to other established cleaning procedures.
Our experiments show that the amount of accumulated carbon contamination strongly depends on many factors that were investigated in our work: We have compared the amount of contamination caused by different solvents that are commonly used during the sample preparation or during the synthesis of a sample (fig. 1). Also, the impact of sample preparation parameters, i.e. the drying time of the sample, the duration a specimen remains in the microscope and the impact of the solvent's purity, was studied. In addition, we have investigated the efficiency of different established procedures for mitigating the formation of contamination. These strategies include established cleaning methods, that are compared to our novel approach of a designated sample cleaning station. Our results show in depth how the sample cleaning station performs compared to other mitigation strategies and can be integrated in the sample preparation process in order to achieve clean TEM measurements. The different methods were compared regarding their impact on the accumulated contamination (fig. 2), but also on their abrasiveness and influence on a sample's properties.
Carbon contamination can be reduced by careful consideration of the sample preparation parameters. Our results give insight in how to mitigate the deposition of contamination using established and new strategies, and can be extended to other challenging specimens, allowing to obtain high-quality, clean TEM measurements of samples that are prone to contamination.

Localisation of nanoparticles in whole cells using correlative cryo soft x-ray tomography and fluorescent microscopy

Mr Kenneth Fahy[1], Sergey Kapishnikov[1], Paul Sheridan[1], William Fyans[1], Fergal O'Reilly[1,2], Tony McEnroe[1]
[1]SiriusXT, Dublin , Ireland , [2]UCD Dublin, Dublin 4, Ireland

IM-13 (2), Lecture Theater 5, august 27, 2024, 14:00 - 16:00

Background incl. aims
In recent years nanoparticles have emerged as important players in modern medicine, with clinical applications ranging from contrast agents in imaging to carriers for drug and gene delivery into tumors. Nanoparticle surfaces can be easily functionalized to target specific disease sites, and their small size and specific material characteristics facilitate their delivery and detection. Current nanoparticles include metals and and other inorganic-based compounds, as well as polymer, lipid, or bioinspired nanoparticles. These are being developed to diagnose and treat a variety of different diseases ranging from cancer to inflammation. In order to assess both the efficacy and the effect of nanoparticle delivery on cells a number of questions arise such as; does the nanoparticle reach the cytoplasm and nucleus of cells where it might exert therapeutic effects on intracellular molecules?, what subcellular compartments does the nanoparticle enter following delivery to cells?, or does nanoparticle uptake influence cell structure? These questions can be addressed by examination of cell structure.
Methods
Cryo-soft X-ray tomography (cryo-SXT) was used to deliver 3D ultrastructural volumes of intact cells without chemical fixation or staining, to reveal nanoparticle uptake for nanomedicine. Initially, integrated cryo fluorescence was used to screen an entire EM grid to reveal the location of suitable cells for tomography. Low magnification/large field of view 2D x-ray mosaics were then acquired over large areas of the grid before acquiring a tilt series from ±60° on selected targets. Data from both modalities were then overlaid to provide the location of nanoparticles in the context of whole cell ultrastructure.
Results
Cryo-SXT volumes combined with fluorescent light images showing the 3D distribution of organic and inorganic nanoparticles ranging in diameter from around 50 nm to 200 nm, in the context of the cellular landscape and surrounding organelles.
Conclusion.
Results prove the utility of lab-based cryo-SXT/FM for nanoparticle localisation in whole fully hydrated cells. The recent availability of the compact soft x-ray microscope will accelerate the further development of novel workflows and biological imaging applications that can benefit from this technique, including integration with electron microscopy.

Poster Group 2

In this collaborative endeavor between SiriusXT and King's College London (KCL), we present our efforts to refine high-pressure freezing (HPF) protocols tailored to facilitate correlative imaging workflows integrating cryo-fluorescence microscopy, lab-based soft X-ray cryo-tomography (SXT), and cryoFIB-SEM for high-resolution three-dimensional (3D) imaging of biological cells. This refined protocol is followed by correlative light fluorescence, SXT, and FIB-SEM studies of biological cells, aiming to compare sample quality vitrified by plunge freezing and high-pressure freezing. Our motivation stems from the persistent uncertainty surrounding the efficacy of plunge freezing in adequately vitrifying thicker cellular components for high-resolution imaging purposes.
The primary objective of our study is to develop strategies to regulate ice thickness in high-pressure frozen samples, making them suitable for correlative imaging by light, SXT, and cryo-FIB-SEM techniques. Subsequently, we employ correlative imaging to investigate regions of interest, initially utilizing light fluorescence and soft X-ray tomography, followed by identification of regions of interest and further imaging of these regions using cryo FIB-SEM. We also compare the quality of frozen samples between high-pressure and plunge-frozen specimens. For our study we use two distinct biological organisms: the nannochloropsis microalgae and single-cell flagellate eukaryotes of the Euglena genus.
Optimal ice thickness for direct imaging by SXT without the need to thin the sample typically falls below fifteen micrometers, a threshold often exceeded by the conventional HPF "waffle" method, resulting in ice thicknesses around 20-25 micrometers. However, through modifications to the freezing procedure - such as liquid wicking and removal of planchettes spacer - we demonstrate the achievement of HPF ice thickness as low as 5-15 micrometers across significant fractions of the grid area.
This improvement eliminates the need to thin high-pressure frozen samples for SXT imaging. Using the lab-based SXT-100 for rapid 3D imaging of large areas with resolutions of 50-60 nm full-pitch, this approach enhances the throughput of cryo FIB-SEM imaging of high-pressure frozen samples by streamlining the process of identifying regions of interest for higher resolution imaging, albeit at a significantly slower imaging pace by cryo FIB-SEM.

Improved conventional TEM sample preparation exploiting the birefringence of materials

Aleksander Brozyniak[1], Karin Stadlmann[1], Philipp Kürnsteiner[1], Heiko Groiss[1]
[1]Christian Doppler Laboratory for Nanoscale Phase Transformations, Center for Surface and Nanoanalytics, Johannes Kepler University Linz, Linz, Austria

Poster Group 2

Background incl. aims
Specimens for quality transmission electron microscopy (TEM) analyses must fulfil a range of requirements, which demand high precision during the prior preparation process. The exploitation of thickness-dependent interference colors occurring in birefringent materials can be used for an optimized procedure for conventional TEM specimen preparation. Birefringent materials display thickness-dependent interference colors in transmitted polarized light, which is analyzed by a second polarizer. The polarized light passing through a birefringent crystal splits into two components based on the refractive indices, resulting in an optical path difference called retardation. Recombining both components with the analyzer leads to annihilation of specific wavelengths through destructive interference, revealing observable interference colors. This phenomenon was first described by Auguste Michel-Lévy at the end of the 19th century along with a color chart of perpendicularly aligned polarizers for various birefringence values.
Methods
Our study leverages this phenomenon to optimize mechanical thinning in conventional sample preparation for transmission electron microscopy (TEM) [1]. For our experiments we employ two prominent semiconductor substrate materials from industry and research exhibiting birefringence: silicon carbide (4H-SiC) and sapphire (Al_2O_3). Figure 1 (a) displays the section of the Michel-Lévy chart containing the orange dotted 0.008-birefringence line of Al_2O_3 and the cyan dotted 0.056-birefringence line of 4H-SiC. We discuss our findings on dimpled and wedge-polished two-materials specimens, which are composed from a two-layer stack combining 4H-SiC and Al_2O_3 in one specimen. Top-view polarization microscopy images of the dimpled Al_2O_3/4H-SiC sample and the wedge-polished Al_2O_3/4H-SiC sample can be seen in Figure 1 (b) and 1 (c), respectively. For materials with small birefringence like Al_2O_3, where interference colors vanish at smaller thicknesses, we propose a complementary color chart for a parallel polarizer orientation, supplementing the Michel-Lévy chart for crossed polarizers.
Results
The thickness of the thinnest sample region can be estimated visually, with its color directly corresponding to the thickness on a color chart. During thinning, simple geometrical models that assume the specimen shape in dimple and wedge geometry can help to determine the thickness at the thinnest specimen position. A more complex RGB analysis of the occurring colors allows for measuring the required lateral fringes position with high accuracy. In all cases the achieved accuracy of thickness monitoring, validated by scanning electron microscopy (SEM), significantly exceeds the measurement capabilities of built-in mechanical gauges in thinning instruments.
Conclusion
Our proposed method facilitates a highly accurate determination of specimen thickness to avoid damage or breaking during mechanical thinning and reduces ion-milling times. The benefits of the approach are shown on sapphire and silicon carbide cross-section samples. The presented method is equally suitable for assessing specimen thickness during dimpling and wedge-polishing, and is

particularly useful at thicknesses below 20 µm, where the accuracy of mechanical techniques is insufficient. It is precise enough to be employed for a visual thickness estimation during the thinning process, but can be additionally optimized by analyzing the RGB spectrum of the occurring interference colors. It is applicable to all materials if additional birefringent materials serve as a thickness reference during polishing.

Poster Group 1

Over the last decade, it has been recognized that different topological structures formed in ferroelectrics significantly influence the physical properties of the material system. Ferroelectric oxides deposited on a semiconductor substrate are of particular interest for applications in nanoelectronics or photonics. A particularly attractive candidate of ferroelectric materials is $BaTiO_3$. We investigated the crystalline structure, defects and the polarization patterns in $(BaTiO_3/SrTiO_3)_{10}$ superlattices epitaxially grown by molecular beam epitaxy (MBE) on a silicon substrate. A thin epitaxial $SrTiO_3$ template directly grown on the substrate is mainly used to compensate for the lattice mismatch between $BaTiO_3$ and Si.
To determine the spontaneous polarization within the $(BaTiO_3/SrTiO_3)_{10}$ superlattice, the in-plane and out-of-plane strain components of the lattice were determined using Geometrical Phase Analysis (GPA) and using a direct peak finding method. Furthermore, a more refined peak finding algorithm was used to analyze the displacements of the Ti atoms relative to the center of their respective unit cells in real space. Therefore, high-resolution HAADF-STEM images, which show a direct visualization of the atom columns in a crystal, were recorded.
The analyses resulted in two-dimensional displacement maps of the Ti atoms, in which the areas of the $BaTiO_3$ layers revealed periodic, wave-like polarization patterns. These patterns are also partially continued in the $SrTiO_3$ layer. The two-dimensional strain maps show a strong modulation of the out-of-plane strain component and a periodic variation of the in-plane strain component in the region of the $BaTiO_3$ layers. The combination of the displacement maps and the strain maps shows a significant correlation between the two.
These investigations of $(BaTiO_3/SrTiO_3)_{10}$ superlattices contribute to the understanding of two-dimensional oxide ferroelectrics for the future integration of topological polar nanostructures in devices.

Charge Particle Optics Simulation Utilizing Hamiltonian Mechanics Perturbation Expansion and Boundary Elements Field Computation

Axel Lubk[1], Dr. Florent Houdellier[3], Dr. Heiko Müller[4], Dr. Stephan Uhlemann[4]
[1]IFW Dresden, Dresden, Germany, [2]TU Dresden, Dresden, Germany, [3]CEMES (CNRS), Toulouse, France, [4]CEOS GmbH, Heidelberg, Germany

IM-02, Lecture Theater 3, august 27, 2024, 14:00 - 16:00

Background incl. aims
Advanced charge particle optics (CPO) requires fast and accurate computational tools for calculating (relativistic) particle trajectories including aberrations that, ideally, handle both arbitrary electrics and magnetic field sources, handle arbitrarily bend optical axis, allow incorporation of symmetries (e.g., rotational or mirror), incorporate optimization of design parameters such as pole piece diameter or pole distances. Ideally such tools should also be available under open source licenses in order to facilitate widespread use as well as distributed and sustainable development. Despite the enormous level of development and usefulness of commercial (e.g. Simion, EOD, Comsol) and open source packages, they often lack a subset of the above functionalities, somewhat hampering a wide spread development and use of advanced CPO for, e.g., Transmission Electron Microscopy, Secondary Ion Mass Spectroscopy, Photo Electron Spectroscopy, in academia, industry, and also teaching. The CPO software development described below intends to address that need.
Methods
Here we report on the development of an open source computational CPO framework incorporating the following principles to allow for an accurate, fast and flexible trajectory calculation: (A) We use boundary element method (BEM) computation of electric and magnetic fields, yielding smooth and accurate potentials, fields and higher-order derivatives at optical axis at arbitrary sampling, while reducing the meshing effort to surfaces (e.g., electrodes and pole pieces) of the CPO device. Herein, single layer representations of both electric and magnetic scalar potential are most efficient, while Green's representation with Calderon preconditioning allows stable single step solution of magnetic field distributions in the presence of high μr materials. (B) We employ semianalytical hierarchical solution of perturbation series of Hamiltonian equations of motion around an optical axis[1] in order to provide computationally effective, fast and accurate built-up of aberrations along particle trajectories. While not implemented yet the Hamiltonian perturbation expansion also facilitates straight forward extension to curved axis and the eikonal representation of aberrations. (C) We integrate the fast field and particle trajectory computation with non-linear optimization routines facilitating automatic optimization of design parameters (e.g., multipole sizes, pole piece gap) with respect to certain target functionalities. This tool chain is written in Python and makes use of advanced open source libraries (namely OpenCascade for CAD, gmsh for meshing, BEMPP for BEM field computation, sympy for semianalytic Hamiltonian mechanics perturbation expansion including automatic code generation, scipy for solving equations of motion, nlopt for geometry optimization) in a modular way, which are partly adapted to the specifics of CPO. Notably, BEMPP was extended by parallel just-in-time compiled numba and opencl kernels for field derivative computations on optical axis as required for computation of paraxial trajectories and aberrations.
Results
We demonstrate and discuss the above tool chain with the help several electrostatic and magnetostatic CPO / building blocks of CPO, notably electrostatic einzellens, electrostatic quadrupole – round aperture assembly (see Fig. 1) and magnetostatic quadrupole, touching implementation

(e.g., CAD import, defining boundary conditions, vector potential gauge), numerical (e.g., mesh size, precision of paraxial solution) and CPO (e.g., chromatic and geometric aberrations) aspects.
Conclusion
A modular combination of adapted BEM field computations and semianalytical perturbation series expansion of Hamiltonian equations of motion admits a computationally efficient modeling of CPO utilizing a combination of powerful and freely available open source software packages. Further development aims at incorporation of curved optical axis and general enhancement of functionality and user friendliness in order to support development of advanced CPO across the community.
Fig. 1: CPO of electrostatic quadrupole – aperture assembly (building block of low-voltage aberration corrector[2]): Computer aided design (CAD) modeling, meshing, and BEM field computation including axial multipoles. The octupole utilized for spherical aberration correction has been multiplied by 10 for visualization purposes.

PS-01 (3), Lecture Theater 3, august 30, 2024, 14:00 - 16:00

Background
The synthesis of new kinds of functionalized carbon nanostructures continues to attract a growing amount of interest within solid-state physics research, due to the wide range of potential applications that it can yield [1]. Within this field, electron irradiation within an electron microscope is a great tool for in-situ studies on these structures, being able to characterize their formation and the changes they can undergo as they are happening at the nanoscale [2].
Within the subject of carbon nanostructures, single-wall carbon nanotubes (SWCNTs) have been a cornerstone in the field, not only as a malleable material but also as a medium for the fabrication of other materials. Within this new realm of materials, carbon 'peapods' (fullerenes and fullerene-based molecules encapsulated inside of single-walled nanotubes [3]) continue to increase interest regarding the controlled formation of nanostructures. A good case of this nanostructure formation is graphene nanoribbons (GNRs) templated by encapsulated functionalized fullerenes, which form the nanoribbons upon heating or beam irradiation [4]. Additionally, doping has been one of the main preferred methods for carbon nanostructure modification, with carbon being a relatively easy-to-dope material, improving the electrical properties of 1D carbon nanomaterials.
In this sense, functionalized C59N using a dithiolane (DT) moiety containing sulfur and oxygen [5] is a very promising material that may give rise to the creation of fine GNRs within SWNTs under beam irradiation, passivated with a combination of S, O, H and maybe N, possibly with some form of doping within their structure. To study these GNRs, previous in-situ studies on similar, non-doped samples offer micrographs before and after the GNR has been formed, but no intermediate states.
This study aims to get a fuller picture of the formation of GNR by acquiring micrographs not just before and after, but throughout the whole GNR formation process, and to delve into the structure these GNRs have.

Methods
In this work, these derivatives (C59N-DT) have been introduced into SWNTs and irradiated in situ within a TEM while acquiring high-resolution TEM videos at 80 kV, to have enough control over the dose to be able to modify the C59N-DT@SWCNTs when the beam was focused while having enough control over it not to damage the sample before the in situ studies.
Additionally, to discern the edge passivation on these nanoribbons, DFT calculations have been performed to discern the energetic viability of different GNR edges, modifying the geometry of the carbon edge, the different elements passivating it, and their relative concentration. The formation enthalpy of each edge configuration has been estimated as a way to discern which are the most

energetically favorable structures and, in turn, which ones are the least likely to prevail in these samples.

Results
Figure 1 shows the functionalized fullerene used for these studies (top left), an image series detailing the formation process of the nanoribbon (top right), and a formation enthalpy comparison for different mixed passivating edges (bottom).
The results of these TEM image series, as well as micrograph integrations from crucial moments in the in-situ study, point out to the formation of a first intermediate structure with the C59N-DT starting to fuse to each other and, later on, passivated, sometimes twisted GNRs.
Likewise, preliminary calculations seem to show that stoichiometrically favorable configurations, such as S-O co-passivated edges, as well as O-passivated edges are more thermodynamically stable than previously proposed S-passivated edges [3].

Conclusion
These results point to a successful way to obtain GNRs from a doped C59N-DT and show their formation in situ. DFT calculations show that the edges of these GNRs are probably made of S-O co-passivated edges.

Background
Cu-based formulations are high-prospect catalysts for their remarkable performance in environmental reactions and their role as a substitute for expensive noble metals. Depending on the reaction of interest, Cu-based catalysts are exposed to different oxidizing/reducing environments, in a temperature regime that may span over 200-800ºC1. Temperature-programmed experiments under H2 or O2 atmospheres have shown that copper phases are susceptible to release or capture oxygen, changing its oxidation state from Cu0 to Cu2+. These variations are concomitant with structural, chemical, and morphological modifications 2.
In relation with the gas-catalyst interaction, each exposed crystallographic facet may exhibit a singular ability to generate/annihilate oxygen vacancies3, and, therefore, a specific reactivity. The diverse and irregular surface of Cu-based nanoparticles hinder a direct relationship between the observed performance and their surface termination. The use of nanoparticles with controlled morphology and well-defined facets4, such as nanocubes, is proving to be a promising approach to address this complexity because it provides particles with homogeneous and explicit facets, facilitating the investigation of the H2/O2 interaction with copper phases and its chemical and structural consequences. To this end, we propose to synthesize CuOx nanocubes and characterize them by means of HR-TEM and EELS after application of different reducing/oxidizing thermal treatments. It will be paid careful attention to aspects such as their oxidation state, crystallographic homogeneity and stability.
Methods
The structural, chemical and morphological evolution of copper oxide nanocubes synthesized in our laboratory using very dilute solutions of Cu(NO3)2.3H2O, NaOH and ascorbic acid5 have been investigated after exposing the catalysts to oxidizing/reducing atmospheres at different temperatures. We have employed a FEI Talos F200X electron microscope operating at 200kV, capable of both transmission and scanning/transmission (TEM/STEM) modes and equipped with a Gatan Continuum Electron Energy Loss Spectrometer (EELS). The Cu-L2,3 white line EELS signals have been the primary focus of this study towards the determination of the oxidation state, processed using DigitalMicrograph software. More specifically the spatial distribution of CuOx phases have been determined with the Multiple Lineal Least Squares (MLLS) method. High quality Cu0, Cu1+ and Cu2+ references have been previously registered to perform the fitting. The EELS data have been complemented with the analysis of HR-TEM images, extracting the copper phase maps from the Fourier periodicities.
Results
STEM-HAADF images of the as prepared samples unveil the success of the synthesis, with particles exhibiting a cubic morphology spanning over 30 and 60 nm in size. The crystallographic analysis carried out by HR-TEM allowed us to confirm the presence of Cu2O phase (Figure a-b). In addition, a

zoomed image of the {100} faces reveals a rough surface assembled by low-dimension facets (Figure c). Aberration-corrected electron microscopy characterization will be used to better define this type of nanofacets.
To confirm the oxidation state of these systems, we conducted EELS analysis. The Cu-L2,3 EELS signal confirmed the presence of Cu2O, in agreement with the results obtained by HR-TEM. Prior to assessing the potential impact of different gas atmospheres on the initial state, we evaluated its stability over time. Thus, the morphology and Cu-L2,3 EELS features have been tracked after 1, 2 and 3 weeks (Figure d, e and f respectively). The evolution shows a progressive deterioration of the cubes, with areas exhibiting undefined morphologies which increase over time. These regions displayed Cu2+, indicating a transformation to CuO. Consequently, the samples are prone to capture O2 from air, triggering the destruction of the cubes. In contrast, when oxidation treatment was controlled in a muffle oven at 300ºC, the sample exhibited a hollow structure while preserving its morphology.
The pristine Cu2O nanocubes were also submitted to H2 at 100 and 150ºC. The reduction at 100ºC slightly altered the morphology, forming small nanoparticles on the surface of the nanocubes. However, at 150ºC, the HAADF images indicated sintering of the cubes, resulting in large (over 500 nm) aggregates, hindering a proper characterization.
An in-depth characterization is required to obtain the fine details ascribe to these thermal treatments. The implementation of Machine Learning routine to process HR-TEM images will provide a spatial distribution of each phase which will help determining the crystallography of the surface at the nanoscale.
Conclusion
In summary, the structural analysis highlights the morphological changes of Cu2O nanocubes under different oxidation conditions, with uncontrolled atmospheres leading to progressive oxidation while controlled treatments maintain morphology with a hollow structure. Further investigations are necessary to fully elucidate these phenomena. Additionally, observations in H2 atmosphere indicate a temperature-dependent morphological changes. Efforts to enhance accuracy in copper oxidation state studies through advanced methodologies are underway, promising deeper insights into nanomaterial behaviour.

Comparison of the FMT assay with the Cell Painting approach in healthy patient derived fibroblasts.

Dr Tabea Hohensee[1], Dr Fredrik Edfeldt[1]
[1]Mechanistic and Structural Biology, Discovery Sciences, R&D, AstraZeneca, Gothenburg, Sweden

Poster Group 1

IPF, a fatal chronic disease of the lung, is caused by an inflammatory response that results in aberrant fibroblast activation, the deposition of excessive extracellular matrix, and progressive fibrotic remodelling of the lungs1. Though the exact pathophysiological mechanisms of IPF remain unknown, myofibroblasts are considered to play a major role in the pathology of IPF. Transforming growth factor β (TGF-β1), a well-established fibrogenic mediator, induces FMT. In cells undergoing FMT, increased expression of α-smooth muscle actin (αSMA) is observed. In vitro, increased αSMA expression positively correlates with contraction of myofibroblast populated collagen gels, indicating that αSMA is a strong marker of myofibroblast differentiation, and thus a relevant readout for lung fibrosis.

A validated, robust TGF-β1-induced FMT cell-based imaging assay in normal human lung fibroblasts (NHLF) with αSMA expression as a readout exists in-house to support multiple R&I IPF projects. As an inhibitor control, the highly specific Alk5 inhibitor SB-525334 is used to block TGF-β1 signalling2.

Cell Painting is a non-target hight content imaging assay to identify morphological profiles of different cell types with diverse compound treatments3. In this study the compounds used for the FMT assay have been simultaneously analysed via cell painting and the data has been compared. The Cell Painting results correlate well with the FMT data and could potentially be used as an alternative to the FMT assay. Especially while the assay is one day shorter.

Additionally, three patient-derived IPF cell lines have been tested with 27 compounds to see if it is possible to reverse the diseased phenotype to the healthy one, with or without TGF-β1 treatment. All three donors showed a different response profile when compared to each other, which made it difficult to distinguish if there are compounds being especially responsive to TGF-β1 treatment or to diseased cells, but not healthy ones. This needs further investigation.

Background incl. aims
Wave-based Scanning Probe Microscopy (SPM) techniques may provide a wealth of information even down to length scales significantly below the probe's extent. Tapping into it is possible thanks to two-dimensional detectors, which enable access to phase and/or absorption contrasts through the beam's interference patterns. The data analysis may then range from complex, stochastic approaches to simple and deterministic ones. One can take phase retrieval in coherent diffraction imaging [1] and center-of-mass (CoM) in field mapping [2-3] via four-dimensional scanning transmission electron microscopy (4D-STEM) as examples. However, with the dataset's enhanced dimensionality (compared to e.g. differential phase contrast imaging with a segmented detector) comes a broader range of field determination methods from which to choose.
Methods
In this presentation, we address the question of reliability in 4D-STEM electric field mapping by way of a comparison between the conventional CoM method on one hand, and several template matching (TM) approaches on the other hand. Our focus being on methodology, we use data acquired on a well-known silicon p-n junction [2-3] for simplicity. The imaged area is a 128-pixels-side square [see Figure 1(a)], with a step size of 5.4 nm, our detector is a 256x256 pixels Merlin camera based on medipix technology from Quantum Detectors, and the TEM is operated at 200 kV. The lamella's large thickness (326 nm of active material) and the electron beam's semi-convergence angle (992 µrad) allow us to preserve both signal-over-noise ratio and spatial resolution. Most importantly, the small probe size leads to a rigid, lateral shift of the electron beam without intensity redistributions; one may therefore expect good performances from TM.
As a first step, a common reference position (on the detector) for all compared methods is evaluated by averaging the beam's center position over 5120 pixels more than 100 nm away from the junction. We then run a standard CoM analysis along with TM and extract the junction's electric field from the corresponding results, after subtraction of the reference position. It must be noted that the TM algorithm we use (from the liberTEM [4] module) possesses sub-pixel accuracy. Denoting R the estimated beam radius on the detector and r the radial coordinate from the center, the tested, rotation-symmetric templates are: (i) a flat disk with radius R, (ii) the same disk multiplied with r/R, (iii) template (i) with a negative annulus around it, (iv) template (ii) with a negative annulus around it. A final template (v) is created from an actual data frame or the average of several of them.
Results
As can be seen on Figure 1, all templates yield distinct results, and none match the output of CoM. The significant spread in extracted field values suggests high sensitivity to the template's shape, and therefore to user input. That is why we now focus on the template resembling data the most: an acquired detector frame. Since the template (v) was created with a square cropping mask in order to exclude a Kikuchi band from the pattern, we first check whether a disk-shaped cropping mask (with a radius clearly above the beam's) produces different results. Not only is it the case, but we also find

out that slightly increasing the mask's radius strongly affects the template matching output, even though the Kikuchi band was still rejected (only background/weak beam tails were included).
This implies that a correlation-based shift determination places too much weight on absolute intensity levels, failing to accurately locate the pattern's edges. In order to alleviate this, we propose to perform template matching using not a raw detector frame, but the corresponding map (still in detector space) of the norm of its gradient [5]. Our goal consists in evaluating the robustness of this approach versus its two free parameters: the smoothing applied before gradient computation, and the threshold applied on the gradient's norm before TM.
Conclusions
With this study, we hope to improve the understanding of TM's limitations and/or biases in the context of quantitative field mapping. In addition to performing a comparison with CoM, we investigate the performance of two pixelated detectors, using direct detection or CMOS with a scintillator respectively. Finally, we develop an analysis which is guided as much as possible by the data themselves, with the objective to restrict the amount of arbitrariness as much as possible.

Box H/ACA snoRNPs are protein-RNA complexes composed of NOP10, GAR1, and the catalytically active DKC1. The latter is known to interact with small non-coding RNAs containing the Box H/ACA motif. Guided by the RNA, the complex finds its target RNAs and converts the nuclear base uridine to pseudouridine, resulting in increased stability of the target RNA due to an additional hydrogen bond. Pseudouridines are vital for various cellular functions, such as protein translation, as they undergo frequent post-transcriptional modifications in ribosomal RNAs.
However, it is still poorly understood how the Box H/ACA snoRNP complexes and their individual protein precursors are assembled. SHQ1, a chaperone-like protein, is proposed to prevent DKC1 from binding to nonspecific ribonuceotides during its assembly in the cytosol and subsequently guide the complex to the nucleus, where it interacts with the AAA-ATPase complex RuvBL1/2. These ATPases are known to interact with PIH1D1 and RPAP3 proteins to form the R2TP complex, which is described to play a role in the assembly of multiple macromolecular complexes. Thus, the R2TP complex could be responsible for sequestering SHQ1 from DKC1, allowing DKC1 to interact with Box H/ACA snoRNAs and ultimately assemble the mature snoRNP.
The aim of this work is to elucidate the maturation of the Box H/ACA snoRNP by characterizing its precursor complexes composed of SHQ1, DKC1, and RuvBL1/2. This was achieved using size exclusion chromatography, dynamic light scattering, differential scanning fluorimetry, surface plasmon resonance, mass photometry, cross-linking mass spectrometry, and cryo-EM.
We were able to confirm the interaction between RuvBL1/2 and DKC1 or SHQ1. Additionally, we purified and stabilized the SHQ1:RuvBL1/2 complex and identified multiple complex species. Revealing the interaction site between the AAA ATPases and SHQ1 helped to reconstruct an initial 3D model of the complex's structure processing the movies collected in Cryo-EM experiments.
The biochemical and biophysical analysis of the interaction between R1R2 and SHQ1 allowed us to identify an additional electron density below the unique and regulartory domain II of the hexameric R1R2 complexes. However, our Cryo-EM reconstruction shows high flexibility for the complex, which is why mild cross-linking using GraFix might to be a valid option to determine a high resolution 3D structure.

Recent advancements in FIB-milling throughput allow production of large tomography datasets from lamellae. Combined with improved processing of tomography data this has made it possible to produce sub-nanometer resolution for large protein complexes abundant in the cell. Despite these advances, in-lamella studies still mostly determine the consensus protein structure. In this study we aimed to correlate structural variability of the target protein with its in situ biological context to structurally describe a biological pathway. In particular we focused on the COPI pathway. Using a large tomography dataset from lamellae prepared by high-throughput plasma-FIB-milling we applied subtomogram averaging to determine the structure of the COPI complex. Next, we used image classification to analyze the biological cues involved in the pathway (e.g. binding of small proteins, cargo sorting, etc.). Further we correlated the results of image classification with different levels of biological context: from local lattice architecture to interactions at the organelle level, to describe different stages of COPI pathway. All in all, we showcase the potential of structural studies of biological pathways in situ.

Background incl. aims
Hepatitis C virus (HCV) infection in cell culture constitutes an excellent model of persistent infection whereby the virus takes control of the infected cell without killing it. This strong interference with host cell homeostasis is manifested by a profound remodeling of the host endomembrane system as well as with a strong induction of virtually all stress response pathways in the cells. The availability of specific direct-acting antiviral (DAA) drugs against HCV provides a unique opportunity to revert this process and to define the ultrastructural events that follow viral replication blockade short after antiviral treatment.
Methods
Using confocal immunofluorescence and transmission electron microscopy (TEM) as well as the correlation of cryo-fluorescence microscopy and cryo-soft X-ray tomography (cryo-FM-SXT), we monitored the HCV replication machinery removal after antiviral treatment with DAA of a surrogate cell culture model of viral replication.
Results
To assess the impact of antiviral treatment of HCV-replicating cells, we treated cells bearing an HCV subgenomic replicon with a DAA combination of sofosbuvir, a polymerase inhibitor targeting NS5B, and daclatasvir, an NS5A-targeting antiviral. Analysis of DAA-treated HCV replicons indicate that most viral antigens and RNA are eliminated within the first 48 hours of treatment, concomitant with the reversion to baseline expression of HCV-induced stress markers, such as ATF3. A general survey of control cells and HCV replicons using correlative cryo-FM-SXT indicates that HCV-induced membranous alterations are no longer visible after 24 hours of treatment and that a substantial fraction of NS5A, a viral component of the replicase is located in pleomorphic, high-absorption contrast organelles in DAA-treated cells. Three-dimensional reconstruction of these cells suggest that these organelles are spatially organized in layers proximal to the cell nuclei in areas with reduced mitochondrial content. TEM and cryo-FM-SXT studies confirmed the rapid elimination of the viral machinery, and the concurrent appearance of large endo-lysosomes and multivesicular bodies, suggesting a major role for this recycling machinery in the elimination of HCV-induced membranous compartments. These and results by others suggest that HCV replication compartment is constantly recycled by the endo-lysosomal system and that this equilibrium is unbalanced by DAA treatment, resulting in a transient activation of the endo-lysosomal system to achieve rapid viral machinery removal.
Conclusions
Overall, these TEM and correlative cryo-FM-SXT studies suggest that HCV replication machinery removal after DAA treatment entails transient proliferation of endo-lysosomes and MVB, but not that of double-membrane autophagosomes. Moreover, live fluorescence confocal microscopy indicates that NS5A remnants co-localize with an acidic compartment labeled with lysotracker green. Given

that a fraction of NS5A is found in endo-lysosomes also before antiviral treatment it is reasonable to propose that HCV replicase compartment size is balanced by a constant flux through lysosomal/MVB compartments.

In-vivo DAB cytochemistry and high-pressure freezing to determine the source of the human cytomegalovirus envelope

Tim Bergner[1], Laura Cortez Rayas[2], apl. Prof. Jens von Einem[2], Dr. Clarissa Read[1]
[1]Central Facility for Electron Microscopy, Ulm University, Ulm, Germany, [2]Institute of Virology, Ulm University Medical Center, Ulm, Germany

Poster Group 1

Background/aims:

The human cytomegalovirus (HCMV), an enveloped DNA virus, significantly alters host cell morphology during infection. Formation of infectious virus progeny requires two critical envelopment processes: primary and secondary envelopment. Secondary envelopment occurs in a specialized juxtanuclear region known as the cytoplasmic viral assembly complex (cVAC), where capsids bud into the lumen of cellular vesicles and by this acquire the final virion envelope. The identity of these vesicles is debated, with both trans-Golgi and endosomal vesicles proposed as potential sources (1-3, and see abstract by T. Bergner, L. Cortez Rayas, J. von Einem, C. Read).

To address this, we adapted the protocol by Ellinger et al. 2010 (4) for cytochemical labelling of endocytic membranes for visualization by electron microscopy (EM). The protocol uses wheat germ agglutinin (WGA) conjugated to horseradish peroxidase (HRP) for labelling and diaminobenzidine (DAB) cytochemistry that is performed in living cells. WGA specifically binds to N-acetyl-glucosamine and sialic acid, abundant in the plasma membrane, whereby it is endocytosed in large quantities. The peroxidase-catalyzed DAB reaction results in a specific labelling of the endocytic compartment. Performing this reaction in vivo allows cryo-immobilization through high-pressure freezing. The combination with freezing within milliseconds allows capturing snapshot of the dynamic membrane system, making this approach suitable for pseudo-dynamic EM studies. Moreover, high-pressure freezing provides excellent structural preservation, allowing differentiated visualization of the endocytic compartment, HCMV capsids in different maturation stages, and their interaction during the secondary envelopment process in EM. This is a prerequisite for detailed 3D EM analysis.

Methods:

The study was performed with human foreskin fibroblasts infected with HCMV for 5 days, following the adapted protocol of Ellinger et al. 2010 (4). For pulse-chase experiments, WGA-HRP was added to the living cells and incubated for specific pulse times (e.g., 60 or 10 minutes). After the pulse, WGA-HRP was removed, and the samples were incubated for an additional chase period of 30 minutes. In vivo DAB cytochemistry was then performed by applying DAB to induce the formation of an insoluble reaction product at intracellular membranes, visible as a dark precipitate in EM. Samples were immediately cryo-immobilized through high-pressure freezing, freeze-substituted, and embedded in epoxy resin. Transmission electron microscopy (TEM) was used for quantitative analysis of 10 infected cells. Capsids were categorized as budding or enveloped and further categorized as either WGA-labelled or not labelled. 3D visualization of the endocytic compartment was achieved using STEM tomography.

Results:

TEM analysis revealed that the WGA-HRP precipitate is clearly visible and located along the intraluminal face of various intracellular membrane compartments, including vesicles, endosomes, multivesicular bodies, and the trans-side of the Golgi apparatus. Examination of the cVAC showed numerous capsids associated with WGA-labelled membranes. Notably, within 90 minutes of WGA-HRP pulse-chase, about 90% of budding capsids and 50% of enveloped capsids were WGA-labelled. This indicates rapid plasma membrane endocytosis, translocation to the cVAC and completion of the secondary envelopment process. Reducing the pulse-chase time to 30 minutes still resulted in WGA-labelled membranes that were used for secondary envelopment, suggesting that this process is even faster. STEM tomography further unambiguously identified capsid budding at the trans-side of Golgi cisternae.

Conclusion:

This study demonstrated that combining peroxidase-catalyzed cytochemistry with high-pressure freezing and freeze substitution ensures optimal structural preservation and specific labelling of the endocytic compartment suitable for EM studies. With this approach, we showed that endocytosed membranes are the primary source of the HCMV envelope. Additionally, the findings highlight the rapidity of secondary envelopment.

Electron energy loss spectroscopy for differentiating of minerals polymorphs

Dr Vladimir Roddatis[1], Dr Elizaveta Kovaleva[1,2], Dr Marcin Syczewski[1], Anja Schreiber[1], Dr Richard Wirth[1], Prof Monica Koch-Müller[1]
[1]GFZ German Research Centre for Geosciences, Potsdam, Germany, [2]Department of Earth Sciences, University of the Western Cape, , South Africa

Poster Group 1

Background incl. aims
Nanoscale phase identification in transmission electron microscopy TEM involves selected area or nanobeam electron diffraction combined with electron energy loss spectroscopy (EELS) or energy dispersive X-ray (EDX) analysis. Scanning TEM (STEM) extends this versatility by applying 4D-STEM and precession electron diffraction (PED) for orientational analysis. Recently, $CaCO_3$ polymorphs, calcite and aragonite, were characterized by STEM-EELS in the valence region (< 50 eV, VEELS) and the obtained results were verified by density functional theory (DFT) [1]. It was demonstrated that the near edge fine structures of spectra in the VEELS range closely relate to the electronic structure of materials and their crystal symmetries [1]. Moreover, VEELS is rather independent on crystallographic orientation which makes it a versatile technique even for nanoscale phase identification and mapping of 2D-materials [2].

In this study we applied Cs-corrected STEM and EELS mapping to visualize the distribution of (i) the $ZrSiO_4$ polymorphs zircon and reidite within the natural sample and distribution and structural relation of (ii) the coexisting SiO_2 polymorphs coesite and stishovite in synthetic high-pressure run products.

Methods
TEM foils of approx. 15 x 10 µm were prepared by a lift-out method using a focused ion beam (FIB). Phase distributions were visualized by applying HAADF imaging as well as the EELS and PED methods. Samples containing zircon and reidite were collected from the 70.3 Ma Kara impact structure crater-infill suevite breccias. Coexisting SiO_2 phases were synthesized in high-pressure multi-anvil experiments.

Results
Low magnification HAADF image (see Graphic section) shows reidite lamellae having various apparent thickness inside zircon matrix. Both phases were identified using SAED and high-resolution imaging. VEELS spectra of zircon and reidite were collected in the blue and green points, respectively. The difference (~ 2.3 eV) between position of the main peak at ~25 eV in zircon and at ~27 eV in reidite as well as other small features marked with the grey dashed lines were used to map the distribution of both phases. Corresponding EDX maps of zirconium, oxygen and silicon demonstrate uniform chemical elemental distribution in both phases. The phase distribution was also imaged using the PED data collected using a DigiSTAR device and the ASTAR software (NanoMEGAS SPRL, Belgium). In order to test applicability of the method, additional experiments were carried out to visualize distribution of stishovite and coesite (polymorphs of SiO_2), and kyanite (Al_2SiO_5) in a few FIB-prepared TEM specimens.

Conclusion
Our data demonstrate that phases having identical chemical composition may have distinct spectra in both low-loss and core-loss regions. This difference can be used to map their distribution in TEM specimens, which can be done at a very high spatial resolution, precision and acquisition speed. This allows minimizing the electron dose and thus the electron irradiation damage, hence, the presented EELS technique could also be applied to a variety of electron beam-sensitive materials. Moreover, a procession time for EELS mapping is much shorter comparing with e.g. PED. Thus, this approach has a great potential for phase mapping with unsurpassed spatial resolution for a series of geoscience applications.

Transport of Intensity Phase Retrieval in the Presence of Intensity Variations and Unknown Boundary Conditions

Daniel Wolf[1], Radmila Kyrychenko[1], Max Herzo[1], Oleksandr Zaiets[1], Axel Lubk[1]
[1]Leibniz Institute for Solid State and Materials Research, Dresden, Germany

IM-03 (4), Plenary, august 29, 2024, 14:00 - 15:00

Background incl. aims
The so-called Transport of Intensity Equation (TIE) phase retrieval technique is widely applied in light, x-ray and electron optics to reconstruct, e.g., refractive indices or electric and magnetic fields in solids [1,2]. The TIE method reconstructs the phase from two or three mutually slightly defocused microscopy images by solving an elliptic partial differential equation – the TIE. Here, we present a largely improved TIE reconstruction algorithm, which properly considers intensity variations as well as unknown boundary conditions in a finite difference implementation of the Transport of Intensity partial differential equation. [3] That largely removes reconstruction artifacts encountered in state-of-the-art Poisson solvers of the TIE, hence significantly increasing the applicability of the technique. Notwithstanding, its widespread proliferation the TIE method in its predominantly employed form suffers from a number of fundamental challenges that often introduce reconstruction artifacts and hence degrade the information obtained from the phase: (I) Intensity variations of the wave functions are frequently either neglected or considered in an incomplete way, e.g., by equating the phase with the scalar "potential" pertaining to irrotational (particle) currents. (II) The boundary conditions (BCs) required to solve the TIE are often not known and strongly deviate from homogeneous Dirichlet, Neumann, or periodic Bcs, used in TIE solvers. (III) The reconstruction of small spatial frequencies in the phase is mildly (i.e., algebraically) ill-conditioned and, hence, requires regularization to suppress error amplification. Indeed, the above three challenges are intertwined in practical applications, because, e.g., erroneous long-range phase variations due to erroneous BCs or neglected amplitude variations are suppressed by regularization at the expense of introducing a regularization error. Here, we report on a TIE reconstruction algorithm that properly considers intensity variations, allows retrieving the correct BCs through a variational scheme, and can be additionally regularized, if necessary.

Methods
We numerically solve the TIE using a finite difference scheme: the equidistant x and y sampling points of the 2D image intensity are interlaced so that the phase and intensity at the sampling points may be represented as vectors. Subsequently, the directional derivatives along x and y are approximated by the left- and right-sided difference to the nearest neighbors, which can be written as a multiplication with bidiagonal matrices. With these building blocks, the whole TIE may be written as a system of linear equations, which can be inverted numerically to yield the phase. In order to suppress error amplification, the linear equation system may be additionally regularized by a Tikhonov scheme. In order to incorporate arbitrary inhomogeneous Dirichlet BCs, the discrete phase image is embedded in a frame comprising one pixel. The values of the phase on this frame (i.e., the unknown Dirichlet BCs) are retrieved through a variational scheme that minimizes the difference between the experimental defocused image intensities and the numerically defocused intensities obtained from the TIE reconstruction. To facilitate sufficiently fast convergence only a small number of Fourier coefficients of the BC function are retrieved in practice. The values on this frame are then

assigned to Dirichlet BCs. The above system of equations is solved in a numerically efficient way by exploiting sparse representations and sparse equation solvers.

Results

We demonstrate the improved performance of the TIE reconstruction algorithm at a set of simulated and experimental image intensities arising from magnetic structures investigated in TEM, focusing on Landau domain pattern in geometrically confined permalloy thin films. They consist of magnetic vortices and antivortices and are suited to demonstrate the main features of the enhanced TIE reconstruction (Fig. 1), namely consideration of intensity variations (Figs. 1a-c), automatic determination of nontrivial BCs (Figs. 1d-f), and its application on an experimental example (Figs. 1g-i).

Conclusion

We have demonstrated that solving the TIE with the help of a finite difference scheme incorporating a variation of the boundary conditions largely mitigates reconstruction artifacts encountered with the previously used Poisson reconstruction schemes. The reconstruction algorithm reduces or even removes the need for additional regularization and mostly improves the reconstruction of long-range variations of the phase. That opens new avenues for TIE reconstructions, where intensity variations cannot be avoided, and long-range fields are important (e.g., vector field electron tomography). Further improvements of the algorithm hinge on further optimization of the optimization algorithm employed for determining the boundary conditions, faster sparse matrix solvers, and transition from a finite difference to a finite elements scheme (that allow adaptive meshing), amongst others.

Poster Group 1

Background and aims: Among the characteristic hallmarks observed in the human brain during aging is the neuronal accumulation of neuromelanin (NM) pigment and iron in substantia nigra (SN) and locus coeruleus (LC), the two brain areas mainly targeted in Alzheimers and Parkinsons disease (PD). The neuromelanin pigment accumulates inside the catecholaminergic neurons of SN and LC and there particularly within specific organelles (with an average size of 1.5 µm), called neuromelanin organelles. Within these organelles, neuromelanin clusters with with lipid and protein-based partitions of less than 100 nm each
Several spectroscopic studies investigated the role of neuromelanin pigments and metal dyshomeostasis in the SN during aging [1] and a found a correlation of both with disease progression. However, conducting chemical analysis on LC proves to be challenging due to the small size of the tissue. It would necessitate a substantial number of specimens which are difficult to collect. Moreover, only few studies attempted high lateral resolution subcellular (re)distribution analyses of iron storage in brain tissue, e.g. for SN [2] in order to find out where exactly the metal is stored on a subcellular basis.
Therefore, the aim of this work is to develop a workflow to study the ultrastructural metal distributions in NM organelles of LC on individual human tissue sections using novel high resolution analytical approaches based on secondary ion mass spectrometry (SIMS) performed on Focused Ion Beam instruments (FIB-SIMS)..o Chemical analysis were corroborated by CLEM (Abbrev.) to correlate the finding with the cellular and molecular changes that take place in relation to PD.
Methods: A total of 11 human LC tissues were collected from elderly (n=9) and PD (n=2) specimen (60-80 years old) and were either formalin fixed paraffin embedded (FFPE), Epon-embedded or just as fresh frozen. Tissue sections were investigated by light, fluorescence and electron microscopy for high resolution imaging and immunohistochemistry, respectively. The standard chemical analysis was performed by analytical electron microscopy and mass spectrometric imaging (MSI), using the CAMECA NanoSIMS 50 with the ability for isotopic identification and highest sensitivity and mass resolution and a lateral resolution down to 50-100 nm. Sub organellar distribution of metals in NM organelles was addressed on selected samples using FIB-SIMS with lateral resolution < 20 nm for SIMS and < 1nm for secondary electron (SE) imaging developed at LIST. A combined “TEM like”

ultrastructural investigation together with SIMS is possible on the so-called npSCOPE, an in house novel cryoFIB-SIMS platform with SE, SIMS and scanning transmission ion microscopy (STIM) detectors [2]. Taking the advantage of the cryo-chamber of the npSCOPE, it can also be used to perform respective analyses on frozen-hydrated brain samples and thereby minimizing preparation artefacts.
Results: A semi-quantitative SIMS approach was implemented here where a single tissue slice was imaged first using CLEM to identify the region of interest in LC tissues of both elderly control and PD subjects. Quantitative EDX maps and qualitative SIMS maps were acquired for regions of interest. Counts/ pixel ratios were calculated to get a semi-quantitative data set that shows different signal abundances for SIMS. Respective data on healthy elderly specimen showed that the melanic moiety of the NM organelle is composed by a mixture of eumelanin/ pheomelanin units with a sulfur/nitrogen ratio of (XXX), as identified by the sulphur signal which derives from the benzothiazines of the pheomelanin part of the NM. NM organells showed increased signal for iron, calcium, and aluminium, in comparison to the lipid moiety of the NM organelles or the cytoplasmic surrounding areas.
Interestingly, copper and zinc signal were at or below the detection limit, which is totally contrast to the isolated NM analysed using the Electron Paramagnetic resonance spectroscopy (EPR) that showed an actual accumulation of these two elements [1].
The higher spatial resolution of LIST's FIB-SIMS instrument in comparison to the nano-SIMS could more precisely identify the localization of these metals and non-metals in different sub-organellar compartments of the NM organelle.
In addition, PO2 signal which is an indicator of phosphorus rich areas like myelin sheath, nucleus and lipids was also week in the lipid moiety and lipid bodies of the NM organelle, which might strongly agree with the fact that the lipid portion of NM is mainly composed of dolichols, and this is to be proved by lipidomic profiling. Another method of molecular profiling is done by IHC, in order to identify the differential expression of the markers related to inflammation, PD and iron storage proteins, and in order to identify the regions that showed, by our elemental analysis, to be rich in iron but are not a NM organelle, who could be glial cells or ferritin rich areas.

Conclusion: We analysed the sub-cellular localization of certain marker elements for subcellular structures (PO for myelin), NM organelle compartments (based on Cl, S, CN, O signal distribution) in addition to the metal loading into these compartments in elderly controls and PD patients using routine and novel high-resolution chemical and structural imaging techniques in the NM in addition to its molecular proteomic and lipidomic profiling. Continued work will be done to identify more the significant differences in LC tissues of PD patients compared to healthy controls at the molecular and elemental levels, with investigations on fresh frozen samples for a better close to native analysis of PD pathophysiology also including molecular MSI,also done at high resolution, like MALDI and TOF-SIMS.

Atomic-scale structure and defect evolution in Σ5 [001] tilt grain boundaries in copper

Dr. Rer. Nat Hui Ding[1], Anoosheh Akbari[2], Dr Esakkiraja Neelamegan[2], Prof. Sergiy Divinski[2], Prof. Gerhard Wilde[2], Prof. Christian H. Liebscher[1,3]
[1]Structure and Nano- / Micromechanics of Materials, Max-Planck-Institut für Eisenforschung GmbH, Düsseldorf, Germany, [2]Institutre of Materials Physics, University of Münster, Münster, Germany, [3]Faculty of Physics and Astronomy and RC FEMS, Ruhr University Bochum, Bochum, Germany

Poster Group 2

Background: Grain boundaries (GBs) are material imperfections that have a strong influence on material properties. They can act as preferred diffusion pathways for solutes and hence impact the transport properties of polycrystalline materials. In many cases, it is assumed that the GB adopts an idealized structure that can be described by the structural unit model in high-angle tilt boundaries that is often used to establish structure-property correlations. However, the relation between the atomic structure of GBs, and possible deviations from the ideal structure, and their transport properties often remains unexplored.
Methods: We fabricated a Cu bicrystal via a modified Bridgman method. The seed single crystals are aligned with their [001] axes being parallel, corresponding to the growth direction, and are misoriented by an angle of 36.9° to form a symmetric tilt grain boundary. Electron backscattered diffraction is then used to characterize the global GB structure, followed by aberration-corrected scanning transmission electron microscopy to study the atomic structure of a series of near-Σ5 (310) [001] symmetric tilt GB segments of the bicrystal.
Results: In the near Σ 5(310)[001] symmetric tilt grain boundaries, the kite-type structural unit is frequently observed throughout the GB regardless of the deviation from the desired misorientation. However, various GB defects are formed at the GB to accommodate deviations from the exact GB misorientation or inclination. We observe disconnections, asymmetric nanofacet segments and an array of secondary edge dislocations that appear periodically between the normal kite-type structural units. Furthermore, a beam-induced GB phase transformation is observed, characterized by the change of the structural unit as well as the re-shuffling of the atoms at the GB.
Conclusions: The variations in GB structure and the formation of GB defects present an intriguing picture, particularly when considering their potential influence on how solutes diffuse along the interface. These aspects are rarely explored and our atomic scale investigation of the evolution of GB structure lays out the stepping stone towards understanding their role on the kinetic properties of interfaces.

Characterization of Precipitates in Petroleum Steels by Using Precession Electron Diffraction Technique

Umut Savaci[1], Servet Turan[1]
[1]Department of Materials Science and Engineering, Eskisehir Technical University, Eskisehir, Türkiye

Poster Group 2

Background incl. Aims
Steel has wide variety of grades and properties and not every type of steel applicable for all applications. Due to that reason, correct type of steel needs to be selected for a specific application. For example, for the petroleum and natural gas pipeline applications where pressurized fluid is transported for long distances, American Petroleum Institute (API) X70, X80 or X100 steels are used due to their properties such as high strength, fracture toughness, weldability, corrosion resistance and deformability. API steels are ferritic steels and to obtain the desired properties like high strength, this type of steels is micro alloyed with elements such as Nb, Ti and V with precipitation hardening. Properties of API steels, are modified by the thermo-mechanical rolling by tailoring the microstructure, in addition to the micro alloying. During production and rolling processes several precipitates with different compositions can be formed. Therefore, it is important to determine which precipitate is present in the produced steels, because mechanical properties of material may change with the type of the precipitate. This study aims the characterization of precipitate particle found in the petroleum steel by both conventional and novel precession electron diffraction methods in order to confirm which phase is formed during production.

Methods
In this study, thermomechanically rolled API-X70 steel sample was used. Samples are characterized by conventional TEM and STEM imaging techniques and in addition Precession Electron Diffraction (PED) technique is applied to characterize present phases as well as orientation relationship between the different phases. TEM sample was prepared with conventional mechanical thinning followed by an Ar-ion beam milling. Electron transparent sample is examined by using 200 keV field emission TEM (JEOL-JEM2100F) equipped with STEM high angle annular dark field (HAADF) detector (Fischione-Model 3000) and energy dispersive X-ray (EDX) spectrometer (JEOL-JED2300T). The TEM phase and orientation mapping results are obtained with nano sized probe (at NBD alpha 5 and 0.5 nm spot size) that is scanned in a user specified area over the sample up to 0.7° of precession angle and obtained diffraction patterns are analyzed with ASTAR™ V2 via template matching algorithm.

Results
Microstructure of the samples were investigated by the TEM and STEM imaging methods and these images revealed that steel matrix contains high atomic number element containing precipitate particles according to its contrast with respect to matrix. The sizes of the precipitate particles were ranging from 20 to 80 nm. Chemical composition of the precipitates was tried to be analyzed with EDX, however due to the thickness of the sample, x-ray signals were collected both from precipitate and over or underlaying matrix phase. Because of that reason exact chemical composition cannot be differentiated from the elements present in the matrix. In order to determine the type of the precipitate, phase identification was done by using the precession electron diffraction method by using the crystal structure differences between candidate precipitate phases. For this purpose, phase identification was conducted with calculation and template matching of diffraction patterns of all the

possible precipitate phases with experimental diffraction patterns. With this method, phase identification with high reliability was conducted with the additional X-ray spectrum obtained from the precipitate particle.

Conclusions

In this study, precipitate particle present in the API-X70 steel was successfully identified by using different TEM/STEM techniques, which cannot be identified by the EBSD due to the size of the precipitates. For the identification of the both X-ray spectrum as well as phase maps, obtained by the precession electron diffraction method, were used as a complimentary technique to each other in order to eliminate limitations of these methods.

Interpretable evaluation of STEM images of nanostructures via homology analysis

Mr. Ryuto Eguchi[1,2], Dr. Yu Wen[1,2], Dr. Ayako Hashimoto[1,2]
[1]National Institute for Materials Science, Tsukuba, Japan, [2]University of Tsukuba, Tsukuba, Japan

Poster Group 2

Background incl. aims
Recently, a mathematical framework called persistent homology (PH) has made it possible to quantify materials structural information at a wide range of scales, from the atomic to the nanoscale. PH quantitatively expresses the hole structures of data in terms of their number and scale. Particularly, it is highly suited for discerning the subtle order within inhomogeneous structures, such as amorphous [1] and glass materials [2]. Until now, PH analysis has predominantly focused on three-dimensional atomic arrangements; however, it is also feasible on two-dimensional image data. Here, we applied PH analysis for two-dimensional TEM images, representing a highly useful approach in structural analysis.
In our previous works [3,4], the homological feature known as 'Betti number' was applied for structures of self-assembled Pt/CeO_2 nanocomposites, which were captured by scanning TEM (STEM). The N-th Betti number corresponds to the number of N-dimensional holes, such as connected components, rings (0- and 1-dimensional holes, respectively), and so forth. This homological feature could successfully quantify CeO_2 phase connectivity and further, relationship with the oxygen ion conductivity.
To explore more effective descriptor for the nanostructures, we apply one of the most used PH methods, Persistent Diagram (PD). The key concept in PD lies in tracking the scale required for the appearance (birth, b) and disappearance (death, d) of the N-dimensional holes by continuous deformation of object which called ‘filtration’. Consequently, it includes information on the shapes of the N-dimensional holes, unlike the Betti number. We aim to demonstrate its effectiveness for nano-structural analysis and extract important homological feature for classifying the Pt/CeO_2 nanostructures. To ensure both quantitativity and interpretability, we employed a consistent approach that directly extract interpretable features from PDs.

Method
Firstly, Pt/CeO_2 nanocomposites were synthesized by the annealing of the Pt_5Ce alloy. The 12 nanocomposites with various nanostructures were prepared by changing annealing temperature (500, 600, and 700℃) and syngas ratio (CO:O2 = 0:1, 1:1, 2:1, and 3:1). The nanostructures were characterized through STEM (JEM-2100F, JEOL, Japan) operating at an acceleration voltage of 200 kV. Then, the obtained images were binarized and noise-removed with the OpenCV library in Python. The sequential procedures related to PD acquisition, vectorization for Principal Component Analysis (PCA) were conducted by using data analysis software “Homcloud” [5]. Finally, we used random forest method to find the most important descriptor for classifying Pt/CeO_2 nanostructures.

Result
The binarized STEM images clearly show the self-assembled Pt/CeO_2 nanocomposites that consist of Pt (white) and CeO_2 (black) phases. We focused on the CeO_2 phase for PH analysis to examine its relationship with oxygen ion conductivity. The nanostructures changed from a maze-like to a striped

appearance as the annealing temperature increased. Their 0th and 1st PDs also changed depending on the structural changes.
To clarify the relationship between the structural changes and distribution changes of b-d points in PDs, we extracted five interpretable features, each based on the understanding of individual quadrants in the 0th and 1st PD. The three features, the average width and total length of the striped CeO_2 phases, and the number of CeO_2 phases can be obtained from the 0th PDs. Their trends toward annealing temperature coincide with those from the actual STEM images. The number of ring and gulf-like structures can be obtained from the 1st PDs, focusing on negative and positive b region, respectively. These quantification with PDs could capture trends more clearly compared with conventional observation.
Furthermore, we conducted PCA with vectorized PDs to extract their critical information, which emphasizes the difference between homological features in structures. By the first and second principal components in the 0th and 1st PDs, the 12 nanostructures were relatively well categorized. Through PD reconstruction using the first principal components in the 0th and 1st PDs, we identified a critical region in the PDs: the region in the 1st PDs with d value smaller than characteristic size. In this critical region, d value corresponds to the size of the CeO_2 gulf-like phases. This result suggests that the number of small gulf-like phases is effective as a simple interpretable feature to differentiate Pt/CeO_2 nanostructures. Finally, we applied all interpretable features extracted from PDs thus far to a random forest classification and evaluated their importance. As a result, two key descriptors emerged: the width of the CeO_2 phase and the number of small gulfs. Remarkably, in the scatter plot of the two descriptors, the 12 nanostructures could be classified effectively. In this manner, using a few simple interpretable descriptors, we can more easily discuss and quantitatively evaluate the structural differences arising from variation in synthesis conditions, compared to PCA.

Conclusion
This study investigated the effectiveness of PH analysis in analyzing the STEM images of the nanostructures. Firstly, five interpretable features could be extracted directly from the 0th (the average width and total length of the striped CeO_2 phases, and the number of CeO_2 phases) and 1st (the number of ring and gulf-like structures of CeO_2 phase) PDs. Regarding the gulf-like structure, the PCA results suggest that the number of smaller structures than the characteristic size could particularly differentiate the 12 nanostructures. Finally, we showed that key descriptors can classify nanostructures through the random forest classification, enabling us to interpret their differences easily.

Strategies for Multimodal Image Data Transformation to a Common Format for Cloud Integration and Visualization

Phd Rafael Camacho[1], PhD Jens Berndtsson[1], PhD Massimo Micaroni[1], PhD Karl Zhang[1], PhD Julia Fernandez-Rodriguez[1]
[1]Center for Cellular Imaging, Core Facilities, The Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden, Gothenburg, Sweden

Poster Group 1

Due to their inherent complexity, biological systems require extensive imaging to achieve statistically significant results. Manual operation of microscopy equipment can be laborious and hinder the acquisition of large datasets, impacting reproducibility. To overcome these challenges, the integration of bioimage analysis with computer-controlled microscopes has led to the development of “smart microscopy”. This approach merges computer-controlled imaging systems, image analysis, and machine learning to execute automated imaging workflows that result in large and complex data sets.
At the Centre for Cellular Imaging of Gothenburg University, we are developing and delivering smart microscopy solutions to our scientific community through open-access services for academia and industry alike. However, with increasing automation comes a significant challenge: the sheer volume of resulting imaging datasets. These datasets can span several terabytes, can be generated in a matter of hours, often consist of “multiscale” and “multimodal” datasets, and in some cases, are stored in proprietary file formats. Understandably, this poses formidable challenges for tasks such as visualization, image analysis, data management and sharing with the community.
To address these challenges, we're employing a multifaceted approach that incorporates cutting-edge techniques and tools. This includes utilizing next-generation file formats like ome-zarr,[1] leveraging advanced visualization software such as napari,[2] and integrating collaborative image analysis platforms like webknossos.[3] This comprehensive strategy not only accelerates insight extraction from microscopy datasets but also ensures efficient resource utilization in the era of data-driven life sciences.
In this contribution, we focus on our efforts to generate open-access software tools that standardize the transformation of complex and proprietary file formats across a wide range of microscope solutions, including high content screening, light-sheet microscopy, and electron microscopy (both scanning and transmission). Of particular interest is our focus on datasets for correlative array tomography, including those obtained from the ZEISS MultiSEM,[4] and strategies for multimodal imaging with other technologies such as nanoSIMS[5]. Utilizing the emerging community standard ome-zarr provides us with access to a chunked, cloud-compatible format that enables rapid visualization and facilitates the analysis of large image datasets.

Phase-controlled formation of NixPy catalyst using environmental TEM for potential application in CO2 reduction

Dr. Kshipra Sharma[1,2], Mr. Tianyi Hu[1,2], Prof. Kimberly A. Dick[1,2]
[1]Centre for Analysis and Synthesis, Lund University, Lund, Sweden, [2]Nanolund, Lund University, Lund, Sweden

Poster Group 2

Background:
The urgent need to mitigate climate change has driven intensive research into efficient strategies for reducing CO2 emission and potentially removing them from the atmosphere. Carbon capture and storage represents a promising approach, together with conversion of CO2 produced in industrial processes and from the environment into useful products and fuels via CO2 reduction reactions. Earth-abundant transition metal phosphides, i.e. nickel-phosphide (NixPy) catalysts, offer several advantages, including, cost- effectiveness, switchable selectivity for a range of reaction products, phase-dependent catalytic activity and potential for facilitating CO2 transformation into value-added products for renewable energy [1–3]. However, the development of this system as a tunable catalyst for CO2 reduction reactions is in its early stages, requiring a comprehensive understanding of synthesis processes to attain control over phases, size, shape/facets, and catalytic activities. Structural evolution that occurs during reactions are still largely unknown, and the relationship between facet structure and product selectivity remains poorly understood. This study aims to investigate the phase-controlled formation dynamics of nickel phosphide nanoparticles and their stabilities at higher temperatures using dedicated in-situ transmission electron microscopy (TEM) coupled with chemical vapor deposition (CVD) system.
Method:
The experiments were conducted using environmental transmission electron microscopy (ETEM) combined with a customized gas handling system. Size-selected nickel nanoparticles (10-30nm) were deposited onto micro-electro-mechanical system (MEMS) heating chips by an aerosol-phase fabrication method. These nanoparticles were then exposed to PH3 gas inside the TEM at appropriate temperatures up to 700°C to transform them into nickel-phosphides. Phase transformation of the nanoparticles was induced by changing the reaction parameters such as reaction temperature and PH3 gas flow inside TEM. The dynamic processes were followed by high-speed high-resolution imaging (up to 300 fps) during gas exposure. Structural information was obtained using power spectra of acquired high-resolution images, while composition was monitored by energy dispersive X-ray spectroscopy. The gas composition inside the microscope was monitored by an integrated residual gas analyzer.
Result:
Our Preliminary results focus on the formation dynamics of phase-controlled nickel phosphide nanoparticles. We investigated the role of reaction parameters, such as phosphene gas flow and heating temperature, on the phase transformation of nanoparticles. Two distinct phases were achieved with varying PH3 flow and temperature. Lower PH3 flow (0.3 sccm) at 300°C resulted in Ni2P phase formation, while higher PH3 concentration at elevated temperatures led to Ni5P4 phase formation. Intermediate experimental conditions, such as higher PH3 flow at lower temperature, resulted in a mixture of Ni2P and Ni5P4 phase particles. All the phases showed high thermal stability. These findings suggest that higher PH3 flow at elevated temperatures favors the incorporation of more phosphorus into the nickel phosphide nanoparticles. According to literature, both phases Ni2P

and Ni5P4 are interesting for catalytic activity for hydrogen evolution reaction [4] and CO2 reduction [2], respectively.

Conclusion:

This work demonstrates an in-situ solid-gas phase strategy for synthesizing nickel phosphide nanoparticles with controlled phase by varying PH3 gas flows and reaction temperatures. Such insights are critical for designing phase-engineered NixPy catalyst for sustainable CO2 conversion technologies, offering significant implications for addressing global climate challenges. The next step in this work would be to investigate these phases for CO2 reduction and to monitor the structure evaluations occur during the catalytic reactions.

Poster Group 1

Background incl.aims: Ovulatory and tubaperitoneal factors constitute an important part of the female infertility factor. At the beginning of the reproductive period, there are approximately 400 thousand primordial follicles in the human ovary. Follicular fluid is the environment in which the oocyte resides throughout oogenesis and is important in oocyte development (1). Follicular fluid is aspirated with the oocyte during oocyte retrieval. By analyzing the follicular fluid, the relationship between the oocyte and surrounding cells can also be evaluated. The most common risk factors for infertility are smoking, body mass index being less than 18.5 kg/m2 or more than 25 kg/m2, excessive exercise or no exercise, alcohol consumption, caffeine consumption, and stress. IL-8 is known as a cytokine growth factor that contributes to the pathogenesis of endometriosis by promoting endometrial cell attachment, invasion, cell growth, proliferation, and immune protection in the endometrium (2). Although IL-8 has been shown to have an effect on many areas such as female infertility, endometriosis and Polycystic Ovary Syndrome, no study has been found showing its relationship with different parameters on oocyte quality. The aim of this study was to investigate the relationship between free fatty acids in follicular fluid, body mass index and oocyte reserve quality. It was aimed to evaluate the effects of data on the relationship between free fatty acid level in follicular fluid, IL-8, lipid droplet count, body mass index and peripheral blood smear in female infertility samples.
Methods: A total of 60 people who applied to the in vitro fertilization clinic for various reasons (male factor, female factor, unexplained infertility) were included in the study. In our study, a sample of 60 patients diagnosed with infertility was created. These patients will be evaluated in two groups according to body mass index. Body mass index of less than or more than 25 kg/m2 was evaluated as group 1 and group 2. Various exclusion criteria were applied to determine the patient groups in order not to affect the study design. In our study, free fatty acid (FABP) and IL-8 parameters in follicular fluid taken for routine treatment from women applying assisted reproductive techniques were evaluated by ELISA (Enzyme-Linked ImmunoSorbent Assay) method. In blood samples, peripheral smears were used to determine the distribution of shaped elements of blood and also to examine whether there was a correlation between them and body mass index. At the same time, Oil red staining of neutral lipids and lipid droplet morphology were identified by light microscopy. All data were analyzed by statistically.
Results: When the differences between the groups were examined, it was determined that FABP and IL-8 levels were higher in the group with high body mass index (group 2). The concentrations of follicular IL-8 and FABP were significantly higher in the group 2 and were positively correlated with the levels of fatty acids. At the same time, when blood smear samples were examined in this group, it was determined that the number of leukocytes and the number of lipid droplets was higher. Accordingly, a semiquantitative histopathological damage score was made and lipid droplet distribution and blood smear between groups was determined. It was observed that over body mass index and cellular degeneration caused infertility, inflammation and increased oxidative damage.

Conclusions: Follicular fluid and blood smear samples taken from women who have used assisted reproductive techniques will become more important in the diagnosis and course of the disease. By evaluating several parameters together, it is aimed to obtain faster and more reliable results in assisted reproductive techniques. IL8 and FABP affects female fertility at both serum level and light microscopic levels.

Poster Group 1

Background incl. aims

Monosodium glutamate (MSG), a flavor enhancer in prepared foods, can lead to harmful effects in different organs and systems. Based on the literature data, monosodium glutamate is known to cause liver injury by generation of reactive oxygen species leading to damage of lipids, proteins, and DNA by the formation of free radicals (1). Ferulic acid, as a potent antioxidant, is mentioned to ameliorate the harmful effect of biomolecules by suppressing the production of reactive species and the oxidative stress. In this experimental study, MSG-induced liver injury putative healing effect of ferulic acid were assessed at histochemical, transmission electron microscopical and biochemical levels.

Methods

In this study, male Wistar albino rats (7 weeks old, 160-200g) were used and kept in a laboratory environment (Acıbadem University Experimental Animal Laboratory) with a temperature of 22±2°C and a standard light/dark (12/12 hours) cycle throughout the experimental period. Rats were randomly divided into 5 groups (n:8/group). Experimental groups were fed by a standard rat chow and tap water. Control group (Gr 1) was treated with 1 ml of distilled water by gavage every day during the experiment for 38 days. Rats in the DMSO+FA group (Gr 2) were given 1 ml of dimethyl sulfoxide (DMSO) for 28 days and FA solution (25mg/kg, dissolved in DMSO) by gavage in the last 10 days of the experiment. To create an MSG-induced liver injury model, MSG solution (600 mg/kg, dissolved in DMSO) was orally administered to the rats (MSG group-Gr 3) for 28 days (2). MSG+DMSO group (Gr 4) was treated by MSG solution (600 mg/kg, dissolved in DMSO) by gavage for 28 days and 1 ml of DMSO was given by gavage on the last 10 days of the experiment. MSG solution (600 mg/kg) for 28 days and then FA solution (25 mg/kg) on the last 10 days of the experiment were administered by gavage to the rats in the treatment group (MSG+FA-Gr 5) (3). At the end of the experiment the rats were sacrificed under anesthesia. Liver tissues samples were processed for light and transmission electron microscopical evaluations. Paraffin sections were stained with Hematoxylin-eosin (H&E), Masson's trichrome stains and Periodic acid-Schiff reaction (PAS). Histopathological scoring of the liver tissue was performed according to; vacuolization in hepatocyte cytoplasm, sinusoidal dilatation, leukocyte cell infiltration and distribution and amount of connective tissue in the parenchyme, as well as glycogen content within the hepatocytes. Oxidative stress markers, as malondialdehyde (MDA), glutathione (GSH), superoxide dismutase (SOD), total antioxidant capacity (TAS), total oxidant capacity (TOS) and oxidative stress index (OSI) values were measured for biochemical assesments (4).

Results

The light microscopical examinations revealed normal morphology of liver parenchyme in control and DMSO+FA groups. Steatosis and vacuolization in hepatocytes, sinusoidal dilatation, leukocyte infiltration, increased connective tissue in the parenchyme and decreased amount of glycogen in hepatocyte cytoplasm were detected in MSG and MSG+DMSO groups. Based on histopathological scoring, liver tissue injury was significantly reduced in MSG+FA group, compared to MSG and MSG+DMSO groups. Transmission electron microscopy revealed the similar ultrastructural data as in light microscopy to point out a prominent recovery in MSG+FA group. In MSG and MSG+DMSO groups, an increase in MDA, TOS and OSI levels were detected whilst GSH, TAS and SOD were decreased. Deteriorated biochemical data has been reversed and ameliorated in MSG+FA group, as the treatment group.

Conclusion

Based on the current biochemical and histopathological data, we could suggest that administration of ferulic acid to rats in this experimental model of MSG-induced liver injury contribute significantly to ameliorate/heal the hepatic damage by regulating the formation of reactive oxygen species.

In situ growth and phase engineering of manganese arsenide nanostructures in environmental TEM

Hedda Christine Soland[1,2], Mikelis Marnauza[1,2], Pau Ternero[2,3], Professor Kimberly A. Dick[1,2]
[1]Centre for Analysis and Synthesis, Lund University, Lund, Sweden, [2]NanoLund, Lund University, Lund, Sweden, [3]Solid State Physics, Lund University, Lund, Sweden

Poster Group 1

Background incl. aims
For magnetic materials, in situ synthesis offers an additional advantage by enabling the exploration of the magneto-structural relationship. Understanding magneto-structural phase transitions is crucial for the development of materials such as those used for magnetocaloric applications. One such material is MnAs, in bulk known for the ferromagnetic transition around 315K coupled with a structural transition from hexagonal (α-MnAs) to orthorhombic (β-MnAs). However, experimental studies of MnAs nanoparticles have shown discrepancies where the ferromagnetic transition occurs even in the absence of the structural transition.

Nanomaterial synthesis is usually done ex-situ, which can sometimes be tedious and time-inefficient, especially when exploring new or metastable materials. An environmental TEM (ETEM) specifically designed for exploring new material systems, allows for simultaneous exploration of synthesis parameters while observing the changing nanostructures with atomic resolution. Parameters can be fine-tuned, and even metastable material systems and crystal structures have been synthesized this way, showing promise for exploring not only new material systems but also those that have previously been discarded.

In this study, we focus on transition metal pnictides, particularly MnAs, due to their promising applications in spintronics, magnetic refrigeration, and data storage devices. During the preliminary work, the goal is to explore the diffusion behaviour of manganese, how to control the growth rate of MnAs and explore the various structural phase transitions, laying the groundwork for a deeper understanding of magnetic transition metal pnictides. In the long term, we would like to integrate Lorentz imaging techniques to also explore the magnetic properties. This way, material growth could be paired with atomic resolution imaging, chemical analysis, and even information about magnetic domains, and pave the way for a new approach to fundamental studies and phase engineering of magnetic nanomaterials.

Methods
MnO_2 nanoparticles were prepared via spark ablation and sputtered directly onto a MEMS chip for further work in the Hitachi HF-3300S 300kV ETEM. In the ETEM, arsine (AsH_3) was used as the precursor gas to facilitate the growth of MnAs nanostructures. Various parameters, including temperature, gas flow, and electron beam effects, were explored to map the parameter space of this material system and optimize the stability of both MnO_2 and MnAs. For analysis, HRTEM, FFT, SE and Z-contrast in STEM mode, and both TEM- and STEM-EDX were performed during the experiments.

Results
It was observed that AsH_3 diluted with H_2 during electron beam irradiation causes MnAs to form outside of the MnO_2 particles. Together with the oxide reducing in size and eventually disappearing,

this might indicate that the manganese atoms diffuse out of the oxide particles to crystallize into MnAs. This effect seems to be correlated with electron dose and is not observed in STEM mode. The fact that MnAs only form under a strong electron beam can be advantageous in the exploration of the parameter space, as no changes were observed for the non-exposed oxide particles. However, using manganese oxide particles instead of pure manganese also introduces some limitations. At lower temperatures, around 200°C, the stability of the MnO_2 nanoparticles under the electron beam was compromised, even without any AsH_3 supplied. However, at higher temperatures, around 400°C, the MnO_2 particles were observed to be more stable and thus preferable for control of the diffusion of manganese into MnAs.

Conclusion

MnAs was successfully synthesized from MnO_2-particles under AsH_3 atmosphere using an in situ ETEM due to what seems like an electron beam-activated process. These preliminary findings demonstrate the feasibility of synthesizing stable MnAs nanostructures in the ETEM environment and underscore the potential of this approach for exploring transition metal pnictides and similar material systems. The results show that this method is promising for future studies of magneto-structural relationships in transition metal pnictides, especially if magnetic imaging techniques are well integrated into the system. Additionally, the results are laying the foundation for further investigations into phase engineering and combinations with semiconducting III-V nanowires, such as GaAs and InAs, which already have been greatly explored in this system.

Advanced image analysis techniques to support and streamline cell manufacturing

Dr Fuad Mosis[1]
[1]bit.bio, Babraham Research Campus,, United Kingdom

Poster Group 2

Background
To achieve a high standard of cell manufacturing, it is imperative to maintain unwavering diligence and meticulous attention to detail throughout every phase of product development. Imaging of cells can play a vital role in research & development; nonetheless innovation is needed to bring the quantification and analysis of the imaging data produced to a standard suitable for cell manufacturing.

Methods
Visually monitoring cells at various stages of their development is an essential part of assessing their purity, function, and overall health. At bit.bio, we utilise bespoke image analysis and machine learning techniques to capture and monitor trends from imaging data that provide insights into cellular behaviours. This includes a combination of open-access and commercially available software, as well as bespoke and custom-made tools. The latter includes the use of Python packages to analyse microscopy-derived data that provides users with metrics to better understand imaging data. We have also developed and trained machine learning models that can process imaging data to provide consistent readouts on cell quality and purity.

Results
We have been able to successfully implement custom and highly-sophisticated image analysis tools that have enabled us to enhance our data mining capabilities from imaging data. These have played a pivotal role in streamlining our cell manufacturing capabilities by providing quality control readouts and supporting key decision-making steps in validating cell culturing and growth protocols.

Conclusions
Advances and developments in image processing methodologies at bit.bio have allowed us to accelerate our analysis workflows to produce a consistently high level of quantification of imaging data. The combination of custom scripts and packages with machine learning tools means that we have a comprehensive understanding of our imaging data, and this knowledge can be applied to make informed decisions on optimal culturing conditions, and provide assurances on cell quality to customers.

Ultra-low voltage SEM observation for battery materials

Ph.D. Yutaka Nagaoka[1], Dr. Yoichiro Hashimoto[1], Mr. Toru Aiso[1], Mr. Shuhei Yabu[2], Mr. Masahiro Sasajima[3]
[1]Solution Development Dept., Hitachi High-Tech Corporation, Hitachinaka, Japan, [2]Electron Microscope Systems Design Dept., Hitachi High-Tech Corporation, Hitachinaka, Japan, [3]Software Design Dept., Hitachi High-Tech Corporation, Hitachinaka, Japan

Poster Group 1

Background incl. aims
The scanning electron microscope (SEM) observation at an ultra-low accelerating voltage can visualize strictly superficial surface of the sample with a little electron beam irradiation damage, since the electron scattering volume into the sample is extremely small. However, interpretation of the captured image becomes complicated because the voltage contrast (VC) depending on emitted electron yield changes its behavior under the ultra-low accelerating voltage conditions [1]. Previously, the VC between binders and active materials of lithium-ion battery (LIB) anodes under ultra-low accelerating voltage conditions below 50 V were studied. As the result, we reported that the VC between the binder and the active material was dramatically changed among the ultra-low accelerating voltage conditions [2]. Especially, particle-like unique contrast, which was thought to reflect the binder structure, was observed at 20 V. Although this VC was presumed to be formed by the surface potential at the specific accelerating voltage, the formation mechanism was unknown. In this study, a simplified experiment simulating the binder on the LIB anode was performed to elucidate the binder VC formation mechanism.
Methods
Styrene-butadiene-rubber (SBR) particles: the primary material of the binder, were dispersed in water. The solution with the dispersed particles were dropped onto an osmium (Os) coated Si substrate. The solution was dried at the room temperature. The SBR particles were observed at accelerating voltages below 50 V using a Hitachi SU8700 field emission SEM [3]. The correlative observation with SEM and atomic force microscope (AFM) was performed using a Hitachi AFM5300E for surface potential measurements after electron beam irradiation. The “Air protection” sample holder was used to retain the sample in vacuum at the transfer between SEM and AFM.
Results
The graphic shows the observation results of the SBR particles, representing the “binder”, on the Os-coated Si substrate at the same area captured at accelerating voltages from 10 to 50 V. The SBR showed darker signal (indicated by the red arrow in image (e)) compared to the surrounding Si substrate at 50 V. As the accelerating voltage gradually decreased to 30 V, the contrast between the SBR and the substrate was almost disappeared. When the accelerating voltage decreased to 20 V, the SBR was observed with particle-like contrast. At the accelerating voltage of 10 V, mirror phenomenon, in which the primary electrons bounced off before impacting the sample surface, occurred. This result showed that the VC of the SBR on the Si substrate showed same manner of the binder on the active material in the previous work in spite of different substrate material. To clarify the principle of the VC formation mechanism, correlative AFM observations of the SEM observed area were also executed to measure the residual surface potential. As the result, the residual surface potential of the SBR, the “binder”, was confirmed to be varied by the accelerating voltage.
Conclusion

VC formation mechanism of the binder was investigated with the simplified specimen. The surface appearances of the “binder” were observed with the SEM and the surface potentials were also measured with the AFM correlatively, and SEM accelerating voltage dependency of the residual surface potential was found.

Structural Study of Polyphasic Mixtures Using 3d Electron Diffraction:A Case Study of Oxyresveratrol

Ms Vincentia Emerson Agbemeh[2]
[1]Electron Crystallography, Center for Materials Interfaces, Istituto Italiano di Tecnologia, Pontedera, Italy, [2]Department of Chemistry, Life Sciences and Environmental Sustainability, University of Parma, Parma, Italy

IM-06 (2), Lecture Theater 1, august 30, 2024, 10:30 - 12:30

Background
Oxyresveratrol is a naturally occurring compound found in Artocarpus Lakoocha which is known for its antioxidant and anti-inflammatory properties. We try to understand more about this compound by studying its crystal structure in the pure anhydrous form. This a crucial information for understanding how the crystal structure can be modified to address one of the problems with this natural product; its low solubility and bioactivity. The only known crystal structure of oxyresveratrol was reported by Deng et al. in a dihydrate form however the anhydrate form has not been reported. So far, there has been no success in growing single crystals of the anhydrate form large enough for structure determination using Single Crystal XRay Diffraction (SCXRD). An initial attempt to solve the anhydrate crystal structure using Powder XRay Diffraction (PXRD) was unsuccessful due to overlapping peaks and the presence of more than one phase. The PXRD pattern of the reported hydrated phase also did not fit all the peaks of the PXRD pattern of our sample. 3D electron diffraction (3DED) is a technique for structure solution of single crystals below 1µm and ideal for identifying phase mixtures. We apply 3DED for crystal structure determination and to better investigate all the possible phases that were present in the sample.

Method
3D ED data collection was performed in the Zeiss Libra 120kV Transmission Electron Microscope (TEM) at both room temperature and at -180˚C. Sample for the cooling experiment were put in water and plunged frozen in liquid ethane by applying a technique commonly used in cryo Electron Microscopy (cryoEM) to prevent sample dehydration. This method is used to identify possible hydrates in our sample whose crystal structure collapses in the high vacuum condition present in the TEM. Experimental PXRD was performed using a STOE Stadi P equipped with Cu-Kα1 radiation.
Results
In the room temperature experiment, we identified a new anhydrate oxyresveratrol crystal structure which has not been reported. It crystallizes non-centrosymmetric space group Pc and refined using dynamical refinement. Additionally, in the cryo experiment, a new polymorph of the dihydrate form of oxyresveratrol with the same space group as the anhydrous phase was found different from the reported hydrated phase which was P-1. The simulated PXRD pattern of the two new structures were compared with the experimental PXRD. We observed the presence of both phases of the new structures and a minor phase of the form 1 hydrated phase and fully fitted the patterns using Rietveld refinement.
Conclusion
The successful structural determination of these two new polymorphs demonstrates the possibility of directly determining structures from polyphasic mixtures by combining the power of both 3D ED and PXRD. This will improve efficiency and broaden the scope of phase identification which plays a crucial role in pharmaceutical development and within the field of crystal engineering.

Poster Group 1

Background: An aqueous, coarse extract called bromelain is obtained from the fruit and stems of the pineapple. Bromelain is a substance that can be easily absorbed into the body without losing its proteolytic activity and without showing any significant side effects. In vitro and in vivo studies have demonstrated various fibrinolytic, antiedema, antithrombotic, and anti-inflammatory activities of bromelain. Experimental studies have demonstrated the properties of bromelain, such as accelerating healing effect in tendon and muscle injuries, faster healing rate in burn wounds, and reducing post-surgical edema. This present study aims to investigate the neuroprotective effects of bromelain on peripheral nerve injuries, specifically through a rat sciatic nerve crush injury model.The study focused on the ability of bromelain to improve nerve regeneration and functional recovery after injury through histological and electron microscopic evaluations.

Materials and Methods: A controlled experimental study was conducted on 36 adult male Sprague-Dawley rats, divided into four groups: Sham, Control (Nerve injury), and two Treatment groups receiving oral bromelain at doses of 25 mg/kg and 50 mg/kg respectively. The sciatic nerve crush injury was induced using a standardized protocol. The intervention groups received their respective doses of bromelain daily for six weeks post-injury. Evaluation of neuroprotective effects was assessed through walking track analysis for functional recovery, hot plate tests for nociception, nerve conduction studies and histological examinations including light and transmission electron microscopy. Sciatic nerve samples taken from all the experiemental groups were fixed in 10% buffered formalin solution. Masson's trichrome stain was applied to paraffin section to reveal myelinated axon morphology. Tisue samples from sciatic nerve, fixed in 2.5% glutaraldehyde solution were processsed for transmission electron microscopy.

Results: The bromelain-treated groups exhibited significant improvements in functional recovery assessed by the Sciatic Functional Index (SFI) compared to the control group. The 50 mg/kg bromelain group showed the most pronounced improvement ($p<0.05$). Nociceptive testing indicated a reduction in pain sensitivity in bromelain-treated groups. Electrophysiological studies revealed enhanced nerve conduction velocities in treatment groups ($p<0.05$) with histochemical and ultrastructural analysis confirming accelerated nerve regeneration and reduced scar tissue formation. Statistically significant differences were observed between treatment groups and the control group with the higher bromelain dose demonstrating superior outcomes.

Conclusion: Bromelain administration in post-sciatic nerve crush injury in rats significantly enhances nerve regeneration, functional recovery, and reduces pain sensitivity. The study highlights bromelain's potential as a beneficial therapeutic agent in the management of peripheral nerve injuries with dose-dependent effectiveness. Further research is warranted to elucidate the underlying mechanisms and explore the clinical applicability of bromelain in peripheral nerve injury treatment.

Poster Group 1

Background incl. aims
The planar surface milling method is effective for sputtering a specimen surface by irradiating an Ar ion beam at an adjusted irradiation angle while the specimen is continuously rotated. This method is used for final finishing of mirror polished specimens by mechanical polishing for SEM observation and EBSD analysis. And the sputtering area is about 5 mm in diameter using the conventional planer surface milling method. However, there is an increasing demand for final finishing by planer surface milling over a larger area, such as a diameter of over 10 mm, where mechanical polishing is generally used. The followings are some of the issues with conventional planar surface milling.
Problem 1: Ion irradiation is performed from one direction at the periphery of the ion irradiation area. This causes a curtaining effect, making it difficult to obtain a flat surface over a large area.
Problem 2: Differences in etching rates are caused by differences in specimen material and crystal orientation, resulting in unevenness on the ion-irradiated surface1).
In this study, we examined methods to resolve these issues.
Methods
Specimen for this test is rolled aluminum foil (100 µm thickness) without mirror polishing or other pretreatments. This is because this specimen has uniform scratches in one direction generated during rolling process, and these scratches were evaluated as polishing scratches.
The Ar ion beam processing system IB-19530CP/IB-10500HMS (JEOL Ltd.), and IB-11550LSRH (JEOL Ltd.) as holders for planer surface milling were used for this study. By combining these units, the stage rotating and stage swinging during planer surface milling can be executed simultaneously. This enables milling over a large area. We named this method to large area planar surface milling. In this method, the center of rotation and the ion beam center are eccentrically aligned during the swing of the specimen stage, allowing ion beam irradiation of the outer periphery from various directions. Therefore, it can reduce the curtaining effect at the outer area of the ion irradiation area. In addition, the tilt angle of the planar surface milling holder is adjusted to make the ion beam irradiation angle lower to 10° or less, which can suppress the unevenness of the ion irradiated surface2).
Experiment 1: Verification of reducing the curtaining effect
Specimens were prepared by the planar milling method using a specimen rotation motion and by the large area planar milling method which combines the specimen rotation with the stage swing motion. Subsequently, the quality of surface was compared. Specimens were processed under the following conditions: an acceleration voltage of 10 kV, a processing time of 1 hour, and an ion beam irradiation angle of 5°. In the large area plane milling method, the stage swing angle was set to ±30°.
Experiment 2: Verification of unevenness reduction
Specimens were prepared using the large area planar surface milling method at ion irradiation angles of 5° and 2°, and the quality of surface was compared. Specimens were processed under the following conditions: an acceleration voltage of 10 kV, a stage swing angle of ±30°, and a processing time depended on irradiation angle of ion beam : 12 hours at an ion beam irradiation angle of 5° and 24 hours at an ion beam irradiation angle of 2°.

An FE-SEM (JSM-IT800 (JEOL Ltd.)) and an AFM (JSPM-5200 (JEOL Ltd.)) were used to observe each processed surface.

Results

1. comparison of the conventional method and large area planar surface milling method

The conventional method produces a flat surface in the vicinity of the milling center. However, striped structures can be seen on the surface about 5 mm away from the milling center due to the curtaining effect caused by the limited direction of ion beam irradiation. On the other hand, the large area planar surface milling method reduced the curtaining effect even at a distance of about 5 mm away from the milling center. (Fig. 1 A).

2. effect of irradiation angle on large area planar surface milling:

Unevenness due to differences in etching rate, such as crystal orientation, could be reduced by changing the ion beam incidence angle from 5° to 2°. In addition, the average surface roughness of the center of the processed area was measured using AFM. The average surface roughness was Ra: 86.7 nm at an ion beam irradiation angle of 5°, and Ra: 24.1 nm at an ion beam irradiation angle of 2°. This indicates that unevenness reduction was achieved even in the center of the processed area. The processing at an ion beam incidence angle of 2° extends the ion irradiation range, and thus reduces the curtaining effect over a wide area of 30 mm diameter (Fig. 1 B).

Conclusions

We examined the reduction of unevenness and increase of the milling area by the planar surface milling. Using a new method that combines a large area planar surface milling method with an extremely low-irradiation angle ion beam, the unevenness caused by etching rate differences in materials or crystal orientation was reduced and a large range of specimen processing could be performed. This method is expected to be applied to specimens that are not easy to mechanically polish or as an alternative technique to buff polishing, because it can produce a fine surface with reduced unevenness over a wide area exceeding 20 mm in diameter.

In this presentation, application examples will be presented in addition to the above results.

Characterization of casting inclusions in superalloys by BSE and EDS

Prof. Dr. Dragan Rajnović[1]
[1]Faculty of Technical Sciences, University of Novi Sad, Novi Sad, Serbia

Poster Group 2

Background incl. aims
Superalloys exhibit remarkable properties such as exceptional mechanical strength, resistance to thermal creep deformation, and robustness against corrosion and oxidation, allowing them to operate efficiently in extreme environments. Their compositions primarily include nickel, cobalt, iron and chromium, whit addition of tungsten, molybdenum, tantalum, niobium, titanium, and aluminum. Innovations in the chemical development of superalloys have enabled the precise tailoring of their properties, ensuring they meet the specific demands of their applications. These materials are crucial in applications demanding high performance at elevated temperatures, such as in aerospace turbine engines and marine engineering.
Superalloys are typically processed by investment casting (also known as lost-wax casting) under vacuum conditions to ensure the highest quality of the casting. During casting, different ceramic materials are used for crucible in which an alloy is melted, for cup in which a molten material is transported, for shell in which casting is performed, or for ceramic slurry used for coating a wax model. All of this is made of different size ceramic particles which during operation could chip and make inclusion in the cast part. For that reason, this work is performed to identify inclusions, and thus identify critical place in casting procedure.
Methods
The casting inclusion are observed at different cross sections of superalloy casted parts which were metallographically prepared and afterwards preliminary examined on Light Microscope Leitz Orthoplan, and further studied in backscatter electrons (BSE) mode on scanning electron microscope JOEL JSM-6460LV equipped with EDS system INCA Oxford Instruments, at 20 kV.
Results
It is found that ceramics inclusions are primarily present in the surface of cast part, thus making a critical place for fracture in operation. In backscatter electron imaging mode it is straightforward to distinguish between the most common inclusions, like: ZrO_2 from crucible, with distinctive white appearance (Fig. 1); Al_2O_3 from cup, with dark gray appearance (Fig. 2); or $ZrSiO_4$ inclusion, originating from ceramic slurry, which could be also simply identified due to the gray shade (Fig. 3). On figure 4, the presence of multiple different inclusions could be observed, also. All observed inclusions are also positively identified by quantitative EDS point or area analysis.
Conclusion
At the end, it could be summarized that backscatter electron (BSE) analysis is a fast and convenient method to identify casting inclusions in superalloys, and thus to identify an origin of inclusion and casting error. Further EDS analysis positively confirms identification of inclusions, and gives additional data about oxidation or other impurities present.

Thin Film Phase Plates for Cryo TEM: Fabrication, and Characterization Using Electron Holography

Marcus Hufe[1], Mads Larsen[1], Prof. Stephan Keller[1], Prof. Marco Beleggia[1,2], Associate Professor Paul Kempen[1]
[1]Technical University of Denmark, Copenhagen, Denmark, [2]University of Modena and Reggio Emilia, Modena, Italy

Poster Group 2

BACKGROUND

Phase plates for transmission electron microscopy (TEM) have been a research field since 2001 and are of continuing interest to enhance contrast and increase resolution when imaging biological samples [1]. Unfortunately, biological samples are weak-phase objects in the electron microscope, providing minimal inherent contrast. This is in part because our detectors are only sensitive to variations in electron intensity and not phase. There are different approaches to overcome these limitations, including heavy metal staining (mass-thickness contrast), defocus phase contrast, and phase plate induced phase contrast.

We utilize phase plates to induce phase contrast. The most promising phase plates for soft-matter imaging are thin-film-based. These phase plates suffer from several limitations that plague their widespread implementation. These challenges include contamination, ease of installation and use, lack of reproducibility, and lack of full understanding and control of the induced phase shift [2]. We aim to develop, design, fabricate, implement and use these phase plate devices to reliably improve the contrast when imaging biological samples while staying close to focus, and that are easy to install, align, and use continuously.

METHODS

In this work we are developing thin film based phase plate devices, operating in Zernike and Hilbert mode respectively, to enhance phase contrast at minimal defocus. We are utilizing cleanroom technology to fabricate these devices to be reproducible and with known parameters. We are employing established CMOS thin film processes including dry and wet chemical etching and thin film deposition to create our devices. These phase plates, when installed in the back-focal plane of our TEMs, introduce a phase shift of $\Delta\phi = \pi/2$ (pi-half), or π (pi) respectively, to the scattered beam. The phase shift produced by a thin film is governed by the mean inner potential of the film, the film thickness and the accelerating voltage of the electron microscope. Using the cleanroom to fabricate these devices gives us both knowledge and control of the induced phase shift [3].

We are also employing the electron holography technique to measure the phase shift induced by our thin films. For that a bi-prism, in our case a biased gold wire, is placed in the selected area diffraction (SAD) plane of our TEM. With this we can make the part of the beam going through our material interfere with a reference part going through vacuum. We are thus creating a hologram in the image plane that contains the phase information of the beam going through the material relative to vacuum. After mathematical procedures to reconstruct and unwrap the phase information we can map the phase shift induced by our thin film material [4, 5].

RESULTS

We are able to utilize off-axis electron holography to reliably characterize the phase shift induced by the thin film material of our devices. Employing the accelerating voltage, the known film thickness, and the measured phase shift, we can determine the mean inner potential for the material. With the mean inner potential in hand we can now produce phase plate devices with the correct thickness to induce the target phase shift. With these devices we are able to optimize the contrast from a variety of weak-phase objects yielding TEM images with both higher resolution and higher contrast.

CONCLUSIONS

With the aforementioned approaches and techniques we are able to build a reliable device that improves the contrast when we image bio samples while keeping the defocus value very close to focus. The device can be reliably aligned in diffraction mode when mounted in the back-focal plane. We can address the most common drawbacks of material-based phase plates: we can make usage simple by installing them in the back-focal plane and alignment by aligning at the material edge visible in diffraction mode. Via employing electron holography we can also track the phase shift induced by our devices, which in turn improves the interpretability of phase contrast images.

Poster Group 1

Hexagonal Boron Nitride (hBN) is a wide-band gap two-dimensional material, which has attracted much attention due to its ability to host luminescent centres with remarkable stability and single-photon in nature. This work explores the generation and characterization of luminescent centers in hBN on a SiO2/Si substrate using irradiation with a Scanning Electron Microscope (SEM) and Focused Ion Beam (FIB). We have investigated the impact of irradiation parameters on the optical and morphological properties as well as reproducibility of the luminescent centers using Photoluminescence (PL) spectroscopy, Atomic Force Microscopy (AFM), and SEM imaging. Our findings demonstrate the successful engineering of VB- centres, consistent with existing literature. We highlight the crucial role of material processing, such as the growth and annealing conditions of hBN and irradiation-specific parameters. This optimized methodology holds promise for generating B centres in hBN in a reproducible manner, providing a robust benchmark for future research in quantum technologies and other related fields.

Figure: a) Post PL map (left) and corresponding spectra from hBN flake treated with PFIB oxygen beam at different beam energies and doses. B) Post PL map (left) and corresponding spectra from hBN flake treated with the electron beam at 15 keV energy and different doses.

Non-toxic clearing and labeling with fluorescent REAfinityTM antibodies for enhanced 3D visualization of tissues

Msc Kevin Bigott[1]
[1]Miltenyi Biotec B.V. & Co. KG, Cologne, Germany

Poster Group 1

Background
Generation of a 3D cellular topography of biological specimens is often essential to understand cellular and molecular processes. Especially, spatial visualization of heterogenous protein expression in solid tumor samples is considered important for advanced phenotyping and potential diagnostic applications. However, for a long time, biologists were limited to the visualization of thin tissue sections, which provides limited cellular context. Furthermore, sectioning is time-consuming and often prone to artifacts, like ripping and folding. While clearing methods in combination with light-sheet fluorescence microscopy have emerged as powerful tools for 3D reconstruction of tissues, most clearing techniques involve toxic reagents which require special safety provisions and generate extra effort for sample preparation as well as imaging. To address these shortcomings, we developed a clearing workflow based on non-toxic reagents that allows for efficient 3D imaging biological samples in combination with directly labeled REAfinityTM antibodies.
Methods
Briefly, samples were fixated with paraformaldehyde and permeabilized to facilitate delipidation and antibody-conjugate penetration during subsequent immunostaining. Whole-mount immunostaining was performed using REAfinityTM antibodies coupled to Vio® dye variants. Duration of the immunostaining depends on the tissue size and tissue type, ranging from 2 - 7 days. After staining, tissues were dehydrated using an ascending ethanol series. Subsequently, refractive index matching was performed; a process referred to as tissue clearing renders opaque tissues transparent and thereby improves optical light penetration depth. For blood-rich organs and tissues a carbamide peroxide based depigmentation module was applied to remove residual blood to facilitate increased light penetration during imaging. In addition, tertiary butanol and pH adjustment during dehydration and clearing process can be used to ensure preservation of endogenous fluorescent proteins. Imaging of large samples was performed using the UltraMicroscope Blaze light-sheet imaging platform. To eliminate noise, intensity inhomogeneities, striping artifacts and to enable deconvolution of imaging data, a postprocessing pipeline based on MACS® iQ 3D Large Volume software was applied.
Results
Our workflow enables 3D imaging of various biological samples, including mouse brain, lymph nodes, lung, intestine, liver, spleen, kidney, stem cell-derived organoids, xenografts, patient-derived tumor samples and tumor spheroids. To enable the effective clearing for blood-rich organs and tissues, an efficient depigmentation module was integrated to increase light transmission. Additionally, the protocol can be also modified to ensure preservation of endogenous fluorescence. For optimal 3D imaging, we combined the clearing procedure with whole-mount immunostaining of mouse tissues, human tumor samples and organoids using Miltenyi Biotec's REAfinityTM antibodies coupled to newly developed Vio® dye variants optimized for application in light-sheet microscopy. REAfinityTM antibodies are recombinant antibodies engineered to provide high specificity, purity, and superior lot-to-lot consistency compared to hybridoma-derived antibodies, whereas Vio® dyes are a new generation of fluorescent dyes characterized by remarkable brightness, photostability and highly

resistant against organic solvents during clearing procedure. UltraMicroscope Blaze light-sheet imaging platform enabled fast high resolution imaging of large samples. Our data indicates highly efficient labeling of the vasculature, different neuronal subtypes in mouse brains, as well as bright staining of neural progenitors and proliferative cells in cerebral organoids. Furthermore, carcinoma cells and lymphocytes were visualized in solid tumors and mouse lymph nodes, respectively. After data acquisition, a profound postprocessing pipeline based on the MACS® iQ 3D Large Volume software enables the elimination of noise, intensity inhomogeneities, striping artifacts and features deconvolution of imaging data, which ensures ideal preparation of 3D data for subsequent data visualization and quantification.

Conclusion

We present a robust, fast, flexible and non-toxic clearing procedure that allows for efficient 3D imaging of a wide range of biological samples. Optional modules for depigmentation of blood-rich organs and preservation of endogenous fluorescence can be applied in order to extend the procedure to applications with further requirements. By combining the advantages of REAfinityTM antibodies and Vio® dyes, we developed staining reagents that significantly reduce staining duration and are thus ideally suited for whole-mount tissue labeling, multiplexing, and imaging with light-sheet microscopy using the UltraMicroscope Blaze. Taken together, we developed an efficient clearing procedure combined with highly specific antibody conjugates and a data postprocessing pipeline for optimal 3D visualization of tissue and whole organs, paving the way for a better understanding of tissue structures and disease mechanisms. Extension of the clearing procedure for additional applications and constant development of further antibody conjugates coupled to additional Vio® dye variants will further increase marker coverage and the range of applications.

Deformation of steel chips due to machining

Dr. Sabine Schwarz[1], Univ.Ass. Dipl.-Ing. Christian Baumann[2]
[1]University Service Centre for Transmission Electron Microscopy (USTEM), TU Wien, Vienna, Austria,
[2]Institute of Production Engineering and Photonic Technologies, Vienna, Austria

Poster Group 2

Background incl. aims
During machining of materials, high temperatures and high pressures can occur. So, the materials are exposed to high plastic strain, high strain rates as well as high temperatures and heating rates. In order to be able to describe this, materials are examined to see how they change.
Chips that were removed by turning are very small in contrast to the remaining workpiece. They heat up so quickly that they reach more than half their melting temperature in just a few milliseconds. This in turn can significantly change the strength of the metal [1] and its resistance to the formation of chips. That´s why chips were chosen to be characterized concerning their microstructure.
Precise predictions through simulations are desired and the material model for the simulations must be examined [2]. Therefore, it is essential to compare simulations with experiments and observe actual changes in the microstructure of the chips and gain knowledge of the material behavior. To this end, microstructural investigations on chips were carried out using transmission electron microscopy (TEM).

Methods
For investigating the microstructure in TEM, electron transparent Focused Ion Beam (FIB) lamellae were prepared (Fig. 1). Chemical analyses were carried out by EDX mapping. Information for determining the grain size depending on the distance to the surface (depth) was obtained by bright field and corresponding dark field images.

Results
Several chips were investigated regarding the change of the microstructure from the surface into the depth of the material. Different cutting speeds and different final cooling rates led to a change in grain size over the depth from the surface. The EDX mappings showed an oxide layer on the surface of each sample of the chip.

Conclusion
Microstructure characterizations are important for investigating materials and improving the associated simulations. The present investigations on the steel chips pointed out a clear diffence between the change in microstructure caused by different cutting speeds and different cooling rates.

Characterization of Cu doped zeolite by MicroED and electron ptychography

Mr. Masahiko Shimizu[1], Dr. Katsuaki Nakazawa[2], Dr. Kazutaka Mitsuishi[2], Dr. Hajime Matsumoto[1], Dr. Hisashi Shima[1], Dr. Takahiko Takewaki[1], Dr. Ayako Hashimoto[2,3]

Poster Group 2

Background incl. aims
Selective catalytic reduction (SCR) of NOx by ammonia has been widely applied to the removal of pollutants from diesel gas engines, and Cu doped small pore zeolites are known to exhibit excellent NOx conversion activity and N_2 selectivity. In particular, Cu doped CHA type zeolites (Cu-CHA) have been widely used in automobiles. One of the requirements for practical SCR catalysts is hydrothermal stability to withstand the harsh environment of over 700°C water vapor, and Cu-CHA is known to suffer hydrothermal degradation[1]. The origin of this degradation is proposed to be atomic-scale structural changes such as degradation of the CHA framework and local coordination environment changes of Cu atoms[2]. However, there are few studies of direct observation of this degradation reaction at the atomic level. The reason is that zeolite is an extremely electron sensitive material, so in widely used TEM technique it is difficult to observe zeolites in atomic resolution due to the poor electron beam efficiency. In this study, direct observation of Cu-CHA was performed using microcrystal electron diffraction (MicroED), which allows to analyze crystal structure at low electron doses, and electron ptychography[3], which utilizes 4D-STEM technology to achieve high electron beam efficiency.

Methods
Zeolite sample preparation: Cu-CHA was synthesized by the method described in the paper[3] (Sample A). The synthesized sample was kept at 800°C for 5 hours under 10%-water vapor/air circulation to test its hydrothermal durability (Sample B). Two types of samples were dispersed on carbon TEM grids for MicroED and TEM observation.
Preliminary observation by Micro ED: Sample A was analyzed by a Micro ED system (XtaLAB Synergy-ED, Rigaku/JEOL). The acceleration voltage was 200 kV, and diffraction patterns were obtained from -50 to 50 degrees in 0.5 degree increments. Structural analysis from the set of the diffraction patterns was performed by CrysAlis (Rigaku/JEOL).
Electron ptychography observation: For the two types of samples (Sample A and B) were heated on a hot plate at 200°C in the air for 20 minutes just before TEM observation for removing water and contaminants. For the ptychography observation, an aberration-corrected TEM (JEM-ARM200F, JEOL) equipped with a high-speed pixelated STEM detector (4Dcanvas™, JEOL) was used. The acceleration voltage was 200 kV. The convergence angle was 13.5 mrad, the probe current was 0.059 pA (49 e- per point), real-space pixels were 512×512, and diffraction patterns were acquired with 264×66 pixels and binned to 66×66 by post-processing. The frame time was fixed at 7500 fps.

Results
Fig. (a) shows the crystal structure of Cu-CHA ([100] orientation) determined from MicroED result. The reliability factor R in this analysis is 0.16 (<0.2), this suggests that the determined structure provides the highest reproducibility of the obtained set of the diffraction patterns. The atoms are shown as displacement ellipsoids in Fig.(a), and the Cu atom positions are predicted to be spread out.

Fig. (b) shows the phase images obtained by electron ptychography after the hydrothermal durability test. It suggests that the Cu site is changed after the hydrothermal durability test, while no structural changes in the CHA framework were observed.

Conclusion

To investigate the origin of hydrothermal degregation of Cu doped CHA type zeolite, which is useful as an SCR catalyst, MicroED analysis and electron ptychography observations were performed. The results suggest that the Cu site is changed without modifying the structure of the CHA framework after the hydrothermal degradation.

From volume electron microscopy datasets to segmentation models, feature quantification, and data reuse

Dr. Ilya Belevich[1], Kirk Czymmek[2], Johanna Bischof[3], Aastha Mathur[3], Lucy Collinson[4], Eija Jokitalo[1]
[1]University of Helsinki, Helsinki, Finland, [2]Donald Danforth Plant Science Center, Saint Louis, USA, [3]Euro-BioImaging ERIC Bio-Hub, EMBL, Heidelberg, Germany, [4]Francis Crick Institute, London, UK

Poster Group 2

Advancements in microscopy techniques have led to the generation of ever-increasing amount of data, demanding efficient analysis methods. Image segmentation tools, particularly those powered by Artificial Intelligence (AI), have become critical components for processing this data. However, segmentation is just the first step in unlocking the wealth of information hidden within these complex datasets. Quantitative analysis methodologies are essential for extracting meaningful biological insights.

Here delves into the power of AI-driven segmentation for quantitative analysis in electron microscopy. We demonstrate the segmentation of a U2OS cell FIB-SEM dataset [1] using a newly developed tools within Microscopy Image Browser (MIB) [2]. Our approach leverages the "segment-anything" model [3] for ground truth generation of training labels alongside a newly developed 2.5D deep learning workflow for image segmentation in DeepMIB tool [4] of MIB. This powerful combination allows for efficient generation of accurate models for various cellular organelles, including mitochondria, endoplasmic reticulum (ER), Golgi apparatus, nuclear envelope, lysosomes, and peroxisomes [5]. These models serve as the foundation for in-depth quantitative analysis.

Moving beyond segmentation, we explore potential analysis pathways. A typical pipeline might begin with volumetric analysis of organelles, providing valuable information about their size and distribution. This analysis can be further extended by developing custom methods to quantify specific features relevant to cell biology research. Examples include measuring the density of nuclear pores, quantifying the sheet-to-tubule ratio of the ER, or analyzing the contact points between ER and mitochondria.

In addition, we showcase the immense potential of large-volume electron microscopy data, extending its utility beyond the scope of the original research project. Sharing these datasets responsibly is crucial for unlocking their full potential and enabling broader scientific exploration. By fostering responsible data sharing practices [5], we can collectively extract even deeper insights from these rich datasets, leading to significant advancements in our understanding of cellular biology.

Temporal characterization of femtosecond electron pulses inside ultrafast scanning electron microscope

Kamila Moriova[1], Martin Kozak[1]
[1]Faculty of Mathematics and Physics, Charles University, Prague,

Poster Group 2

Background incl. aims
In recent years, ultrafast electron microscopy has been proved to be a promising method for examination of the dynamics of the most fundamental processes. The visualization of processes with high temporal and spatial resolution can be achieved with laser pump and electron probe experiments using single electron pulses from a nanoemitter to avoid temporal spread of the pulse by Coulomb forces. In order to perform pump-probe experiments, the exact knowledge of electron pulse duration is required. Only few techniques have been developed to perform the temporal characterization of ultrashort electron pulses with low electron density. One of the approaches, often used in ultrafast transmission electron microscopes (UTEMs), is based on electron-light cross-correlation utilizing the inelastic scattering of electrons induced by the interaction with optical near field around a nanostructure [1]. Such scheme is limited by the fact that the electron microscope has to be equipped with a high-resolution spectrometer, which allows to spectrally filter the inelastically scattered electrons. In this contribution we demonstrate the use of a different method for electron pulse characterization, which is based on scattering of electrons mediated by ponderomotive potential of an optical standing wave. This method is suitable for ultrafast scanning electron microscopes (USEM), for which the experimental determination of the length of the electron pulse is still challenging to this day.
Methods
Free electrons are scattered by an optical standing wave created by two counter-propagating pulsed optical beams of the same frequency in vacuum. This effect is driven by the ponderomotive potential of the optical field and is used as a technique to characterize duration of electron pulses [2,3]. Electrons traveling through the oscillating electromagnetic field of generated standing wave experience ponderomotive force proportional to the gradient of light intensity and are deflected from their original direction of motion. Electron pulse duration is then reconstructed from a time trace, which is given by the measured electron scattered signal taken at different electron pulse-laser pulse time delays, and which is a direct cross-correlation of electron and laser pulse. Although the described method is known, up until now it has not yet been used to characterize electron pulse durations for wide range of electron energies in a commercial scanning electron microscope (SEM).
Results
In our experimental setup, we generate low density electron pulses by a laser-triggered emission from a Schottky emitter in Verios 5 XHR SEM (energy range 1 to 30 keV) by illuminating the apex of the emitter tip with 257.5 nm laser pulses. Inside the SEM chamber, we implement a compact optical setup for the generation of optical grating with two counterpropagating laser pulses with central wavelength of 1030 nm and duration of 220 fs. The scattered electron signal is detected by a hybrid-pixel detector Timepix3. We characterize electron pulse durations for electrons in energy range from 5.5 keV to 30 keV. For the optimal setting with the electron emission regime with less than one electron per pulse, the electron pulse duration at the sample location spans from 0.4 ps full-width-half-maximum (FWHM) for 30 keV electrons to 2.7 ps FWHM for 5.5 keV electrons.
Conclusions

In the past, the development of methods for direct measurement of the temporal characterization of electron pulses has been focused primarily on UTEMs. Electron pulse durations in USEMs were only estimated on the basis of theoretical calculations. We describe the implementation of all-optical method for direct temporal characterization of femtosecond electron pulses in a commercial SEM.

Optimizing optical STEM detection for faster acquisition speeds in scanning electron microscopy

Arent J. Kievits[1], Monika Molnar[1], Jacob P. Hoogenboom[1]
[1]Department of Imaging Physics, Delft University of Technology, Delft, The Netherlands

Poster Group 1

Background

Optimization of acquisition speed is important for large-scale and volume electron microscopy (EM) experiments of tissues and cells, as these are characterized by long acquisition times due to the low inherent throughput of electron microscopes. Developments in scanning electron microscopy (SEM) techniques have increased acquisition speed by orders of magnitude through the use of more sensitive detectors, electrostatic and magnetic immersion fields, and multibeam scanning electron microscopes (mSEM), in which the sample is scanned in parallel with an array of beams (1,2). Optical scanning transmission electron microscopy (OSTEM) offers a way to discriminate the signals from the individual beamlets in mSEM (3). In OSTEM, ultrathin biological sections are placed on a thin film-coated scintillator substrate, which converts transmitted electrons into photons. These photons are collected by a high NA optical objective and projected onto a multipixel photon counter (Figure 1A).

We have recently shown that OSTEM performs similar to backscatter electron detection (BSD) and SE detection on ultrathin biological samples (3), in terms of contrast, image resolution and signal-to-noise ratio (SNR). At short dwell times, OSTEM outperforms BSD and SE detection in SNR. However, BSD in combination with electrostatic immersion still outperforms OSTEM. Moreover, the SNR of OSTEM stagnates for moderate to high beam currents, suggesting a potential saturation point in the detection scheme. In general, signal generation and collection in OSTEM has not been thoroughly investigated and as a result, optimization of the OSTEM detector layout has not yet been performed.

To better understand signal generation and collection in OSTEM, a physics model is required that describes electron scattering in the substrate, its conversion to light, and the subsequent collection of this light signal. This model then must be verified with experimental results to be used to optimize the substrate design. We aim to develop this OSTEM signal generation model and use it to obtain a rational substrate design optimized for detection efficiency and acquisition speed.

Methods

In OSTEM, ultrathin biological sections are placed on a cerium-doped single-crystal yttrium aluminum garnet (ce:YAG) scintillator, coated with a thin (~30 nm) conductive Molybdenum coating. OSTEM is implemented in a Verios 460 (FEI Company) equipped with a SECOM integrated fluorescence microscope (Delmic) without the emission filters (Figure 1A). In an alternative setup, photons are directly detected by a multipixel photon counter array placed underneath the scintillator (Figure 1B). The photon output and SNR are evaluated by focusing the electron beam on the empty substrate surface or a biological sample respectively, and recording the photon intensity with the MPPC or a CCD camera, for a given beam current, dwell time and landing energy. The SNR is computed by averaging the spectral SNR over the full frequency space of every electron micrograph.

Electron scattering is modeled with Monte-Carlo simulations in CASINO (4) and NEBULA (5), by computing the electron energy loss per voxel. The material properties of ce:YAG and molybdenum are taken from literature. We assume that energy conversion to photons fully relies on low energy loss events (<50eV). Different possible saturation mechanisms are modeled by limiting the photon output as a function of the input energy per voxel. Additionally, the loss of photons in the detection is taken into account by a transmission coefficient that depends on the thin-film coating composition.

Results

The photon output of the empty substrate demonstrated a sublinear relationship with the beam current (Figure 1C), suggesting a partial saturation effect. MPPC saturation was excluded as the main cause, since validation experiments with a neutral density filter and a CMOS camera showed similar sublinear relationships. The photon output does increase linearly at higher beam energies (Figure 1D), indicating the partial saturation is prevented in a larger electron interaction volume. Initial modelling with CASINO software showed proportionally more scattering events in the thin-film coating than in the scintillator (Figure 1E), although the majority of secondary electron generation takes place in the scintillator. However, CASINO does not accurately model low-energy secondary electrons. To better understand the signal generation and simulate the energy deposition at low energy (0-50eV), for which most of the energy transfer to the active scintillator dopant is expected, we intend to use NEBULA to calculate the energy loss per voxel as a function of the electron beam energy and current. NEBULA has been developed to provide fast and accurate simulations of low energy electron-matter interactions with first-principle physical models (5).

Conclusion

Optical scanning transmission electron microscopy (OSTEM) is an alternative SEM detection technique for imaging thin biological samples, and can be used for electron detection in multibeam scanning electron microscopy. Partial saturation of the scintillator and energy loss in the thin-film coating of the scintillator are hypothesized to limit the signal generation in OSTEM. In this work, a first attempt is made to model energy conversion from a focused electron beam to a photon signal. With a physically valid model, different substrate combinations can be tested. Subsequent optimization of the OSTEM substrate may increase acquisition speeds in single-beam and multi-beam scanning electron microscopes.

HR-EBSD Analysis of High-Entropy Alloys: Understanding the Role of Alloying Elements in Mechanical Performance

Mr Pedro Henrique Fernandes Oliveira[1,2], Mr Julio Spadotto[2,3], Mr Edward Pickering[2,3], Mr Francisco Coury[1], Mr Claudemiro Bolfarini[1]
[1]Federal University of Sao Carlos, Sao Carlos, Brazil, [2]The University of Manchester, Manchester, United Kingdom, [3]Henry Royce Institute, Manchester, United Kingdom

Poster Group 2

High-entropy alloys, like $Cr_{33}Co_{33}Ni_{33}$, boast remarkable mechanical strength attributed to solid solution strengthening. Research underscores the pivotal role of plastic deformation in these alloys, governed by the interplay of slip and twinning mechanisms, alongside the emergence of nanometric lamellas of HCP phase during advanced deformation stages. Grasping these deformation intricacies is imperative for elucidating the alloys' mechanical and microstructural characteristics. Yet, in-depth investigations into $Cr_{30}Co_{30}Ni_{30}Pd_{10}$, $Cr_{30}Co_{30}Ni_{30}V_{10}$ alloys remain limited. A meticulous characterization of these materials holds promise for unlocking valuable insights pertinent to their engineering applications.

Methods

Samples of $Cr_{30}Co_{30}Ni_{30}Pd_{10}$, $Cr_{30}Co_{30}Ni_{30}V_{10}$ alloys underwent interrupted tensile tests at various deformation levels, employing a deformation rate of $1X10^{-3}s^{-1}$. Following each deformation stage, high-resolution Electron Backscatter Diffraction (HR-EBSD) analyses were conducted using a FEG-SEM ThermoScientific Apreo 2 high-performance, equipped with an Instruments Symmetry 2 EBSD detector. This detector boasts indexing speeds exceeding 5700 patterns per second, coupled with a high-sensitivity CMOS camera. Data analysis was performed using CrossCourt software, enabling comprehensive assessments including simple orientation measurements, quantitative evaluations of elastic strain fields and stress, and precise measurement of residual stress within the sample. These analyses were conducted with a remarkable sensitivity of 1 part in 10000 and a spatial resolution of 100 nm.

Results

EBSD analyses facilitated the comprehensive mapping of microstructural evolution in both the $Cr_{30}Co_{30}Ni_{30}Pd_{10}$, $Cr_{30}Co_{30}Ni_{30}V_{10}$ alloys during tensile testing. Through the utilization of KAM (Kernel Average Misorientation) and GOS (Grain Orientation Spread) mapping techniques, the distribution of deformation across the microstructure was effectively delineated, alongside the discernment of deformation twin formations during the deformation step. Furthermore, it was discerned that the introduction of V facilitated mechanical deformation through twinning mechanisms, while the incorporation of Pd tended to increase alloy brittleness. This brittleness was notably evidenced by low KAM and GOS indices immediately preceding fracture in the Pd-containing alloy.

Conclusions

The employment of HR-EBSD emerged as pivotal in thoroughly scrutinizing these findings. Its capacity to furnish intricate microstructural insights empowered a profound comprehension of deformation

mechanisms and the nuanced impact of alloy constituents on mechanical performance. This underscores the indispensable role of advanced characterization methodologies in unraveling the intricate behaviors exhibited by materials under mechanical stress, thereby enriching our understanding of material science and engineering.

SEM-Cathodoluminescence Imaging and Spectroscopy - Applications in Archeology and Life Science

Dr. Ifat Kaplan-Ashiri[1]
[1]Electron Microscopy Unit, Department of Chemical Research Support, Weizmann Institute of Science, Rehovot, Israel

IM-05 (3), Lecture Theater 3, august 27, 2024, 10:30 - 12:30

Scanning electron microscopes (SEMs) are widely used as an imaging technique for any solid materials found on Earth. Newly synthesized materials, frozen biological samples, and geological and ancient materials can all be studied by SEMs. SEM-based spectroscopies, such as energy dispersive X-ray spectroscopy (EDS) and cathodoluminescence (CL), are applied to study the composition and structure of various samples. SEM-CL imaging and spectroscopy detect the emitted photons in the visual range. The luminescence results from band transitions can be related to different material properties, such as band gap, crystallinity, impurities, and defects in the structure.
We have been using SEM-CL as an imaging and spectroscopy tool in different fields, including less-studied ones such as archeology and life science. CL spectral measurements of $CaCO_3$ samples were performed as part of research in archeology, and the CL imaging of cholesterol crystals was implemented as part of a complete workflow to study their 3D structure.
Materials such as calcium carbonates ($CaCO_3$) found in archeological excavations can be studied with SEM-CL as their intrinsic defects and dopants create luminescent centers that can be detected. The various forms of $CaCO_3$ have unique defects that can be revealed by detecting the luminescence of the crystals. SEM-CL was used to study $CaCO_3$ in different forms: calcite and aragonite, which nucleate through geogenic and biogenic pathways, and pyrogenic lime plaster. The structural variations in $CaCO_3$ from various origins were measured by SEM-CL and correlated with radiocarbon dating (1-3). Using SEM-CL and complementing it with other analytical techniques, we formed a database of $CaCO_3$ samples from different sources. This database is of great importance in identifying the form of $CaCO_3$ when sorting materials from archeological excavations and increasing the accuracy of age determination by carbon dating.
SEM-CL of organic materials is quite challenging as their luminescence decay very fast under the irradiation of the electron beam. Cholesterol crystals are CL active and stable enough to be detected and imaged. Cryo SEM-CL was used as a first step in a correlative workflow that was developed to study atherosclerotic lesions in three dimensions at the nanometer scale. The cholesterol crystals and lipid droplets, both luminescence active, were identified by CL imaging. Following the CL imaging, the crystals were identified using SEM and moved to the FIB-SEM for volume imaging, all done under cryo conditions. The results of this workflow show that thin crystals appear to be associated with intracellular or extracellular lipid droplets and multilamellar bodies. The large crystals are independently positioned in the tissue and are not associated with specific cellular components (4).
In summary, SEM-CL studies of $CaCO_3$ samples and cholesterol crystals revealed the opportunity to use this method to explore materials and systems in fields such as life science or archeology.

Detection of quasicrystalline symmetries in electron diffraction data

Oskar Ryggetangen[1], Dr. Ruben Bjørge[2], Dr. Sigurd Wenner[2], Prof. Randi Holmestad[1]
[1]Department of Physics, Norwegian University of Science and Technology, Trondheim, Norway,
[2]Department of Materials and Nanotechnology, SINTEF Industry, Trondheim, Norway

Poster Group 2

Introduction
Under certain alloying conditions, quasicrystals have been demonstrated to appear as nano-precipitates in aluminium alloys [1]. In addition to these exotic structures, crystalline approximant phases with similar compositions may appear in the very same systems. The approximants accommodate local icosahedral coordination, giving rise to pseudo-fivefold symmetric diffraction patterns when viewed along given irrational crystal directions [2]. In principle, the distinction between quasicrystalline and approximant diffraction patterns is sharply defined. However, in dealing with experimental data – especially from nano-sized precipitates – the difference is not necessarily obvious. In the following, we utilize scanning precession electron diffraction (SPED) in mapping out fivefold and pseudo-fivefold symmetries in selected material systems and discuss the designation of quasicrystalline precipitates based on diffraction data alone.
Methods
Four model systems were selected for the investigations: A powder of quasicrystalline AlCuFe, a modified 6082 aluminium alloy containing dispersoids of the α-AlFeSi approximant phase, an AlMgCuAg alloy, and a sample of this same alloy which was rapidly solidified though melt-spinning. A JEOL JEM-2100F transmission electron microscope equipped with a NanoMegas precession system and a Quantum detectors Merlin direct electron detector was used in the acquisition of the diffraction data. Data analysis was carried out using the PyXem python library [3].
Results and discussion
The quasicrystalline AlCuFe powder contained particles with large grains with a seeming lack of defects, producing dense fivefold symmetric diffraction patterns. The melt-spun AlMgCuAg was found to contain ~100 nm sized quasicrystalline particles, without any immediately obvious orientation relationships to the Al matrix. Diffraction patterns obtained from these particles were less dense than those from the large-grained AlCuFe sample, although a diffraction tilt-series confirmed their quasicrystallinity. Several different phases were present in the heat treated AlMgCuAg samples, some of which exhibited approximate fivefold rotation symmetries. The particles in question were sparsely distributed in the sample, and ~5 nm in diameter.

Figure 1 (a) shows a precession electron diffraction (PED) pattern obtained through SPED from a particle of interest in the heat treated AlMgCuAg alloy. The diffraction pattern exhibits approximate fivefold rotational symmetry, and sets of reflections fall onto rings with relative spacings which are roughly multiples of the golden mean $\tau=(1+\sqrt{5})/2$. The same diffraction pattern is shown in (b), represented in polar coordinates. Here, the first-order ring is clearly discernible.

Figures 1 (c) and (d) show electron diffraction patterns from particles found in the melt-spun AlMgCuAg sample and quasicrystalline AlCuFe particles, respectively. Both patterns exhibit a striking tenfold rotational symmetry, though it is noted that the patterns obtained from the – comparatively small – particles present in the melt-spun AlMgCuAg are considerably less dense than those acquired from the large-grained quasicrystalline AlCuFe powder.

The classification of presumably quasicrystalline nano-precipitates in aluminium solely by employment of (S)PED is non-trivial. However, we were able to designate these small particles as quasicrystals up to some tolerance. SPED allows for simultaneously sufficient spatial resolution and field of view to record the sparsely distributed ~5 nm precipitates in the AlCuMgAg sample and show that they are essentially quasicrystalline. Especially, as may be seen in Figure 1 (a), the quasicrystallinity of these particles dominate in the low-resolution domain of the diffraction pattern, hinting at long-range icosahedral ordering.

Complementary diffraction techniques, such as combining SPED with rotation electron diffraction, may help to further improve the accuracy of quasicrystal identification in complex sample systems. As such, it is possible to envision a fast and accurate routine for the mapping of quasicrystalline precipitates over relatively large projected regions – greatly aiding the study of the nucleation and growth of these exotic phases in metallic matrices.

Poster Group 1

Background
EELS in the STEM is capable of oxidation state quantification by analyzing the fine structure of the elemental ionization edges. The exact analysis procedure has been1 and continues to be2 a major focus of EELS research. In the last decade, oxidation state mapping at the atomic level 3 has become common and advances in data analysis have enabled 3D oxidation state mapping through tomographic reconstruction of EELS oxidation maps tilt-series4.
To date, most methods of oxidation state analysis involve ionization edges with onset energies above 100 eV. For example, the standard method for iron oxidation state analysis is based on the fine structure of the Fe-L2,3 ionization edges at ~708 eV. However, the small ionization cross-section of these ionization edges presents serious experimental challenges for beam-sensitive samples. For instance, beam damage and contamination issues limited the EELS tilt series in 4 to just half of the angles needed to obtain a full tomograph.
In this context, we explore the new possibilities for oxidation state analysis offered by the new generation of hybrid-pixel direct electron detectors5. Thanks to their almost-perfect DQE and zero read-out noise, using the standard oxidation state analysis methods, the same results can be obtained with a lower electron dose. Less obviously, we show that these detectors' high speed, large dynamic range and small point spread function facilitate EELS analysis using ionization edges that lie below 100 eV. This comes with mainly two advantages with respect to edges situated at higher energies: a much higher signal-to-noise ratio for the same electron dose, and the simultaneous acquisition of the full low-loss spectrum needed for accurate absolute quantification.
To demonstrate the novel oxidation state analysis method, we perform EELS oxidation state tomography on the FeO/Fe3O4 core-shell nanoparticles from 4 by analyzing the Fe-M2,3 ionization edges at ~54 eV.

Methods
FeO/Fe3O4 core-shell nanoparticle EELS spectrum images were acquired on an FEI TITAN Themis 300 S/TEM with a dwell time of 1 ms and a pixel size ranging from 0.2 nm for single maps to 0.4 for tomography studies. EELS maps were taken at 9 different angles ranging from -70 to 70 degrees for these tomographic studies.
Spectrum images were then analyzed using a combination of SVD decomposition of the four-dimensional dataset, blind source separation, and curve fitting EELS quantification.

Results

Figure 1 shows the EEL Fe-M2,3 spectra and maps corresponding to Fe3+ (in blue) and Fe2+ (in green) extracted from the dataset by blind source separation, which has proven successful. Furthermore, the 3D reconstruction of both oxidation states has been achieved, showing a differentiation between the core and the shell of the particle, and with minimal damage to the sample. A frame from this reconstruction can also be seen in Figure 1.

Conclusion

The combination of direct electron detection and the extension of oxidation state analysis to low-energy ionization edges has proven successful in performing EELS oxidation state tomography in beam-sensitive FeO/Fe3O4 core-shell nanoparticles, with a much lower electron dose than standard methods, notably minimizing sample damage and increasing the acquisition speed. This method sets a new standard for EELS analysis of suitable beam-sensitive materials.

Poster Group 2

Ultrafast electron diffraction (UED) facilitates the time-resolved investigation of structural dynamics on an ultrafast timescale. In a UED experiment, a pump laser pulse triggers electronic and structural dynamics inside an investigated sample, which is diffractively probed by an ultrashort electron pulse at a variable time delay. Repeating the experiment with different time delays between the laser excitation and electron probing allows for a tracing of the dynamics with femtosecond resolution [1]. The performance of a UED instrument is largely determined by the electron source. Current dedicated setups are predominantly employing planar photocathodes [1]. In this contribution, we present a newly developed ultrafast electron diffraction setup based on a high-coherence electron microscope gun using a nanotip photoemitter [2]. Due to the small emission area of the tip, the electron source generates a low-emittance and high-peak-brightness photoelectron beam for ultrafast microbeam diffraction.
The setup is based on a ZrO/W(100) Schottky-type field emitter, as shown in graphic a). We trigger photoemission from the emitter's front facet by illumination with femtosecond laser pulses (515 nm center wavelength, duration about 200 fs) generated at a maximum 610 kHz repetition rate. The electron pulses are accelerated to a kinetic energy of 15 keV into the sample chamber hosting the sample mounted on a 3-axis manipulator. The diffraction pattern is recorded by a phosphor-screen microchannel-plate assembly and a CMOS camera. For quantitative beam characterization, we use a Faraday cup with fA-resolution and a knife-edge at the sample position to measure the beam current and emittance, respectively. By a measurement of the transient electric field effect, we characterize the temporal overlap at the sample plane and the overall current-dependent time resolution of the instrument [3]. To demonstrate high spatio-temporal UED performance, we carry out ultrafast microdiffraction on a free-standing 1T-tantalum disulfide film (1T-TaS_2).
The emitter operates in the linear photoemission regime with approximately one electron per pulse at the typical laser powers applied in the experiment. Using knife-edge scans, we determine a root-mean-squared (rms) beam size at the sample of 2.54(8) µm and an rms divergence of 0.27(1) mrad, leading to an energy-normalized emittance of 167(7) nm mrad. Measurements of the transient electric field effect yield upper limits to the full-width-at-half-maximum (FWHM) electron pulse duration of 1.02(3) ps and 2.10(3) ps for photoemission fluences of 0.05 mJ/cm² and 0.24 mJ/cm², respectively. The difference in pulse duration follows from increased stochastic and space charge broadening for higher pulse charges.
The small electron beam diameter at the sample position allows us to acquire a scanning electron diffraction dataset of a free-standing 1T-TaS_2 film. Using this 4D-Dataset (x, y, kx, ky), we can map the intensities of a selected diffraction spot in real-space as shown for the (01) spot in graphic b). We attribute the local maxima in the real-space image to a wrinkled structure of the flake. 1T-TaS_2 is subject to a charge-density-wave phase (CDW) accompanied with a periodic lattice distortion. At room temperature, the CDW structure is nearly commensurate (NC) to the underlying lattice (locally commensurate with a nearly regular array of discommensurations). However, upon heating above

353 K, the CDW becomes incommensurate (IC) to the underlying lattice with wave vectors aligned to the host lattice. This structural phase transition can be laser-driven, which was extensively studied in the past, allowing us to use it as a benchmark UED experiment for our setup [4,5]. We observe the NC-IC phase transition in 1T-TaS_2 with an intensity decrease of the NC diffraction spots and a rise of IC spot intensities after laser pumping, as plotted in graphic c). We measure the reduction in NC peak intensity with a FWHM time resolution of 1.09(7) ps. Combining the emittance, beam current, and pulse length, we can calculate a peak brightness of $3.0(3)\times10^{11}$ A/m²/sr for our electron gun.
We developed an ultrafast electron microdiffraction setup with enhanced spatial and momentum resolution at an energy of 15 keV. The low-emittance source allows us to conduct high-resolution spatial scans of crystalline samples and carry out time-resolved studies of the dynamics in inhomogeneous structures and for small sample dimensions. Furthermore, the setup is ideally suited for in-situ measurements under ultrahigh vacuum and/or cryogenic conditions.

Poster Group 2

Background incl. aims

Exposing a sample to an electron beam leads to growth of amorphous carbon contamination [1] deposited due to beam induced polymerization of hydrocarbons. This contamination is a challenge in electron microscopy because it can obscure fine details of the specimen, distort the signal obtained in elemental analysis and artificially modify surface reactions during reactive in situ experiments.
The sources of hydrocarbons are the residual gas in the instrument chamber and the sample surface itself, where the latter is often assumed to have the bigger impact on contamination growth [1].
This work is designed to quantify the contribution of these sources of hydrocarbons on the contamination growth using a suitable model [2] and is based on measurements from dedicated experiments. Similarly to other works [3], the contamination process is assumed to be a time-dependent reaction diffusion process driven by the electron beam. A source and a sink term are introduced to describe the supply of hydrocarbons from the residual gas in the microscope chamber and the removal of mobile hydrocarbons through polymerization by the electron beam. The contamination formation predicted by the model is compared with experimental results to determine the differently contributing parameter of the process.
This study analyzes the direct contribution of contaminants from the residual gas to polymerization by the electron beam and the indirect contribution by reestablishing an equilibrium density of surface contaminants. In addition, the contribution of surface contaminants to contamination growth by diffusion into the irradiated area is analyzed. It is intended to find from the specific process parameters not only insights regarding the supply of contaminants, their type and size, but also methods to reduce the contamination growth on illuminated sample surfaces.

Methods

To quantify the contamination growth, a thin amorphous carbon substrate (thickness < 10 nm) is illuminated homogeneously with a defocused electron beam in a FEI DualBeam Strata 400S. This is done for distinct time steps up to 20 min resulting in the growth of contamination rings.
The thickness and shape of the contamination rings is obtained through comparison of MC simulations with high-angle-annular-dark-field (HAADF) images taken in between 5 minutes of illumination. Both, irradiating and imaging are performed at primary electron energy of 20 keV and a current of 120 pA. The illuminated area is chosen to be sufficiently large (radius ~ 700 nm) to separate the individual parameters describing the contamination process.
The theoretical model used describes the change of the relative surface density of contaminants $n = N/N_0$, where $N_0 = N(t=0)$ is the density of contaminants prior to illumination [2].
The diffusion into the irradiated area is described by a diffusion constant D while the contribution of the residual gas in the microscope chamber is modeled by an adsorption frequency η that tends to reestablish the equilibrium surface density of contaminants. The removal of contaminants through polymerization into immobile contamination is described by a reaction cross section σ.

To obtain the dependency of these parameters on the residual gas condition, contamination growth experiments at different pressures are performed while evacuating the microscope chamber and also by using a cold trap. Mass spectrometer measurements are conducted to analyze the components of the residual gas in the microscope chamber, which could contribute to the supply of contaminants. Furthermore, contamination growth measurements are performed after removing contaminants from the sample surface by in situ plasma cleaning.

Results

The parameters of the model are obtained by fitting the simulated contamination shape and thickness to the experimental data.

The reaction cross section σ = 2.22e-20 m² and the diffusion constant D = 1.15e-15 m²/s don't change significantly between measurements with different residual gas pressures of the microscope chamber. The initial density of contaminants on the sample surface slightly increases from N_0 = 1.25e20 1/m² to N_0 = 1.60e20 1/m² with higher pressure indicating the adsorption of hydrocarbons from the ambient gas to the sample surface.

Figure 1 a) shows the concentration of small hydrocarbons in the residual gas of the microscope chamber as a function of the evacuation time. It can be seen that the partial pressure of these components decreases with a similar rate as the total pressure in the vacuum chamber. Figure 1 b) shows the adsorption frequency of the contaminants onto the sample surface with respect to the pressure inside the instrument chamber. Thus, lower pressure leads to a decrease of the adsorption frequency and a lower buildup of carbon contamination on the sample surface. Anyway, the value of η smaller than 0.001 Hz is very low compared with the other frequencies governing this process.

Experiments with in-chamber plasma cleaning of the sample indicate a substantially reduced contamination growth. Measurements before and after cleaning for 100 s show a decrease in the initial density of contaminants from 7e19 1/m² to 2.2e19 1/m² pointing out the effective removal of contaminants from the sample surface. Simultaneously, the diffusion constant D increases by 28%, while the reaction cross section decreases by 83%.

Conclusion

Comparing the adsorption frequency η to the other parameters leads to the conclusion that even though the residual gas has a perceivable impact on the contamination growth, its contribution remains low in comparison to that of the contaminants present on the sample surface prior to illumination. Besides the direct add to the irradiated area, the supply of contaminants from the residual gas to the whole sample surface to an equilibrium density must be considered for longer experimental durations. However, these contributions can be reduced by lowering the chamber pressure.

The alterations in the diffusion constant and reaction cross section after plasma cleaning imply the presence of more mobile and smaller contaminants [4]. This suggests that contaminants adsorbed from residual gas might be smaller than those removed from the sample surface, being probable for the molecules shown in Figure a).

The effectiveness of in situ plasma cleaning to remove several of the present mobile contaminants is shown by a lower carbon contamination.

Poster Group 2

Background incl. Aims
AlGaN LEDs have been greatly researched these last years for the development of ultraviolet emitters for many applications including disinfection [1]. For that purpose, we need AlGaN alloys with high Al content and high active dopant concentrations. In this presentation, we will discuss the potential of Ge as an alternative n-type dopant instead of Si for AlGaN structures with different Al contents. Indeed, silicon is a widely used n-type dopant but it contributes to edge-type dislocation climb and induces tensile stress. The interest of Ge is that it introduces less strain than silicon in the AlGaN lattice. Moreover, the distribution and activity of the dopants and the location of the electrical junction are very important parameters in the design and optimisation of LED structures. These properties can be measured by off-axis electron holography, which records both the amplitude and the electron phase from an interference pattern. As the change in phase of the electron beam is directly linked to the electrostatic potential, this allows us to measure the potentials across the structures with a nanometer resolution.
Methods
In this study, we examined 6 samples consisting of 675-nm-thick Ge-doped AlGaN grown by plasma-assisted molecular beam epitaxy (PAMBE) on 1µm-thick AlN-on-sapphire templates [2]. The first and the second samples were grown with an Al mole fraction of 12% and varying Ge concentrations (the temperature of Ge cell was 928°C and 1011°C respectively). The third and the fourth samples were grown with 36% Al and varying Ge concentrations (the temperature of Ge cell was 928°C and 840°C respectively). The fifth and the sixth samples were grown with 64% and 66% of aluminum respectively, with a temperature of 1011°C for the Ge cell. Lamellas for transmission electron microscopy (TEM) studies were prepared by in-situ lift-out focused ion beam (FIB) milling in an FEI Strata 400. Each lamella contained areas with different thicknesses to obtain information about the samples such as the inactive thickness and to find the optimum experimental conditions. Electron holography and electron dispersive x-ray (EDX) spectroscopy were then performed using a double-corrected FEI Titan Ultimate TEM operating at 200 kV equipped with a Gatan One View 4k camera.
Results
Using electron holography, we were able to map the electrostatic potential in the specimens. This requires a good sample preparation and optimized experimental parameters during the TEM experiments [3]. The measurement conditions are particularly demanding in the case of AlGaN, since dynamical diffraction is a problem and wide bandgap materials have a tendency to charge during examination. Additionally, the total potential measured in electron holography depends on strong polarisation fields, the mean inner potential (MIP) of our material and additional contributions from dopants. To get reliable measurements, we first deposit a thin carbon layer on the specimen to provide a conductive channel to evacuate the charge. Then, the MIP in the AlGaN is calculated from DFT simulations, which provides values of 15,9 V for bulk AlN and 16,9 V for bulk GaN [4]. Using a linear interpolation, we can estimate the MIP of Al0,12Ga0,88N (16,8 V), Al0,36Ga0,64N (16,5 V) and Al0,66Ga0,34N (16,2 V), so that the MIP contribution can be removed from the total measured

phase. Figure 1(a) shows a FIB lamella with several steps of different thicknesses, prepared from the sample with 36% Al and TGe=928°C. In order to measure accurately the thicknesses of these steps, we use the Convergent Beam Electron Diffraction (CBED) method [5]. Figure 1(b) shows an experimental CBED pattern compared to 1(c) a simulation for a 374nm thick specimen using the JEMS software. Figure 1(d) shows an amplitude image of this specimen. The amplitude image has homogenous contrast, suggesting reduced diffraction contrast, which means that the corresponding phase image can be correctly interpreted. Figures 1(e) and 1(f) show the corresponding phase image before and after carbon coating respectively. The comparison of the images shows the relevance of carbon deposition to reduce charging of the specimen. From Figure 1(f), we can deduce the phase difference across the AlGaN layer (3.2+/-0.1rad), as shown in the profile in Figure 1(g). Finally, it is possible to determine and compare the electrostatic potentials across the AlGaN layer using $\Delta\Phi 0(x,y)=CE.V(x,y).t(x,y)$ where CE = 7,289 × 10^−3 rad/V/nm for 200kV electrons. Thus, a step in electrostatic potential of 1.17+/-0.02 V has been measured in the AlGaN layer.

Conclusion

By optimising the experimental conditions, we will be able to show the effect of Al content on the activity of the dopants in the AlGaN layer. With this study, we also show that the off-axis electron holography is a useful method to measure the electrostatic potential with a nanometer resolution, and thus can be used to optimize the structures grown for the development of UV LEDs. We will couple holography with EDX to determine the dopant concentrations that provide the highest carrier concentrations.

This research was performed on the Platform for Nanocharacterisation (PFNC) at the CEA-LETI of Grenoble and was funded by the French National Research Agency (Grant ANR-22-CE09-0024).

PolSpec – broadband cost-effective hyperspectral imaging

Huihui Liu[1], Sunil Kumar[1,2], Edwin A Garcia Castano[1], Paul French[1,2]
[1]Physics Department, Imperial College London, SW7 2AZ, , UK, [2]Francis Crick Institute, 1 Midland Road, NW1 1AT, , UK

IM-05 (1), Lecture Theater 3, august 26, 2024, 10:30 - 12:30

Background incl. aims
Spectrally-resolved imaging is implemented in almost every optical imaging modality – from endoscopy through microscopy, tomography, and remote sensing. It is typically used to provide spectroscopic contrast, e.g., between different species or states of molecules or different “colour” labels, e.g., for pathology, spatial proteomics, etc., as well as diverse applications outside biomedicine. Increasingly, it is used with machine learning, e.g., to increase performance or automated identification/classification tasks. Spectrally resolved imaging can be classified as multispectral imaging, where detected photons are assigned to a relatively small number of discrete spectral bins, or hyperspectral imaging where photons are allocated to part of a continuous a wavelength range. Spectrally resolved imaging techniques based on filters that reject “out-of-band” photons are inefficient and techniques that acquire the full (x-y-λ) hyperspectral image data cube, e.g., using spectrographs, tend to be slow since at least one dimension requires sequentially acquisition. Where photons are “sorted” into multiple spectral bins for wide—field imaging, e.g., using (cascades of) dichroic beam splitters, multispectral imaging can be fast and efficient at the cost of complexity and limited flexibility. Here we present a new low-cost approach to flexible wide-field hyperspectral imaging using polarization optics instead of dielectric coatings or dispersive devices, including a demonstration of single-shot full-field hyperspectral imaging.
Methods
Our approach we describe as “PolSpec” is to use a Lyot filter to provide continuously varying loss modulation across the desired spectral range to generate orthogonal “spectral modulation vectors” (SMV) that can represent specific spectral components, as indicated in figure 1(a). If the modulation functions are contrived to be sinusoidal and cosinusoidal, then these SMV correspond to spectral phasors, but other orthogonal (or near orthogonal) modulation functions can be used. Direct acquisition of spectral phasor images (as opposed to lossy calculation of spectral phasors from hyperspectral image data) has recently been demonstrated [1,2] utilising specific (fixed) sinusoidal spectral filters with sequential image acquisition [1] or using a cascade of image splitters for single-shot acquisition [2]. We have implemented single-shot full-field hyperspectral imaging using SMV with $\cos(\theta)/\sin^2(\theta)$ spectral modulation with the configuration depicted in figure 1(b) for a system component cost of <€2500 using low-cost polymer films to provide the required polarisation and retardance components. The spectral range and discrimination of this approach can be easily tuned using different retarders (typically half-wave plates) or can be made electronically tuneable using a liquid crystal retarder (LCR). Single-shot operation can be achieved using a polarisation-resolving camera (“Polarsens™”) [3].
Results
Figure 1(c) shows a demonstration of single-shot full-field hyperspectral imaging using the system depicted in figure 1 to image a colour test chart displayed on a computer screen. The SMV plot clearly separates the different spectral components and by filtering in the SMV plane, we can generate colour images in object space.
Conclusion

We have demonstrated a flexible approach to full-field “hyperspectral” imaging using SMV and implemented a singe-shot version with low-cost polarisation optics components and a Polarsens™ camera. Most implementations of PolSpec begin with a polariser that will present up to 50% loss, e.g., when imaging fluorescence. In addition, the Polarsens™ camera also presents a 50% loss. For fluorescence imaging, it is desirable to use a cooled camera with which PolSpec can be implemented using a polarisation image splitter. If the retardance required for the SMV is provided using an LCR, the full SMV data set can be acquired in two (rapid) sequential photon efficient polarisation-resolved camera acquisitions. Many other PolSpec configurations are possible, including ~lossless polarisation-resolved hyperspectral imaging with some increased system complexity.

PS-05 (3), Lecture Theater 3, august 30, 2024, 10:30 - 12:30

Introduction
Cu/ZnO catalysts have been used since the mid-1960s for both the water-gas shift (WGS) reaction and methanol synthesis. The key to understanding the activation, performance and deactivation of this catalyst system seems to lie in the delicate interplay between the formation of a CuZn alloy phase and the wetting of Cu nanoparticles by ZnOx after partial reduction through strong metal-support interactions (SMSI) [2,3]. The highly dynamic nature of the catalyst requires the use of in situ techniques. Using operando transmission electron microscopy (TEM), we aim to provide unprecedented insight into the morphological and structural evolution of an industrial catalyst during reductive activation and in CO2 hydrogenation conditions. These results are compared to model Cu/ZnO thin film heterostructure and Cu2O nanocube catalysts.

Materials and Methods
The catalyst (Cu/ZnO/Al2O3) was synthesized by calcination of a zincian malachite precursor with a Cu:Zn ratio of 70:30 and 3 mol % Al, following a protocol published previously. A sample was mounted in a DENS Climate environmental TEM holder, which was connected to our homebuilt gas feed setup. Selected area electron diffraction (SAED) temperature series were corrected for astigmatism [5], enabling us to track small lattice parameter changes and phase fractions from Rietveld refinement with the fast time resolution of SAED.

Results
The calcined sample is first activated (pH2 = 79 mbar, 10% H2, 4K.min-1) during a 2-step process involving the segregation of CuO NPs from a decomposing (Cu,Zn) carbonate phase from 110°C to 200°C, then reduction and sintering of these NPs from CuII to Cu0. A CuI intermediate is detected as well between 200°C and 250°C, with all 3 oxidation states co-existing at these temperatures until only Cu0 remains after 2h at 250°C. The final morphology consists of a network of Cu metallic nanoparticles linked by wurtzite ZnO. This was confirmed by in situ STEM-EELS measurements. A ZnOx overlayer, is sporadically observed after the reduction is complete after 2h at 250°C. Cooling the sample to 50°C then reveals a much fuller coverage, indicating that the overlayer is not stable at high temperatures and forms reversibly.

Observations in MeOH synthesis conditions (H2:CO2:He = 3:1:0.5) and reverse water gas shift (rWGS) conditions (H2:CO2:He = 1:1:0.5), shed tremendous insight into how Cu wetting by ZnOx is mediated by temperature as well as H2 and CO2 partial pressures through a delicate balance of Cu-Zn alloy formation and reoxidation on Cu NPs surfaces [5]. rWGS products (CO and H2O) were detected alongside these observations.

Increasing the temperature to 400°C showed a sudden increase of the Cu lattice parameter above the thermal expansion baseline, indicating CuZn alloy formation. Remarkably the lattice parameters then levels off over 30 minutes. This corresponds to a delayed increase of the water content in the reactor, suggesting that water plays a critical role in the reoxidation of Zn in the catalyst, and demonstrating the transient nature of CuZn alloys in this system.

Conclusion
In summary, extensive operando TEM experimental capabilities were leveraged to shed unprecedented insight into the morphological and structural evolution of Cu/ZnO catalysts during CO2 hydrogenation. Coupling mass spectrometry, electron diffraction and imaging yields a comprehensive description of the activation and reaction process. Altogether our results suggest that a frustrated phase transition between CuZn alloy and Cu-ZnO surface states, rather than one of the two being more active, could be key to the high performance of CZA catalysts for methanol synthesis.

Poster Group 2

Background incl. aims
High-k dielectric thin films such as HfO_2, ZrO_2 and $Hf_{0.5}Zr_{0.5}O_2$ for semiconducting memory devices was selected as model systems. Metastable orthorhombic phase of $Hf_{0.5}Zr_{0.5}O_2$ (HZO) has ferroelectricity and has been the potential materials to next generation nanoscale electronic devices based on its superior physical scalability. In order to increase the ferroelectricity of HZO, understanding the basic generation mechanism of ferroelectric crystalline phases is crucial and is investigated structurally and electrically in this study.

Methods
10 nm thick $Hf_{0.5}Zr_{0.5}O_2$ films were deposited using atomic layer deposition (ALD) on 200 nm thick TiN electrodes as the top and bottom was crystallized by post-metal rapid thermal annealing (RTA) in the temperature range from 400 to 900℃. The crystalline phase of HZO was determined with high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM) in TEM (JEOL, ARM-200F). The capacitance-voltage (C-V) characteristics were obtained by Agilent E4980A. Electrostatic Force Microscopy (EFM) and piezoresponse force microscopy (PFM) imaging was performed using NX-10 (Parks systems) on the HZO surface without the top electrode.

Results
From GI-XRD analysis results, the HZO samples annealed at 600 and 700 ℃ showed the higher orthorhombic phase and was consistent with the C-V measurement (Figure 1). The orthorhombic phase is confirmed with HR-STEM. The amplitude and phase images of EFM clearly showed the presence of ferroelectricity at the 600 ℃ RTA-treated sample. The C-V measurement showed that the dielectric constant was 8.8e-18 F/μm for a thickness of 10 nm and an area of $3.14e^4$ μm^2.

Conclusion
We investigated the basic generation mechanism of ferroelectric hafnia crystalline phases as a function of RTA temperature. We found that the higher ferroelectricity was shown from the samples annealed at 600 and 700 ℃ and that orthorhombic phases were dominant on the sample annealed at 600 ℃.

Background
The development of sustainable, renewable energy requires novel solutions that enabling energy storage and conversion, for example for smoothing unstable/variable energy sources.
In order to do so, we can design nanostructures that can trap charge, utilising metal oxide (MO), such as Sn-doped In2O3 nanocrystals (ITO NCs). In ITO, aliovalent substitutional doping can effectively modulate charge carrier density. (1) The bandgap for ITO NCs, crucial for band engineering, is between 3.5 eV and 4.3 eV. (2) (3)
Molybdenum disulphide (MoS2) is a transition metal dichalcogenide (TMDC) semiconductor with an indirect bandgap of 1.3 eV in bulk form, while a direct bandgap of 1.8 eV when in a monolayer. (4)
In this work we use a combination of optical and electron spectroscopy to locally analyse the photodoping phenomenon, a light-driven charge accumulation of electrons, on ITO NCs when coupled with MoS2 monolayer, that act as a sacrificial hole scavenger, deposited on a SiO2 substrate. The innovation of this device lies in the dual role of converting solar energy and storing the resulting charges.

Methods
Photoluminescence (PL) denotes the emission of light from a material after the absorption of photons (electromagnetic radiation). The light emission occurs following photoexcitation, wherein incident photons promote electrons to higher energy states. The Micro-PL was measured using an inVia Renishaw Raman microscope with an excitation laser at 488nm.
Cathodoluminescence (CL) is an optical and electromagnetic phenomenon wherein electrons, typically in a scanning electron microscope, induce the emission of photons, often characterised by wavelengths within the visible spectrum.
CL data were acquired in an Attolight Allalin 4027 Chronos SEM-CL. The spectra were acquired with an iHR320 spectrometer) and an Andor 1024 pixel charge-coupled device. All the measurements were performed at room temperature under high vacuum (<10−7 10 80 100 mbar) with an acceleration voltage of 3 kv. Data were analysed using Lumispy / Hyperspy.

Results
By studying local PL and CL in correlation to the presence of specific MoS2 morphologies, such as monolayer, folded layers and other localised alterations, particularly in the vicinity of the ITO NCs, we aim to understand the local charge dynamics and the interplay between the MoS2 and the NCs.
Our observations reveal a notable reduction in emission intensity in areas surrounding and within the ITO-rich region, which we ascribe to successful charge transfer. The extent of the process is studied in 2D, and results from PL and CL are compared, providing information on different lengthscales and response to different excitation intensities.

Conclusion
Devices incorporating Indium Tin Oxide (ITO) nanocrystals (NCs) and MoS2, where photodoping occurs, present promising solutions for direct solar-to-charge conversion and storage. The parallel use of cathodoluminescence (CL) and photoluminescence (PL) enables a comprehensive evaluation of these properties at sub-micron lateral resolution.

Poster Group 2

Additive manufacturing (AM) techniques impose an advantageous methodology for the fabrication of devices, providing the ability to reproduce complex geometries, unattainable by traditional manufacturing technologies. The continuous growth of these techniques promotes the development of new materials meeting the requirements of the fabrication methods while providing enhanced properties, where the development of nanocomposites is an effective strategy [1]. Understanding characteristics such as the 3D distribution of nanoadditives within the polymeric matrix is crucial for the potential functionality of the nanocomposites. Transmission electron microscopy (TEM) can play an essential role here, among which electron tomography (ET) outstands, as it provides relevant information at the nanometer and atomic scale in 3D to understand and correlate the material structure and its properties [2].
ET consists in acquiring series of projections from the sample in different orientations over a large angular amplitude, so-called tilt series. The tilt range and the tilt increment have a direct impact on the resolution of the final 3D reconstruction. However, when studying specimens that are electron-beam-sensitive, such as polymer nanocomposites, there is a restriction on the number of projections that can be acquired. Therefore, despite the numerous advantages rendered by ET, its implementation to polymeric materials remains largely under-exploited. One of the major reasons is that polymers are prone to damage under the electron beam resulting in the ease degradation during TEM-ET measurements, either by chain scission or cross-linking [3]. Consequently, the resolution limit achievable depends, among other parameters, on the total electron dose to which they can be exposed before being degraded [4]. To this end, the development of low dose TEM approaches and methodologies for imaging vulnerable materials is crucial.
Additionally, specimen preparation to electron-transparency represents a challenge when working with polymeric materials since the performance of TEM analyses requires from clean and thin specimens. The use of focused ion beam (FIB) instrument allows to obtain specimens with tailored geometry, such as needle-shape specimens, of interest for ET due to the possibility of doing full tilt range experiments [5]. However, FIB conditions need to be optimized as well in order to avoid damaging the polymer.
In this work, we demonstrate that low dose ET of polymers is feasible, which is extremely important in the development of AM nanocomposites. More specifically, this work relates to the study of the 3D distribution of metal nanoparticles and 2D metal dichalcogenides (TMDs) throughout acrylic resins used for stereolithography (SLA) using ET (figure 1). For that, FIB nanoneedles of the nanocomposites have been successfully fabricated and the electron-induced damage in the SLA acrylic resin has been studied to design optimal low dose ET experiments.

IM-05 (3), Lecture Theater 3, august 27, 2024, 10:30 - 12:30

Background incl. aims
Fluid preserved animal specimens in the collections of natural history museums around the world constitute an invaluable archive of past and present animal diversity. Many researchers rely on these collections for e.g. anatomical, taxonomical and genetic studies. In recent years, non-invasive imaging techniques such as x-ray computed tomography (CT) and magnetic resonance imaging (MRI) are increasingly being used to extract anatomical information from preserved specimens without harm. Although conventional CT allows for precise measurement of radiodensity (often corresponding to physical density) and MRI can be weighted to highlight contents of interest (e.g. water, fat, bone, etc.), these techniques generally do not allow for high resolution element specific mapping i.e. only showing contrast agents or foreign objects made of a certain element.
In museum specimens, sometimes foreign objects have been introduced perimortem or postmortem e.g. projectile residues from the collection process or objects used for mounting the specimen. These foreign objects often consist of heavy metals and thus severely impact imaging and related measurements such as the estimation of bone mineral content. Also, they may constitute a health issue for collection staff. Therefore, a non-destructive method to identify elemental contents deep within museum specimens is desirable. Here we aimed to use hyperspectral micro-CT imaging to non-destructively determine the elemental content of a prized platypus specimens in the vast collection of fluid preserved mammals at the Natural History Museum of Denmark. This was the Dana platypus from The Carlsberg Foundation's Oceanographical Expedition round the World 1928-30 (a.k.a. the fourth Dana expedition). This specimen contained large centimeter-sized nodules with an unknown content.
Methods
The neurocranium and part of the bill of the Dana platypus was imaged using a UniTOM XL Spectral system (TESCAN GROUP, Brno, Czech Republic) equipped with a hyperspectral detector (channel size of 1 keV) with the following parameters: x-ray tube voltage = 160 kVp, x-ray tube current = 94 µA, x-ray tube power = 20 W, integration time = 83 ms, field-of-view = 76.4 × 76.4 × 27.1 mm3, spatial resolution = 0.108197 mm, acquisition time = ~10 h. K-edge subtraction to highlight the lead (Pb) signal (K-edge at 88.0045 keV) was performed using 1 channels width and 3 channels separation (91 keV – 85 keV).
Results

Different elements have different x-ray attenuation signatures in function of the x-ray photon energy. Hyperspectral CT clearly detected a K-edge at 88 keV in regions of interest placed within the foreign objects of the Dana platypus, which was not observed within bone voxels. This allowed for K-edge subtraction (integrating and subtracting channels on either side of a K-edge to produce element specific images) and the precise mapping of Pb in the neurocranium of the Dana platypus. In addition to confirming the presence of large concentrations of Pb in the foreign objects within the Dana platypus, hyperspectral imaging also showed that the widely distributed small dense particles within the fur of the specimen were not corroded lead residues nor another heavy element material e.g. arsenic or mercury residues from previous preservation methods.

Conclusion

In addition to widely used CT imaging and increasingly used MRI for museum specimen imaging, hyperspectral CT adds another dimension by providing element specific information. In this case demonstrating the content of heavily corroded lead shotgun pellets inside a >100 years old platypus specimen.

FIB-SEM/microtoming prepared Cross Section of a Stone Wool Fiber enabling (S)TEM investigation

Phd Student Krestine Hofstedt Rasmussen[1,2], Ph.D Denis V. Okhrimenko[2], Ph.D Louise J. Belmonte[2], Ph.D Dorthe B. Ravnsbæk[3], Ph.D Espen D. Bøjesen[1]
[1]Interdisciplinary Nanoscience Center, Aarhus University, Aarhus, Denmark, [2]ROCKWOOL A/S, Hedehusene, Denmark, [3]Department of Chemistry, Aarhus University, Aarhus, Denmark

Poster Group 1

Stone Wool Fibers (SWFs) are aluminosilicate fibers widely used for building and housing insulation. Rocks are melted in a high-temperature furnace (~1500°C) and spun into elongated and cylindrical amorphous fibers approximately 5 µm in diameter and 2 mm in length [1]. ROCKWOOL is a world leading producer of mineral wool fibers used for building and housing insulation. ROCKWOOL continuously transitions to a greener production. This transition potentially influences the redox chemistry and thus the atomic scale network, which consequently could influence the fire resilient properties of SWFs. Our goal is to create a thin (approx. 40-140 nm) cross section of a single stone wool fiber to be able to obtain sub-nanometer scale structural and compositional information using (scanning) transmission electron microscopy ((S)TEM) based techniques. Only by exploring and understanding the structure of SWFs on all length scales (micro, nano, and atomic), will we fully be able to understand the mechanisms behind the fire protective properties of SWFs.
Current strategies used by ROCKWOOL to prepare cross sectional samples include mechanical polishing of SWFs embedded in an epoxy matrix. However, this technique is not suitable for STEM-based investigations due to the large sample thickness and the high likelihood of surface contamination caused by polishing. Thus, a new approach for thin sectioning optimal for (S)TEM analysis is needed. A major obstacle to obtaining the sought-after cross-section cross section is the non-conductive nature of the SWFs. Here, we present the current state of our exploration using focused ion beam scanning electron microscopy (FIB-SEM) and testing of using ultra-microtoming of fibers cast into an epoxy matrix for the preparation of cross sections of SWFs for further (S)TEM investigations. While bombarding the fiber with ions in the milling process, high precision is obtained by continuously monitoring and guiding the process by scanning the electron beam across the area of interest [2,3]. The non-conductive nature of the fibers will lead to build up of charge on the fiber surface and may cause deflection of the beam that otherwise enables the high-resolution imaging, which ensures a precise milling process. The cross-sectional lamella is prepared using a FEI VERSA 3D FIB-SEM system equipped with a Gallium ion source or a Leica EM UC7 ultra-microtome with a diamond knife. In our approach, the fibers for FIB-SEM are carefully placed in/on carbon paste that is added to a silicon wafer. Hereafter, the fibers are coated with 600 nm gold (Au) to shield the fiber throughout the milling process. Preliminary results have shown that optimal conditions for the milling include a low I-beam current of a maximum of 5 nA to avoid damage to the fiber upon sputtering.
Furthermore, the tilt angle used to properly clean and mill the thin section of a fiber is further under improvement. Currently, tilt angles of 50.5° and 53.5° are used as the FIB column is located at 52°. In general, the aim is to estimate the right trade-off between acquiring optimal imaging and milling without too much charge build up on the specimen [4]. A test of using ultra-microtoming for thin sectioning is investigated simultaneously to acquire the best possible cross section. This technique also ensures that no damage to the structure of the fiber is created as with FIB-SEM might lead to. A thin section of approx. ~40 nm was acquired with microtoming and initially investigated in STEM

mode using a TESCAN Clara scanning electron microscope. Both techniques show promising initial results on our way to creating a thin cross section of fiber. However, both techniques also show some obstacles to overcome in the process. For FIB, damage upon sputtering should preferably be avoided and strategies to minimize charging need to be optimized. For microtoming, a major current obstacle is to optimize the mechanical properties of the epoxy to match those of the fibres to optimize the cutting process. The process of acquiring this cross section for TEM investigations is still in the primary stages, focusing on practicing the lift-out process of the cross section and mapping out the charging effects.

The importance of an open camera system demonstrated with wide-ranging applications of MerlinEM detector

Dr Matus Krajnak[1], Dr Gearoid Mangan[1]
[1]Quantum Detectors Ltd, Harwell Oxford, United Kingdom

Poster Group 1

Background inc. aims
The MerlinEM detector has gained widespread acceptance in the transmission electron microscopy (TEM) community due to its versatility and adaptable integration with various systems. The detector provides hybrid pixel electron counting based on Medipix3 technology, bringing in high detective quantum efficiency, rapid readout speed, high dynamic range, and radiation hardness.
Methods
Enabling direct access to data and camera operation is essential in exploring new applications and improving established techniques. The MerlinEM system provides this, together with live 4D scanning transmission electron microscopy (4D-STEM) capabilities (Fig. 1). Additionally, Quantum Detectors recently redesigned the retractable version of the MerlinEM platform, MerlinEM RDP, which now fits more microscopes and will support future generations of hybrid pixel detectors (Fig. 2).
Results
Open data formats and remote operation capabilities were essential in exploring new applications and improving established techniques, such as imaging electromagnetic fields [1] and ptychographic imaging [2]. Rapid data streaming to third-party software has been utilised for live ptychography [2] and integrated centre of mass imaging [3], while collaborations with commercial partners like NanoMegas (scanning precession electron diffraction toolkit), CEOS and Université Paris-Saclay (spectrometer systems) enhanced the capabilities of TEM instrumentation.
Conclusions
The openness of the detectors has fostered community collaboration, exemplified by projects like LiberTEM [4], pyXem [5] and others. These initiatives facilitate sharing data processing routines, accelerating the development of innovative methods for extracting sample information and addressing a wider range of specimens more efficiently.

PS-06, Lecture Theater 1, august 29, 2024, 10:30 - 12:30

Background
The Hayabusa2 space mission from the Japan Aerospace Exploration Agency returned materials from the Ryugu C-type asteroid to Earth in 2020. Due to its lack of atmosphere and low mass, Ryugu is less altered than other space bodies in the Solar System, preserving information about its primordial stages. One of its most interesting features is its phyllosilicate fibrous matrix, which can feature absorbed water and organic matter, as evidenced by remote infrared measurements[1] and laboratory analyses[2].
This matrix contains two families of phyllosilicates with different, albeit similar, chemical compositions and crystallographic structures: saponites (with a higher Si stoichiometry) and serpentines (with the presence of Al), intimately mixed at the nanoscale in a fibrous matrix and surrounded by various other systems such as sulfurs, and organic matter.
Until recently, the high sensitivity of the material to the electron beam[3] made it very difficult to perform electron microscopy analysis at the resolution required to address some intriguing questions, such as the presence of organic matter in the interlayers and the precise morphology of the intermixing of the different phyllosilicate families. Fortunately, the advent of direct electron detection, along with other instrumental and data analysis advances, has begun to expand the scope of analyses that can be performed in such beam-sensitive systems. Exciting recent developments include vibrational EELS[4] and 4D-STEM [5] analyses on Ryugu samples.
Here, we bring together several state-of-the-art techniques to achieve EELS analysis of FIB lamellas at unprecedented spatial resolution and EELS analytical tomography of nanopillars of these beam-sensitive samples. In particular, we utilize a hybrid-pixel direct electron detector for EELS acquisition, which offers almost perfect DQE, high-speed acquisition, and a wide dynamic range. This enables the development of a highly sensitive EELS analysis approach for all elements of interest in the sample. In particular, we acquire EELS low-loss spectrum images (SIs), instead of the usual core-loss and corresponding low-loss SIs. Since most of the elements present in these samples (Fe, Al, Mg, Si and S) showcase a major EELS edge in the 25- 200 eV spectral range, we can perform EELS quantification with a single, fast SI acquisition. This approach offers the potential of a higher signal-to-noise ratio in comparison to the more conventional ionization edges at higher energies, at the expense of a more convoluted spectral analysis.
Methods
FIB lamellas from the Ryugu asteroid were fabricated from Ryugu grains and, subsequently, nanopillars for tomography were created also using FIB. EELS spectrum images were acquired on an FEI TITAN Themis 300 S/TEM, in muti-frame mode (developed in-house), with a dwell time varying between 0.5 and 2 ms and a pixel size ranging from 1 to 2nm. For the tomographic tilt series, EELS spectrum images were acquired at 9 angles ranging from -70 to 70 degrees.

The resulting spectrum images were then analyzed using SVD decomposition of the three- and four-dimensional datasets, blind source separation and curve-fitting EELS quantification.

Results
Figure 1 illustrates the successful EELS elemental mapping of a FIB lamella using curve fitting with enough spatial resolution that allows us to discern the different types of fibers in the phyllosilicate matrix and the characterization of Fe-rich minerals at the nanoscale. This allows to separate the two main phases in the phyllosilicate matrix (saponite and serpentine) by means of EELS analytical tomography.

Conclusion
We present a new method for the EELS analysis of astromineral samples at the nanoscale that, thanks to its dose efficiency, enables unprecedented spatial resolution and EELS analytical tomography on beam-sensitive samples. The method can be extended to other samples presenting EELS ionization edges at low energies. Results show that this technique can provide at least as much information as other microscopy-based techniques like EDX, but with a higher spatial resolution and a fraction of the dose.
Our findings not only provide deeper insights into the structure and chemistry of samples from Ryugu but also show the potential of this methodology for broader application to beam-sensitive astrominerals and geomaterials, such as biominerals.

Setting up fringe-free imaging for SPA on Talos Arctica and Titan Krios microscopes

Dr Nadav Elad[1], Dr Roman Kamyshinsky[1]
[1]EM Unit, Department of Chemical Research Support, Weizmann institute of science, Rehovot, Israel
IM-11 (1), Lecture Theater 5, august 29, 2024, 10:30 - 12:30

Background:
Single particle cryo-EM requires large image data sets, while instrument time and sample availability are in many cases limiting factors. Increasing the data collection efficiency is therefore highly advantageous. One of the methods for increasing imaging efficiency is by reducing the diameter of the beam, such that more images can be taken from suitable sample areas on the TEM grid. In normal TEM imaging mode, the diameter of the beam is limited by appearance of Fresnel fringes from the C2 aperture. Fringe-free illumination reduces Fresnel fringes at the beam edges by simultaneously imaging the sample and C2 aperture in focus. The beam diameter can therefore be reduced significantly, allowing the collection of a larger number of images per-hole and higher throughput.

Methods and Results:
Installation of fringe-free illumination is commercially available from Thermo Fisher Scientific (TFS) and includes mechanical adjustment of the stage's eucentric height. However, purchasing and implementing the TFS product is not always possible or is simply unnecessary. Instead, the microscope can be aligned for fringe-free imaging by the local facility, and the alignment stored in a separate file. We have implemented this method on our Titan Krios G3 (3-condenser lens system) and Talos Arctica (2-condenser lens system), both resulting in equally high-resolution structures as in the normal alignment mode. On the Talos Arctica, fringe-free alignment using a 20 um condenser aperture results in a parallel illumination beam diameter of about 750 nm. The use of a small condenser aperture and imaging far from the original eucentric focus introduces several challenges in alignment and automated acquisition, however these are solvable.

Conclusions:
Fringe-free illumination increases SPA imaging throughput and can be implemented by experienced microscopists in both 2 and 3-condenser lens EMs. I will present the procedure for aligning both microscope types, as well as a script for quickly switching between the two alignment modes before starting EPU sessions.

Imaging ultrafast spin dynamics at the nanometer scale

Dr Gaolong Cao[1], Sheng Jiang[2], Yuzhu Fan[1], Johan Åkerman[3], Jonas Weissenrieder[1]
[1]Royal Institute of Technology (KTH), Stockholm, Sweden, [2]South China University of Technology, Guangzhou, China, [3]University of Gothenburg, Gothenburg, Sweden

Poster Group 2

Background incl. aims
Understanding magnetic dynamics is not only important to fundamental physics but also critical to the development of future energy-efficient spintronic devices. Detection of ultrafast magnetic dynamics with high temporal-spatial resolution remains a great challenge. In recent years, the UEM (ultrafast electron microscope) has been rather active in ultrafast magnetism[1-4]. Based on a commercial TEM platform, UEM inherits the capability of high space resolution (nanometer scale) and versatile imaging modes. Moreover, the pulse duration of the photo-emitted electron can reach lower than 1 ps in the premium condition, which is compatible with most of the scenarios for the spin dynamics.
However, it is noteworthy that all these experiments rely on topological magnetic structures. Such limitation originates from the imaging mechanism of the Fresnel mode in the Lorentz TEM, which is the beam-deflecting effect driven by the transverse Lorentz force between the electron beam and local spin state. In short, the Lorentz image contrast in Fresnel mode relies on the in-plane spatial gradient of magnetization other than the magnetization itself. This means the Lorentz UEM could only image the ultrafast perturbations of the topological magnetic structure, and rule out other critical magnetic dynamics, such as ultrafast demagnetization, spin waves etc, which usually do not relate to a static topological structure.

Method and result
Here, we report a novel method of Lorentz ultrafast electron microscope (UEM), which can directly image the spin wave in real space [5]. Unlike traditional methods, our Lorentz contrast does not rely on topological magnetic structure. We introduce a structured-light pulse (transient optical grating (TOG)) onto the ferromagnetic sample, which can induce transient spatial magnetic gradient and then create time-resolved magnetic contrast under Lorentz mode. Then, the propagating spin waves, which are driven by the magnetic-elastic coupling, become ‘visible’ in the UEM.

Conclusion
In summary, we have for the first time directly imaged spin waves in the UEM via structured light, which opens a new door to detect and manipulate ultrafast magnetic dynamics with high temporal-spatial resolution.

Sequential tilting 4D-STEM for reliable electric field mapping across junctions

Christoph Flathmann[1], Ulrich Ross[1], Andreas Beyer[2], Jürgen Belz[2], Kerstin Volz[2], Michael Seibt[1], Tobias Meyer[3]
[1]4th Physical Institute, Georg-August-University Goettingen, Göttingen, Germany, [2]Department of Physics and Materials Science CenterPhilipps-University Marburg, Marburg, Germany, [3]Institute of Materials Physics, Georg-August-University Goettingen, Göttingen, Germany

IM-03 (1), Plenary, august 28, 2024, 10:30 - 12:30

Background incl. aims
Momentum-resolved scanning transmission electron microscopy (MRSTEM) is an increasingly popular technique to map nanometer range electric fields [1]. Such measurements are of particular importance for device structures, for example pn-junctions [2], in order to understand functional properties of devices at the relevant length scales. To measure electric fields, MRSTEM determines the momentum transfer from an electric field to an electron beam via the deflection of the electron beam. However, relating the momentum transfer to the electric field is significantly complicated under dynamic diffraction conditions. Therefore, strategies are required to reliably determine electric fields from MRSTEM measurements under dynamic diffraction conditions. One such approach is tilting the incident beam relative to the sample in order to probe different diffraction conditions [3]. In this contribution, we explore how tilt patterns can be optimized and how MRSTEM based electric field mapping can be improved.

Methods
To get full control over the beam tilt, we use a custom developed beam tilt procedure. Here, we first calibrate the beam tilt and de-tilt coils of our microscope to allow us setting arbitrary beam tilts in STEM mode. In a second step, we calibrate the beam shift pivot points to obtain negligible beam shift at the sample for different beam tilts. These alignments enable us to repeatedly scan over the same sample region with different beam tilts, generating the data required for detailed MRSTEM analysis. We apply this acquisition technique to high quality lattice-matched AlAs/GaAs multi layers. These samples have the advantage that the mapped momentum transfer originates almost exclusively from a change of the mean inner potential across the materials interface, making assessment of the MRSTEM results easier.

Results
To analyze the effects of beam tilt on MRSTEM measurements, we scan across the AlAs/GaAs interface as shown in Fig. 1 a). We apply the scan patterns shown in Fig. 1 b), both consisting of 61 beam tilts, by sequentially scanning across the interface 61 times and collecting MRSTEM data for each tilt. Fig. 1 c) compares the measured electric fields for the annular and the full circle tilt patterns. The full circle pattern results in a sharp peak at the interface and an electric field close to zero away from the interface, as expected for AlAs/GaAs layers, while the electric field measured with the annular pattern shows stronger deviations from the expected behavior. In addition, we also have access to diffraction patterns of individual beam tilts. Fig. 1 d) shows the electric fields mapped with the beam tilts marked in Fig. 1 b). The strong differences for different beam tilts demonstrate that having access to this information is essential to improve MRSTEM measurements.

Conclusion
Our results show that full control over beam tilts and the capability to create arbitrary tilt patterns has a huge potential to improve the quality and reliability of MRSTEM measurements. Particularly, the sequential acquisition of the data, giving access to individual beam tilts, is very beneficial for post-acquisition data examination and thus being fully consistent with the spirit of 4D-STEM of using as much information encoded in the data as possible.

Fig. 1: a) shows an annular dark field STEM image of the investigated AlAs/GaAs junction. The green line indicates the region scanned for field mapping. b) shows schematics of annular and full circle beam tilt patterns in reciprocal space, both consisting of 61 individual beam tilts with a maximum tilt angle of 7 mrad and a beam semi-convergence angle of 1 mrad. c) shows the electric field profiles obtained for the tilt patterns in b) scanned along the line indicated in a). d) shows electric field profiles of the same scan but for individual beam tilts. The corresponding beam tilts are indicated by colored circles in b).

A validation methodology for size and shape measurement of nanoplastics by transmission electron microscopy

Charlotte Wouters[1], Denrich Morales[1], Khariklia Tsilikas[1], Eveline Verleysen[1], Jan Mast[1]
[1]Trace Elements and Nanomaterials, Sciensano, Brussels, Belgium

Poster Group 2

Background incl. aims
The spread of plastics in the environment has led to the formation of microplastics (MPs) and even smaller nanoplastics (NPs) through processes such as aging, degradation, and fragmentation. While significant research has focused on quantification and understanding the potential harmful effects of larger MPs [1], characterizing NPs proves to be challenging, especially within complex matrices [2]. A comprehensive physicochemical characterization is however imperative, especially for evaluating their potential toxicological impacts. In this study, we establish a foundational framework for such measurements by validating a transmission electron microscopy (TEM)-based approach, in the context of the European project PlasticTrace [3]. This validation encompasses all analysis steps, from sample preparation to image analysis, focusing on reference materials composed of polystyrene nanoplastics. By establishing the full measurement uncertainty balance, we aim to determine the accuracy, precision and reliability of NP size and shape characterization by TEM.
Methods
The method is validated supporting on the Nanosphere size standards 3060A (60 ± 4 nm), 3200A (202 ± 4 nm) and 3500A (510 ± 7 nm), purchased from Thermo Fisher Scientific. They are part of a series of polystyrene micro/nanospheres with certified mean diameters traceable to the Standard Meter through the National Institute of Standards and Technology (NIST). The sample preparation consists of optimally diluting the colloidal sample suspension and bringing it on an Alcian blue pre-treated TEM grid. For each material, 15 different TEM specimens are prepared and imaged on 5 different days (3 per day). For each specimen, 10 images are recorded systematically and randomly over the grid surface. Each series of 10 images is analyzed using the ParticleSizer software in ImageJ. The intermediate precision of the quantitative TEM measurement is evaluated using a top-down approach [4] combining the uncertainty related to repeatability (within day) and uncertainty related to day-to-day variations (between day) obtained by ANOVA analysis. Adding the uncertainty related to calibration of the microscope and to trueness, allows to estimate the total combined and expanded uncertainty for the mean, mode and percentiles of parameters including the minimum and maximum Feret diameter (Fmin & Fmax), the equivalent circle diameter (ECD), the maximum inscribed circle diameter (MICD) and the aspect ratio (AR).
Results
Material stability was pertained throughout the validation study and homogeneous distribution of particles on the grid was achieved for all materials. Material 3060A is polydisperse with particle sizes ranging from 10 nm to 70 nm. Materials 3200A and 3500A are more uniform in size, however, a small fraction of particles (<2%) have a significantly larger or smaller diameter. STEM-EDX was performed to verify that all particles have the same elemental composition and thus belong to the polystyrene sample. The intermediate precision obtained is similar for all size parameters. It ranges from 1.1-6.7%, 0.7-1.5% and 0.3-0.7% for materials 3060A, 3200A and 3500A, respectively. The highest values correspond to the d10 percentile and the lowest values to the d75 or d90 perecentiles due to left skewedness of the size histograms (see graphic). The intermediate precision is highest for material 3060A due to the higher degree of polydispersity. For the AR, the intermediate precision is below 1%

for all materials and measurands. The main source of uncertainty is related to the trueness uncertainty for all materials. To assess the accuracy of our approach, a comparison with the certified size values (see Methods section) is required [5]. Specific information on how the certified diameter was obtained is lacking, however, we assume it corresponds to the mean ECD of the material. The values and expanded uncertainties we obtained for the mean ECD are 51±4 nm, 198±7 nm and 518±13 nm, for the three materials respectively. Based on a comparison with the certified values, we conclude that the two largest materials are accurately measured, however the smallest material presents a significant difference with respect to the reference value. Since the mode of the distribution is closer to the reference value of 60 nm, a difference in analysis algorithm e.g. leading to exclusion of a fraction of the smaller particles, might be at the origin of this discrepancy. We see indeed that for material 3060A, the outcome of the validation study is less robust against variations in image analysis settings. However, to make a final conclusion on the trueness of our approach, more detailed information on the certification of the materials is required.

Conclusion

This study establishes a robust methodology for the validation of TEM-based measurements on reference materials of polystyrene nanoplastics. By evaluating the measurement uncertainties associated with size and shape analysis, considerable precision is achieved, however, ensuring trueness can be challenging and requires detailed information on the reported certified diameters. These findings underscore the importance of ongoing refinement and harmonization in analysis algorithms to enhance the accuracy of nanoplastic characterization.

TEM 3D Spectroscopic Imaging for Catalytic Activity Evaluation

Dr. Hionsuck BAIK[1], Dr. Taekyung KIM[1], Dr Yongju Hong[2], Dr. Kwangyeol LEE[3]
[1]Korea Basic Science Institute, Seoul, South Korea, [2]Korea Institute Science of Technology, Seoul, South Korea, [3]Korea University, Seoul, South Korea

Poster Group 2

Changes in the shape of nano catalyst particles have a significant impact on catalytic activity. Basically, the smaller the particle, the more desirable it is for the surface volume increasing of the small particle to be rough, even down to the atomic level. Through previous of research[1,2], we have tried to increase the reaction volume of nanoparticles and to have a form that remains stable during catalytic reactions. In the beginning, the surface roughness was controlled in spherical particles, but then changed to a shape with multiple faces, induced so-called high-index crystal planes, and induced stress in a core-shell shape etc
However, now, from the point of view of economic feasibility and performance improvement, it is necessary to form holes inside the frame structure through the surface structure having three or more components, to create several frames and place clusters of three or four atoms on top. Maximization of catalytic activity is occurring through the training method.

In the field of analytical science, especially high spatial resolution transmission electron microscopy, these changes in nanoparticles present very challenging issues. Based on counting the shape or number of sides, now it is necessary to identify more than 10 sides, quantify the overall stress of the particle, and detect the components of three or four atoms. It is necessary to obtain three-dimensional information rather than the two-dimensional information of the past, and to measure performance. Due to the advancement of technology, a method has become necessary to connect which structural factors are important to the performance mechanism.
From this point of view, we present an analytical science approach protocol with the results obtained by applying the evaluation technology described in the previous section to particles that have secured excellent catalytic performance by synthesizing atomic-level clusters in a Ir-Ru based hetero-frame nanostructure.
First, we synthesized Ir2P/Ru2P particles and performed transmission electron microscopy crystal structure analysis and surface analysis spectroscopic mapping to reveal the particle formation mechanism for proper performance evaluation. 3D reconstruction of spectroscopic images was actually a very difficult and tedious task, and the results were difficult to draw conclusions about. In the end, machine learning was implemented and better results were obtained, but there are still many things to be solved.
The further work is to establish a method to evaluate the total volume of sites that affected catalytic activity through spectroscopic images through full-scale machine learning.

Poster Group 1

Background incl. aims
In recent years, cryo-electron tomography (cryoET) has proven to be a powerful tool for studying the organization and complexity of cellular ultrastructures in their near-natural state. Nevertheless, its applicability was primarily restricted to single cells and monolayers due to the limited capabilities of volume vitrification techniques. Advances in cryo-electron microscopy (cryoEM) aim to overcome these limitations, which has led to the development of methods that can vitrify larger volumes. Despite these advances, further thinning of samples remained a challenge until focused plasma ion beam (PFIB) microscopy and the lift-out technique were introduced. By combining these improved technologies, we have succeeded in pushing the boundaries of sample preparation for cryoET. In particular, we set out to develop and optimize methods for the preparation of large-volume samples, focusing on samples from fungi and plants to facilitate the study of plant-microbiome interactions at the cellular, and ultrastructural level, and we present our results in this context.

Methods
Samples were collected from an arbuscular mycorrhizal (AMF) fiber network, known for its symbiotic relationship with approximately 80% of plant species. Additionally, samples of plant roots were obtained from both Arabidopsis thaliana seedlings and Ri T-DNA-transformed plant root organs cultivated on a standard MSR medium. Cryogenic preservation by high-pressure freezing (HPF) was performed in 3 mm planchettes and the waffle method on grids. Using hexadecane and phosphate buffer solution as filler to prevent the formation of gas bubbles. Prior to vitrification, all samples were fluorescence stained with Nile Red and Calcofluor to enhance visualization of lipid-rich structures and cell walls, respectively. Following, grids were evaluated and processed in Arctis cryo-PFIB, while planchettes were processed in Helios Hydra V a PFIB dual beam scanning electron microscope. Trenches were prepared, enabling both 3D large-volume imaging and preparation for cryo-lift-out on planchettes. Lamellae were prepared on grids and from lift-out samples and subsequently transferred to Titan Krios for data collection.

Results
This study demonstrates the successful vitrification of AMF, enabling the visualization of the cellular organization in a near-native state. Fluorescence staining with Nile Red and Calcofluor white facilitated the differentiation of cellular structures, including the distinction between filled and empty AMF hypha. In Addition, 3D volume images of both, the AMF network and plant root tissue, were generated, providing insights into their respective structures. In particular, plant organs provided better results compared to other plant tissue used in this study. Furthermore, the used methodology

enabled the imaging of plant tissue in a near-native state without additional fixation steps after HPF, which is a remarkable advance over previous approaches. The combination of methods offers a promising approach for studying plant-microbe interactions on a structural level and provides valuable insights into complex biological systems.

Conclusion
The combination of methods used for large-volume sample preparation in cryoET represents a significant advance in the study of plant-microbiome interactions at the structural level. The inclusion of fluorescent staining in the sample preparation facilitated the identification of areas of interest on the PFIB and enabled the precise alignment for lamella milling of different cellular structures. The acquisition of 3D volume images of both AMF networks and plant organs provides comprehensive insights into their structures and interactions. In particular, our approach demonstrates the enhanced vitrification quality of plant organs over other plant tissues. Furthermore, the ability to image plant tissue in a near-native state without additional fixation steps preserves tissue integrity and ensures accurate visualization of cellular ultrastructure. Overall, our methodology offers a promising opportunity to improve our understanding of plant-microbiome interactions. By elucidating complex dynamics at the cellular level, our work contributes to the broader knowledge of complex biological systems. Further refinement and application of our methodology have the potential to unravel the mechanisms underlying the interactions between plants and microbiomes.

The Development of Japanese ceramic ware (pottery and porcelain) Technology as Revealed by EPMA

Dr Rie WAKIMOTO[1], Dr Susumu KAKUBUCHI[2], Dr Sergei Matveev[3]
[1]JEOL Ltd., Musashino Akishima, Japan, [2]SAGA University, SAGA , Japan, [3]JEOL (GERMANY) GmbH, Gute Aenger, Germany

Poster Group 1

Introduction

The quality of Japanese ceramics ware has improved dramatically since the importation of advanced ceramics, especially percaline technology from the continent in the 17th century. In particular, Old Imari, (Ko-Imari), made after the 17th century using highly refined continental techniques, was loved by celebrities not only in Japan but around the world [1]. Of course, even before the 17th century, ancient Japanese pottery techniques had developed and many potteries were produced.
This report describes an observation and analysis of the development of medieval ceramics in Japan before and after the high level of ceramic ware technology was introduced.

Methods

The samples for analysis were pieces collected from the Chita kiln site [2] of Paleo-Tokoname, old pottery ware (early Sengoku period (late 800s)), the Komizo kiln site of early Arita porcelain ware (early 1600s), and the Kakiemon kiln site (late 1600s) [3] where ceramic porcelain technology was established. Thin sections were created by gluing a small piece of pottery onto a glass slide, and then grinding it. The thin sections were observed and analysed with an electron probe microanalyser (JEOL JXA-iHP200F).

Results

The backscattered electron (compositional) image (BEI) and the panchromatic cathodoluminescence (CL) image and Si mapping analysis results are shown in Figure 1. The upper part of the BEI shows the glazed part of the ceramic surface. The glazed width of the paleo Tokoname piece (Very initial period) (a) is thin and contains many impurities. Also, the Komizo piece (early period) (b) contains many impurities in the glaze, whereas the Kakiemon piece (established period) (c) contains fewer impurities. The panchromatic cathodoluminescence (CL) images show strong luminescence in the glazed areas of the Tokoname piece and the Komizo piece. On the contrary, no CL luminescence is observed in the Kakiemon piece glaze part. Also, the base of Tokoname piece shows stronger CL luminescence than the Komizo and Kakiemon pieces. Si mapping results show that the impurities in the glaze of the Tokoname piece and Komizo piece include Si-particles (Single arrows in the figure), indicating that many quartz fragments are still present. On the other hand, in the Kakiemon piece, these mineral particles are not found.
.

Conclusion

The BEI and CL images and Si maps show that the glaze width of the Tokoname piece is thin and contains many impurities, indicating that the glaze firing technique is immature. Normally, pottery are made from low-glassy materials, while porcelain is made from high-glassy materials. Strong CL luminescence in the base of Tokoname piece indicates a high content of crystalline quartz fragments. The glaze width of the Komizo piece is well present, on the other hand Si and CL strong luminescence is observed in the glaze area, suggesting that early Arita ware glaze still contains unmelted quartz. In

the Kakiemon, glaze width is sufficient and these mineral particles are not found. These results suggest that the Kakiemon ware was produced at higher temperatures with better quality glaze than the Tokoname ware and Komizo ware was due to the development of pottery techniques. In other words, Japanese ceramics technology has improved at a very fast pace in just 100 years since the importation of pottery technology developed from the continent in the early 1600s.

Figure 1. BEI, CL images and Map analysis results. (a) Paleo Tokoname piece. (b) Komizo piece. (c) Kakiemon piece. Si grains with strong CL luminescence are identified in the Tokoname and Kamizo glaze parts (single arrows).

Relative thickness study of TEM samples

Dr Sandra Drev[1], Petra Drnovšek[1], Dr Miran Čeh[1,2]
[1]Center for Electron Microscopy and Microanalysis, Jožef Stefan Institute, Ljubljana, Slovenia,
[2]Department for Nanostructured Materials, Jožef Stefan Institute, Ljubljana, Slovenia

Poster Group 1

Sample preparation methods have an important role in transmission electron microscopy (TEM). New materials (ceramics, thin films, composites, etc.) that are now present have a specific property and have to be precisely treated and usually post-treated. This poses ever-new challenges, constant adjustments, and improvements in advanced TEM preparation techniques like focused ion beam sample preparation, conventional sample preparation, and other TEM preparation methods.
In this paragraph, we compared two nowadays most frequently used TEM sample preparation techniques; conventional sample preparation and focused ion beam sample preparation. TEM samples were, in the last stage of preparation, final-treated using NanoMill® (model 1040, Fischione Instruments, Inc.) to achieve the best results for further TEM/STEM analysis. The study was created for a discussion about using different approaches to achieve the best result for the TEM sample preparation.
The first TEM sample was prepared using FEI Helios NanoLab NL650 dual-beam Focused Ion Beam (FIB). The sample was finally treated (thinned and cleaned) with NanoMill under specific conditions for FIB-type samples. The second TEM sample was conventionally prepared. The sample was thinned, dimpled down to transparent thickness (Dimple grinder, Gatan Inc.), and ion-milled using PIPS (Precision Ion Polishing System, Gatan Inc.) to achieve perforation. In the last stage, the sample was finally treated with NanoMill under specific conditions for conventional-type sample preparation.
We want to expose how important is to choose the proper technique and appropriate conditions for TEM sample preparation. Relative thickness study distinctly revealed improvement in sample quality that affects the final STEM investigations.

Background incl. aims
Iron phosphide is an earth abundant material with several applications, such as an electrocatalyst for the hydrogen evolution reaction (HER) and the oxygen evolution reaction (OER). Water-splitting as a way of producing hydrogen gas is essential to explore due to its low carbon footprint, and using earth abundant catalysts such as iron phosphide is preferred due to being inexpensive, active, and electrochemically stable (1). Therefore, it is of interest to explore methods to manufacture iron phosphide and aim to achieve perfect crystallinity in combination with tuning the different crystalline phases, since they exhibit different catalytic activity. With an environmental transmission electron microscope (ETEM) it is possible to reveal the mechanism of the gas synthesis at an atomic scale in-situ.
Methods
The iron nanoparticles used are created by using spark ablation in a spark discharge generator and deposited on MEMS chips allowing for heating. The ETEM, Hitachi HF-3300S, interfaced with a metal organic chemical vapor deposition (MOCVD) system is the instrument used and the gases induced are PH_3 and H_2. Energy dispersive X-ray (EDX) spectroscopy is used for elemental information and enabled by the SDD X-MaxN 80T detector. Post-experiment data analysis is performed by utilizing FFT spectra obtained from the high-resolution TEM (HRTEM) images and videos from the Gatan OneView IS camera.
Results
By tuning gas flows and temperature synthesis of different iron phosphide phases were observed directly, currently the phases found are Fe_2P and FeP. The transformation into iron phosphide is nearly instantaneous when PH_3 enters the system, however by using dilution with H_2 it is possible to somewhat slow down the process. It also appears that using pure versus oxidized iron nanoparticles still seems to produce iron phosphide. Moreover, there have been observations of a transformation from FeP to Fe_2P by increasing temperature. Fe_2P has been proven to be very stable in various gaseous and temperature conditions, as well as in air.
Conclusions
Different phases of iron phosphide have been synthesized in the ETEM and dynamics of phase transformations have been investigated. The transition between phases has been observed, as well, indicating that it might be possible to realize phase engineering on iron phosphides even after phosphorus has entered the particles. Our future work will aim towards studying the transformation to iron phosphide further, exploring and characterizing the possible phases and achieving selection of crystal structure in a more controlled manner. By finding a reliable way of creating phases it can pave the way for comparing different phases and for example their catalytic activities in a fair way.

Poster Group 1

Background incl. aims
Using environmental transmission electron microscopy, researchers can observe - with high resolution and in real time - transformations and reactions under realistic conditions. Such studies benefit from precise control, monitoring, and variability of ambient gas, potentially including multiple independently controlled species to which a sample is exposed at the same time. This represents a challenge for ETEM analysis and has required the design of systems that integrate the capabilities of advanced crystal growth instrumentation with the specific requirements of TEM to allow elevated sample pressure and temperature, as well as a better understanding how the environment influences the analysis and vice versa. To address these challenges, we developed an ETEM system based on a Hitachi HF3300S instrument, which is integrated with a metal-organic chemical vapor deposition (MOCVD) system designed for real-time investigation of crystal growth processes of semiconductor nanostructures[1].
Here, we demonstrate how the design of the ETEM-MOCVD instrumentation enables independent control of the gas composition and flow that reaches the heated sample region, as well as rapid adjustments of the gas supply. We focus on the implemented solutions used for controlling gas concentration and pressures in the system and at the sample region. Solutions for calibration and monitoring partial pressures as well as total pressure in the microscope and at the sample are presented and evaluated, together with pressure correction factors of the pressure gauges for nitrogen (N_2), arsine (AsH_3), and phosphine (PH_3). In addition, we explore the influence that the temperature and gas supply to the microscope itself have on imaging and analysis, and conversely, how the imaging via electron beam influences the experiment. Effects of temperature and gas environment on spatial resolution are quantified, and we also demonstrate and quantify how X-ray energy-dispersive spectroscopy (EDS) analysis is influenced by the local reactive sample environment.

Methods
The ETEM is based on an image corrected Hitachi HF-3300S 300 kV TEM, with additional ion pump and differential pressure aperture. The gas handling system is custom built but based on industrial standard mass flow controllers, pressure controllers and vapor concentration measurement units (HORIBA). Nine different gases are controlled via the gas handling system, primarily for III-V semiconductor growth: trimethylgallium (TMGa), trimethylindium (TMIn), trimethylaluminum (TMAl), trimethylantimony (TMSb), AsH_3, PH_3, nitrogen, hydrogen, and oxygen. Other gases are possible by either replacing any of the existing sources, or by using external gas delivery and leak valves. Heating is done using MEMS heating chips.

Results
The design of the gas handling system and particularly the ability to dilute the precursor species with additional high flow of H_2 allows for a very wide range of precursor flows and partial pressures to be

achievable, spanning over four orders of magnitude (approximately 4 × 10-6 to 0.1 Pa of TMGa, or 7 × 10−5 to 2 Pa of AsH_3). These partial pressures are comparable to conventional MOCVD growth of binary semiconducting nanostructures.
Since the microscope is of an open design with local gas injection close to the heated area of the holder, a local higher pressure at the holder compared to the column pressure gauge location is expected. Using a MEMS heating chip as a pulsed Pirani gauge, we correlate pressure at the holder to the microscope column pressure. Depending on gas delivery method (via gas injection holder or side port injector) and holder tilt, pressure at the MEMS chip was found to be 1.6 to 2.8 times higher than column pressure gauge. If using additional lid on gas injection holder, pressure at the MEMS chip was found to be 200 times higher than the column pressure.
Achievable spatial resolution during gas exposure on a heated MEMS chip was estimated using Young's fringes. Measured resolution is slightly worse than the 0.86 Å achievable under optimized conditions[2], mainly due to stability of the holder and MEMS chip. Elevated temperature and gas exposure had a very minor effect on resolution.
Increasing temperature on the SiNx based MEMS chips, the thermal radiation of the chip increases. Such thermal radiation affects the EDS measurement mainly by increasing the strobe peak intensity, but at high enough chip temperature also energy shift of strobe peak and elemental peaks.

Conclusion
We present a system that merges an environmental TEM with an MOCVD setup for real-time study of crystal growth. The open holder design allows for a wide sample tilt range, quick gas switching, and various analysis techniques. The gas handling system replicates standard MOCVD conditions and is flexible for different gas pressures, flows, and precursor types. We found no significant effect of heating or gas pressure on spatial resolution, and minimal interaction of the electron beam with the gas.

Quantitative Elemental Mapping Of Bimetallic Nanoparticles From Atomic Scale STEM-HAADF Images

Adrien Moncomble[1], Damien Alloyeau[1], Guillaume Wang[1], Nathaly Ortiz-Peña[1], Hakim Amara[1,2], Riccardo Gatti[2], Maxime Moreaud[3], Christian Ricolleau[1], Jaysen Nelayah[1]
[1]Université Paris Cité / CNRS, Paris, France, [2]Université Paris-Saclay / CNRS, Chatillon, France, [3]IFP Énergies Nouvelles, Solaize, France

Poster Group 2

Background incl. aims

Alloying of metal at the nanoscale is often used to enhance nanoparticles' physical/chemical properties and engineer new ones leading to multimetallic nanoparticles (NPs) with different chemical structures [1]. Access to composition is paramount for a fundamental understanding of nanoalloys' chemical and physical properties. In transmission electron microscopy (TEM), particle composition can be accessed by spectroscopic techniques such as energy-dispersive X-ray spectroscopy (EDX). However, EDX requires a set-up with a high-brightness electron source and wide-angle detection to collect as much signal as possible. Even then, if we work at atomic resolution, the quantification of the composition of atomic columns is possible but limited as there is a lot of noise as compared to signal [2]. A promising alternative for quantitative composition determination is atomic-resolution high-angle annular dark field scanning TEM (HAADF-STEM) with strong compositional sensitivity [3]. In this contribution, we propose an innovative method to quantify the composition of individual atomic columns in bimetallic NPs from their intensities in 2D HAADF-STEM images using deep learning.

Methods

In this work, we studied CuAu NPs between 5 and 10 nm synthesized via pulsed laser deposition (PLD). The HAADF STEM images were acquired on a double-corrected cold FEG JEOL ARM 200F. Elemental composition from individual columns was retrieved from the corresponding HAADF signal with regression-based deep learning, U-Net [4]. The network was trained on simulated images, obtained with a multislice algorithm, and their corresponding elemental maps. The predicted elemental maps were compared to the ground truth STEM EDX profiles to assess the accuracy of our methods.

Results

Multislice simulations show that the aberration-corrected HAADF-STEM intensity of atomic columns is influenced by their composition, atomic configuration, and thickness. As these parameters are intertwined, a simple regression-based statistical analysis of the local variations of intensity is not enough to access the full underlying information. Therefore, we developed a deep learning approach with U-Net to be able to disentangle the complex relation of these parameters and predict the composition of atomic columns of the whole particle [Figure 1]. We show that for robust prediction the training dataset is of paramount importance and it needs to span across all possible configurations from the size, and shape, up to the composition and ordering of the atoms. Here, we

will present the implementation of this method for the study of chemically disordered and ordered CuAu NPs.

Conclusion

We have developed a deep-learning approach to predict the composition of bimetallic NPs at the atomic columns scale from a single HAADF-STEM image. Our method is adapted to high throughput and on-the-fly prediction which is suitable for in situ experiments. One other advantage of this method in comparison to EDX is the quantification of the composition without contaminating and damaging the NPs.

Poster Group 1

In recent years, there has been significant emphasis on enhancing lithium-ion batteries, crucial for electric vehicles, stationary storage technologies, and portable electronics. Their lifespan, particularly concerning capacity fade, is primarily influenced by electrode degradation and the deactivation of active materials. Another critical factor affecting battery lifespan and performance is the solid electrolyte interphase (SEI). Choosing the right analytical technique to study lithium-ion battery degradation and SEI properties is challenging due to the need for detailed structural and chemical composition data, including the distribution of light elements like lithium.
In this study, we utilized a unique combination of a Scanning Electron Microscope equipped with a Focused Ion Beam (FIB-SEM) and a compact Time-of-Flight Secondary Ion Mass Spectrometer (ToF-SIMS) [1,2] to explore the topography and chemical composition of both non-cycled and cycled lithium-ion battery electrodes. Our goal was to pinpoint degradation mechanisms, including parasitic chemical reactions [3]. By integrating SEM observations with ToF-SIMS and other analytical techniques such as Energy Dispersive X-ray Spectroscopy (EDS) [4] and Raman spectroscopy [5] on the same FIB-SEM system, we achieved comprehensive 2D and/or 3D characterization of lithium-ion battery materials. This approach offers insights into degradation processes, SEI properties, and electrode composition, enhancing our understanding of battery behavior at its core.

Morphological characterization of the electric field aligned block copolymers containing liquid crystal moiety

Monika Król[1], Isaac Álvarez Moisés[2], Janne Ruokolainen[1], Jean-François Gohy[2]
[1]Aalto University, Espoo, Finland, [2]Université catholique de Louvain, Louvain-la-Neuve, Belgium

Poster Group 2

Background incl. aims
Block copolymers (BCP) arose to be an interesting class of materials for the energy storage application. The conventional system consist of at least two covalently bound homopolymer blocks which are usually thermodynamically incompatible. It results in the phase separation at nanoscale, providing a wide array of self-assembled morphologies. Nanostructured periodically spaced discrete regions of different phases are characterized by respective properties similar to the pure homopolymers.
Solid polymer electrolytes (SPE) are composed of salt dissolved in a polymeric host. Here, BCPs are an attractive choice as a matrix due to the aforementioned qualities. Phase separation enables the possibility of merging intuitively contradictive functionalities in one material: solid state electrolyte with competitive to liquid alternative ionic conductivity, and mechanical stability. It is achieved by connecting the soft block which has ability to solvate the salt and favors ion transport, with rigid block, ensuring robustness. The length scale and type of the obtained microstructure can be swiftly tuned by careful molecular design of the polymer, including molecular weight, chain architecture, relative volume fractions, number and type of the constituent blocks. However, the phase separation itself is not the only requirement for BCPs sufficient performance as battery component. Due to the membrane thickness, the final structure is mostly isotropic and consists of multiple grains with different spatial orientation. This forces to consider not only intragrain ion transport, but also intergrain to fully understand the material performance as SPE. Liquid crystalline block copolymers (LC BCP) could be the pathway to manipulate the nanochannels orientation and ensure grain continuity. The addition of the mesogenic groups to the system allows to influence diamagnetic and dielectric constant properties of the materials, giving the promise of the highly ordered structures upon subjecting the material to external electric or magnetic fields. The main objectives of this study were to investigate the native hierarchical microstructure of LC BCP and to identify the self-assembled morphologies during solvent casting without and with the applied electric field. The analyzed material is composed of soft, ion conducting block and high glass transition temperature block with LC moiety. Both pristine and LiFTSI salt doped systems were structurally analyzed, as it was expected that addition of the ion to the matrix may change the system response to the external stimuli. As the next step, we examined alignment, grain size along with orientation and phase behavior of diblock copolymers while subjected to the applied (either alternating current (AC) or direct current (DC)) electric field during film casting. We also related both aligned and non-aligned electrolytes performance in terms of ionic conductivity to derive how the material morphology translates to its application as SPE.
Methods
Morphological characterization of the BCP was performed by means of SAXS (Small angle X-ray Scattering) and cryoTEM (cryogenic Transmission Electron Microscopy). SAXS provided statistical information of the BCP microstructure and alignment, whereas TEM provided more insight regarding

the grain size and magnitude of the long-range order. Ionic conductivity was investigated by impedance spectroscopy.
Results
Phase separated BCP of conventional morphologies were obtained, where the hierarchical self assembly at two length scales was recognized (LAM-in-HEX for salt doped and LAM-in-LAM for pristine). The addition of salt to the BCP caused phase transition from lamellar morphology to hexagonal, which can easily be explained by the swelling of the conducitive phase due to solvating of the salt and hence actively increasing its volume fraction. Salt/BCP composites casted in presence of electric field resulted in increase of the ionic conductivity of the system by magnitude. Samples casted in AC field were characterized by perpendicular alignment of BCP in regards to the applied electric field and small grain size, whereas samples casted in DC field showed similar tendency in direction of reorienting the grains. However, the domain size was significantly increased.
Conclusion
The spatial grain orientation and size of BCP containing liquid crystal moiety was manipulated both via in DC and AC field, resulting in enhancement of the longer-range order and grain continuity. The increase of the ionic conductivity can be directly correlated to beneficial influence of electric field on the nano-channels alignment, which was proven by means of SAXS and TEM. This work highlights the importance of designing the nanostructured system which is susceptible to electric field directed self-assembly for BCP to find wide application in the energy storage field.

Poster Group 2

Some nitrides can have a good potential for photocatalytic applications, notably for antibacterial applications. AlN combined with copper could be one of those. The action of photocatalytic materials being conditioned by the value and electrochemical positions of electronic bands, it is necessary to start by specifying precisely the nature of composing phases of the nitrides after their synthesis.

Although recent theoretical calculations [1] (using ab initio DFT –Density Funtion Theory- and thermodynamics) can predict the stable and metastable routes of bi-metal nitrides on high ranges of composition, nothing can replace the microscopic observation of materials experimentally synthesized by an out of balance technique such as reactive magnetron sputtering.

AlN-Cu(O) material was prepared under the shape of thin films by D.C. -Direct Current- reactive magnetron sputtering under synthesis conditions chosen for facilitating film nanostructuration. The progressive addition of a third element to the binary nitride AlN could either lead to solid solution AlCuN or to a material composed of AlN and Cu rich phases. Whereas, XRD –X-ray Diffraction- was systematically performed for preliminary checking, TEM-Transmission Electron Microscopy-investigation is an essential and ideal step to discriminate the actual microstructure of the films and to position the experimental synthesis route towards the limit of solubility of copper in the nitride. Electron diffraction patterns exploited through collection of rotational signals allowed the use of EVA software classically used by X-ray Diffraction experimentators to confront diffraction data to ICDD - International Center for diffraction Data- database. This work lead to the identification of phases. Chemical localization of copper could be detected by chemical mapping (STEM-EDS: 4DSTEM-ScanningTEM-), and crystallized zones could be tracked by diffraction and subsequent filtering (dynamical dark fields or numerical ones thanks to FFT –Fast Fourier Transform- of HR-High Resolution-TEM images).
The modification of the microstructure (change of nature of phases, their chemistry, crystalline structure, changes of morphology…) will be given as a function of the amount of copper used to elaborate the samples.

FRET and TIRF microscopy for single molecule characterisation of synergistic antimicrobial peptides in artificial bilayers

Miss Hannah Baird[1], Dr William David Jamieson[1], Dr Oliver Castell[1]
[1]School of Pharmacy and Pharmaceutical Sciences, Cardiff University, Cardiff, United Kingdom

Poster Group 1

Background incl. aims
Droplet Interface Bilayers (DIBs) function as artificial membrane models for electrical and optical measurements [1]. This project uses total internal reflection fluorescence (TIRF) microscopy and Förster Resonance Energy Transfer (FRET) in DIBs to investigate the dynamics of peptides and proteins interacting with membranes. Membrane pores have vital roles in neuronal and cardiac signalling, as well as in the mechanism of certain antibiotics.
The lytic antimicrobial peptides Magainin 2 (Mag2) and PGLa, part of the immune system of the African clawed frog (Xenopus laevis), have a synergistic antimicrobial effect when applied to Gram-negative bacteria in a 1:1 ratio. The aim of this project is to uncover the mechanism behind this synergy at the membrane level.
Methods
When an agarose surface and a droplet are submerged in a lipid/oil environment, a monolayer spontaneously self-assembles at the aqueous-oil interface. DIBs form when the lipid monolayers make contact. The protein or peptide of interest, contained within the droplet, can then form pores in this bilayer. Ions flux through these pores, and this pico-ampere current can be measured by electrophysiology. Simultaneously, TIRF microscopy is used to observe ion flux by illuminating the fluorescent calcium binding dye, Fluo-8, with totally internally reflected laser light.
Alternatively, the single-molecule dynamics of fluorescently tagged peptides on the membrane surface can be investigated. By tagging PGLa with a donor fluorophore and Mag2 with an acceptor fluorophore, single molecule FRET with TIRF microscopy can act as a so called "molecular ruler"[3]. When the donor fluorophore is being excited and is less than 10nm from the acceptor fluorophore, a non-radiative energy transfer can occur from the donor to the acceptor, causing the acceptor to fluoresce. This offers distance-dependent insights into the interaction and dynamics of Mag2-PGLa. The formation of heterodimers and higher order structures is of particular interest in these experiments.
Results
Spatiotemporal data from electrophysiology and TIRF experiments has revealed that the Mag2-PGLa pore is a highly dynamic pore that visits multiple conductance states. Single molecule FRET data of Mag2 and PGLa has been obtained for the first time, confirming the existence of Mag2-PGLa heterodimers. Data suggests that very few Mag2-PGLa heterodimers exist at any time. These experiments have allowed better understanding of the interaction of the peptides with one another and with the membrane, thus shining a light on the mechanism behind the Mag2-PGLa synergy.
Conclusion
DIBs, TIRF microscopy, and single-molecule FRET have been employed to investigate the dynamics of Mag2 and PGLa interacting with one another and the membrane. Experimental results reveal the highly dynamic nature of the Mag2-PGLa pores and confirm the existence of Mag2-PGLa heterodimers. These findings provide valuable insight into the molecular mechanism driving the Mag2-PGLa synergy. Future work will focus on achieving pseudo-simultaneous pore-imaging, electrophysiology, and FRET of Mag2 and PGLa.

Background

The fabrication of halide perovskite-based heterostructures represents a promising avenue in the field of optoelectronics due to their unique properties arising from the heterointerface between a perovskite domain and a domain of another material [1]. When CsPbBr3 is interfaced with a compound with a different band gap, the heterointerface acts as a barrier for charge carriers, affecting their transport properties and recombination dynamics, which consequently leads to significant changes in electronic structure [1, 2]. Such tunable optical and electronic properties, together with increased structural rigidity introduced into the perovskite lattice, allow for the development of novel optoelectronics with improved performance and functionality compared to the standalone CsPbBr3-based devices. Nano-scale understanding of the structural and compositional characteristics of such heterostructures within the two domains as well as across the interface plays a pivotal role in the design and engineering of advanced optoelectronic devices. Herein, we conduct a study to characterize the structural features in CsPbBr3/AgBr heterostructures obtained via a colloidal synthesis method [3] by using advanced electron microscopy techniques at the nanoscale.
By combining HRSTEM, hyperspectral imaging, and harnessing advanced data treatment approaches, we sought to explore the structure, morphology, and subtle compositional changes at the heterointerface as well as the crystal domains of such beam-sensitive materials for optimization of optoelectronic performance.

Methods

The heterostructures were prepared for TEM analysis by dispersing the powders in hexane and then drop-casting them onto Cu grids with a carbon support film. Preliminary investigations of the nanocrystals were carried out using an image-Cs-corrected JEOL JEM-2200FS with a Schottky emitter gun operated at 200 kV, equipped with a Bruker XFlash5060 silicon-drift detector (SDD) for energy-dispersive X-ray spectroscopy.
To visualise the crystal lattice of the heterostructure domains, scanning transmission electron microscopy (STEM) images were acquired using Annular Bright Field (ABF) and High-Angle Annular Dark Field (HAADF) detectors on a probe-aberration-corrected ThermoFisher Spectra 300 S/TEM microscope with an X-FEG source, operated at 300 kV. For precise structural imaging, a drift correction frame integration technique in Velox was used to minimize image distortions. Elemental distribution maps and line scan profiles at high spatial resolution were recorded by collecting Energy-Dispersive X-ray (EDX) signals on a Dual-X system, which comprises two EDX detectors positioned on

either side of the specimen, with a total collection solid angle of ca. 1.76 sr, allowing for efficient signal acquisition from nanocrystals.
Furthermore, we combined a machine learning-based segmentation algorithm with hyperspectral EDX datasets to obtain a comprehensive statistical understanding of the chemical composition of the nanocrystals.

Results

STEM-HAADF images showed different possible morphologies for the nanocrystal heterostructures. We identified well-defined heterostructures with a sharp heterointerface in lateral projection, composed of 2 structural domains. EDX elemental maps revealed that Ag was localized in the higher contrast domains correlating with a uniform distribution of Br, which was consistent with the retention of AgBr composition in such domains. The lower contrast domains contained predominantly signals from Cs, Pb, and Br, corresponding to the CsPbBr3 according to the quantification of the compositional EDX spectra. In these heterostructures, we also noted the segregation of metallic Ag within the structural features, which we ascribed to local electron beam damage.
In addition to intact cubes of CsPbBr3 nanocrystals, CsPbBr3/metallic Ag as well as non-stoichiometric silver bromide nanostructures, compositional maps additionally showed the formation of potential heterostructures with a spherical morphology in which Ag was mainly localized at the nanocrystal edges, producing a core-shell structure. We also characterized nanocrystals preserving the superimposition of AgBr and CsPbBr3 stoichiometries without a clearly defined interface. However, differentiation of such potential heterostructures from other nanocrystals in this nanosystem is difficult due to similarity in elemental composition, resulting in insufficient contrast in HAADF images. While the analysis of individual particles by hand is often inconclusive, we apply machine learning-based routines to segment nanoparticles in hyperspectral images on large fields of view, followed by quantification of composition for each, enabling us to obtain operator-agnostic statistical insight into the composition of nanocrystals in this complex system.
Furthermore, by combining ABF and HAADF imaging, we were able to visualise atomic columns of light and heavy elements in CsPbBr3/AgBr lateral heterostructures simultaneously, providing crucial details about the crystal lattice structure and the interface.

Conclusion

Through the combined use of electron microscopy techniques, including imaging and spectroscopy, we achieved a comprehensive understanding of the structural and compositional characteristics of heterostructures formed via the incorporation of Ag-precursor during colloidal synthesis of lead halide perovskites – in particular CsPbBr3 – at nanoscale resolution. This spatially-resolved structural information, together with high-throughput analysis of compositional hyperspectral EDX datasets using machine learning-assisted methods, contributes to the efficient interpretation of unique optical properties such as tunable band gap, new charge carrier transmission modes, and high photoluminescence quantum efficiency in such materials for application in high-performing optoelectronic perovskite devices.

A novel pipeline to elucidate the adaptation response to the G2/M DNA damage checkpoint

Doctor Ambra Dondi[1], Ms. Sara Spreafico[1], Dr. Simona Rodighiero[1], Dr. Rosella Visintin[1]
[1]Department of Experimental Oncology - European Institute of Oncology IRCCS , Milano, Italy

Poster Group 1

Background
The DNA damage checkpoint (DDC) is a surveillance mechanism evolved to preserve genome integrity in response to DNA lesions. Checkpoints halt cell cycle progression to provide cells with the opportunity to repair the damage before dividing. When the DNA damage is successfully repaired, the checkpoint is satisfied and cells can resume the division in a process called checkpoint recovery. Conversely, when the DNA damage is irreparable, cells eventually die. Possibly, a few cells reenter the cell cycle with damaged DNA. This process, known as adaptation to the DDC, poses a threat to genomic stability, as daughter cells can accumulate genomic aberrations. Indeed, evidence exists that adaptation contributes to genomic instability and may drive the selection of therapy-resistant cells in oncology patients. Despite the dangerous nature and the clinical relevance of the process, adaptation is largely overlooked and has not been investigated in depth, likely because of the difficulty in experimentally tackling the question. Most commonly, adaptation is explored either by assessing the phosphorylation status of DNA damage checkpoint proteins, detectable solely by Western blot analysis on bulk population. Since adaptation is an asynchronous process (cells undergo adaptation with their own kinetics) and partial (only a fraction of the population adapts), we set to investigate adaptation in single cells by live-cell imaging measuring cell cycle parameters, with the ultimate goal of enhancing the reproducibility and reliability of adaptation studies.

Methods
We investigated adaptation to the G2/M DNA damage checkpoint in Saccharomyces cerevisiae, a highly amenable microorganism, whose genome is easily manipulated. Since in yeast checkpoint activation blocks cells in metaphase by preventing sister chromatid separation and segregation, via inhibition of cohesin cleavage and spindle elongation, respectively, these two processes can be considered the cell cycle events defining adaptation. To follow cohesin and spindle elongation, the Scc1 subunit of the cohesin complex was tagged with GFP (SCC1-yEGFP) while alpha-tubulin was tagged with the mCherry protein (mCherry-TUB1). In our experimental setup, cells are synchronized in G1 and released in presence of unrepairable DNA damage in a microfluidic chamber for live imaging where cells are immobilized and continuously supplemented with fresh media. Images are taken every 7.5 minutes for 20 hours. To analyze the resulting movies, we developed a Python script to automatically segment and measure the mitotic spindle for each cell at each timeframe, as well as to measure the SCC1 signal intensity. Anaphase onset (i.e., adaptation) is defined as the first timepoint where either reduction of the SCC1 signal or spindle elongation was observed. We applied our script to all imaged cells, gaining information about the timing of adaptation for each cell, and the overall percentage of adapting cells in the population.

Results
As a proof of concept, we analyzed wild-type (WT) cells (i.e. adaptation-proficient), as well as cells carrying mutations known to result in an adaptation-defective phenotype, including the well-characterized cdc5-ad mutant. In WT cells, we were able to discriminate adapting cells from arrested

ones in the heterogeneous population, while in cdc5-ad mutant cells, we detected only metaphase arrested cells, as expected for an adaptation defective mutant. Interestingly, certain mutants previously classified as adaptation-defective in the literature were discovered to be capable of adaptation but unable to progress through subsequent stages of the cell cycle. These data, alongside highlighting the reliability of our approach in discriminating checkpoint-arrested cells from those that escaped the checkpoint surveillance in the whole population, strongly support the idea that assessing cell cycle progression is key to understanding the molecular bases of adaptation.

Conclusion
Given the limits associated with both the experimental procedures in use and more generally with population-based experiments, we propose to investigate adaptation by live-cell imaging monitoring cell cycle parameters. Taken together, by coupling the power of live-cell imaging, which allows to investigate dynamic processes at a single-cell level, with the power of cell cycle parameters, which provide a clear picture of cellular behaviors, could provide direct insights into the molecular processes underlying adaptation and survival in cells that divide with damaged DNA, thus contributing to making the study of adaptation reproducible and reliable.

Differentiation of phases in phase change memory materials using 4D STEM

Xue Bai[1], Dr. Janghyun Jo[1], Prof. Dr. Rafal E. Dunin-Borkowski[1]
[1]Ernst Ruska-Centre for Microscopy and Spectroscopy with Electrons, Forschungszentrum Jülich, Jülich, Germany

Poster Group 2

Background incl. aims
With the rapid development of modern information technology, the novel approaches for storing and processing large volumes of data are being developed, from general concepts such as memory in computing, multi-level storage and neuromorphic computing to specific techniques such as new designs of circuits and storage devices. Different electronic devices are under development, such as magnetoresistive random access memory, resistive random access memory, phase change memory (PCM) and ferroelectric memory. PCMs that are based on chalcogenide materials are promising choices for data storage because phase transitions between amorphous and crystalline phases are quick and efficient. Such phase transitions result in changes between high and low resistance states, which correspond to “0” and “1” logic levels in data storage, respectively. They are also promising for realizing multi-level storage. However, the resistance of the amorphous phase in a PCM cell can drift over time. It is important to determine the underlying mechanism of resistance drift and to develop methods that can be used to differentiate between local crystalline and amorphous phases efficiently. 4-dimensional scanning transmission electron microscopy (4D STEM) enables structural identification at nm resolution. In this project, new analysis methods based on 4D STEM are applied to phase identification in phase change materials.
Methods
With the help of a fast pixelated detector (EMPAD), full 4D STEM datasets of diffraction patterns were collected as the electron beam was scanned across areas of interest. Approaches based on fluctuation electron microscopy (FEM) and radial Fourier analysis (RFA) were applied to analyse the datasets to create radial spectra from the diffraction patterns. Multivariate statistical analysis based on principal component analysis and non-negative matrix factorization was used to distinguish between different phases in the PCM materials, allowing the creation of maps showing the distribution of amorphous and crystalline phases.
Results
The approach was applied to study crystalline nanomaterials on amorphous layers to differentiate between different phases. First, test samples were studied to find optimal experimental parameters. The developed method was then applied to the PCM material Ge2Sb2Te5 (GST). Crystalline clusters in the amorphous GST layer could be distinguished using both FEM and RFA based methods. The two methods were compared with each other. RFA was found to have better robustness to noise.
Conclusions
We have developed a method that can be used to differentiate between amorphous and crystalline phases in PCM materials by combining 4D STEM with FEM and RFA. Both FEM and RFA could distinguish successfully between amorphous and crystalline phases. However, RFA was more robust to noise than FEM. The two methods are complementary and can be used alongside each other to study unknown phase change materials, ultimately during switching.

Imaging-based methods to identify prognostic and predictive biomarkers for Hereditary Spastic Paraplegia

Phd Student Gaia Fattorini[1,2], Researcher Valerio Licursi[1], Professor Filippo Maria Santorelli[3], Professor Gabriella Silvestri[4], Professor Carlo Casali[5], Researcher Cinzia Rinaldo[1], PhD Francesca Sardina[1]
[1]Institute of Molecular Biology and Pathology (IBPM), Consiglio Nazionale delle Ricerche (CNR), Rome, Italy, [2]Department of Biology and Biotechnology "Charles Darwin", Sapienza University of Rome, Rome, Italy, [3]IRCCS Stella Maris, Pisa, Italy, [4]UOC Neurologia, Fondazione Policlinico Universitario 'A. Gemelli' IRCCS, Rome, Italy, [5]Department of Medico-Surgical Sciences and Biotechnologies, University of Rome Sapienza, Latina, Italy

Poster Group 1

Background
Hereditary spastic paraplegias (HSPs) are rare motor neuron diseases characterized by axonal degeneration involving the lateral corticospinal tracts. The most common is caused by haploinsufficient mutations in the SPG4 gene, which encodes spastin, a microtubule (MT) severing ATPase, that controls cytokinesis, endosomal traffic, lipid droplets (LDs) homeostasis, and axonal transport. Clinically, HSP-SPG4 age of onset and the severity of symptoms are strongly variable even among individuals belonging to the same family. Given this heterogeneity, it is important to identify prognostic biomarkers. To date, no effective disease-modifying therapies are currently available, but approaches based on drugs counteracting dysfunctional mechanisms or spastin-elevating treatments are emerging, so it will be crucial to identify biomarkers that can help to monitor the effects of spastin recovery treatments.
We have developed an automated, simple, rapid, and non-invasive cell imaging-based method to quantify the organization of the MT-cytoskeleton. By using this method, we demonstrated that the dcnc-parameter, measuring the distance between cell and nucleus centroids, is able to distinguish HSP-SPG4 from healthy donor (HD) lymphoblastoid cell lines (LCLs) and peripheral blood mononuclear cells (PBMCs).
We are now extending the dcnc-based method to a larger cohort of SPG4 patient cells to evaluate its sensitivity and specificity in relation with molecular and clinical patient features and to detect the effects of different spastin-elevating drugs. Additionally, we are also focusing on other subcellular components affected by spastin mutations, such as LDs.

Methods
The study included 13 HDs and 18 SPG4 patients with different types of mutations (12 truncating mutations and 6 missense mutations). Cell image analysis was performed using PBMCs or LCLs stained with specific antibodies (anti-β-tubulin-cy3 for MT-cytoskeleton) and dyes (Bodipy™ 493/503 for LD and Hoechst for Nucleus). Automated image acquisition was achieved by using the inverted Nikon Eclipse-Ti microscope and the JOBS module of NisElements 5.11 software to obtain a file containing more than 50 images and 500 cells related to each single sample. The acquired images were then analyzed using Cell Profiler 4.3 software, with an ad hoc designed pipeline that recognizes cellular compartments using thresholding segmentation and measures several parameters, including “dcnc” and “number of LD in each cell (nLD)”.

Results

We performed correlation analysis between the “dcnc” parameter and molecular patient features, showing that SPG4 cells from patients with missense mutations have higher “dcnc” than those with truncating mutations. Correlations with clinical features, such as the age at onset of the disease or the Spastic Paraplegia Rating Scale (SPRS) score, are ongoing.
By assessing the effect of three different spastin-elevating drugs, we observed that dcnc-based method is able to detect the reduction of MT defects induced by spastin recovery in cells from SPG4 patients carrying truncating mutations. Similar analyses on cells carrying missense mutations are ongoing.
We have implemented our pipeline to evaluate other cellular components, such as LD, so it automatically recognises the staining of the nucleus, cytoskeleton and LD, in our cells. By using this tool, we have analysed the parameter “nLD”. Correlation analysis between dcnc and “nLD” was performed, showing a positive correlation in SPG4 patients.

Conclusions and future perspectives
Our analyses revealed that the dcnc-based method is able to sense the effects of spastin elevating drugs in cells from SPG4 patients carrying truncating mutations, suggesting a predictive role. Now, we are performing correlation analyses among molecular and clinical patients features and the “dcnc” and “nLD” parameters to evaluate whether our method might have prognostic value. These results will open the possibility to identify new prognostic and predictive tools for HSP-SPG4.

Poster Group 1

Background incl. aims
Nanoscale 3D imaging techniques, such as electron tomography, are increasingly essential in material science and engineering. Extracting quantitative information from these techniques requires robust processing methods. This study presents several approaches for evaluating magnetic properties, such as magnetic shape anisotropy energy and demagnetization factors, as well as of magnetic nanoparticle ensembles using electron tomography data.
Methods
We extend a previously developed in-house software for processing 3D data to retrieve quantitative morphological information about nanoparticle systems [1]. Our focus is on iron oxide (magnetite) nanoparticle systems prepared via coprecipitation methods. Transmission electron microscopy (TEM) tomographic series were acquired using a JEOL 2100 TEM, and the reconstruction was performed using GENFIRE software. The raw 3D data is segmented with an in house developed software and the retrieved quantitative morphological information on nanoparticle size and shape is saved in a suitable format for use by the Object Oriented Micro Magnetic Framework (OOMMF) [2].
Results
The micromagnetic simulations are employed to obtain several magnetic features including demagnetization energy maps of the nanoparticles as well as a statistical perspective of magnetic shape anisotropy energy and demagnetization factors of the studied system. By comparing magnetic information obtained from OOMMF simulations with approximation based morphological data, we seek a better understanding of how morphological features influence the magnetic phenomena.
Conclusion
Morphological information, such as size and shape, coupled with magnetic parameters like demagnetization factors and shape anisotropy energy, holds significant importance in diverse fields such as gas sensing [3], catalysis, spintronics, and magnetic hyperthermia-based therapies [4]. By integrating electron tomography with micromagnetic simulations, this study aims to advance our understanding of the intricate relationships between morphology and magnetic behavior in nanoparticle systems.

Background incl. aims
Creep cavitation is an important degradation mechanism in metal alloys at high temperatures, such as in aerospace engines, gas turbines and nuclear fission and fusion reactors. During operation, metal components such as 316H stainless steel boiler headers are subjected to elevated temperatures and stresses, particularly close to weldments and geometrical features [1]. Over extended service lifetimes, these temperatures and stresses result in vacancy and dislocation movement that can gradually accumulate at microstructural features in the alloy, resulting in the formation of creep cavities that can develop into cracks and eventual failure of the component. This mechanism starts at the microstructural level, and to understand the process, it is important that the evolution of creep cavitation from nucleation to growth is characterized using advanced microscopy.
Previous work [1] has shown that in ex-service material after 65,000 hours in service in an advanced gas-cooled nuclear reactor (AGR) at 490°C–530°C, the heat-affected zone close to a weld in a 316H boiler header became extensively cavitated as a result of creep cavitation. Detailed microstructural analysis using scanning electron microscopy (SEM), electron backscatter diffraction (EBSD) and transmission electron microscopy (TEM) showed that cavities in this material were correlated with precipitation on the grain boundaries of the steel, most significantly at the interface between $M_{23}C_6$ carbides and ferrite which had formed during thermal ageing. This detailed understanding of the interaction between microstructure and creep cavitation is essential to determine component lifetimes and design new creep-resistant materials.
However, to fully understand the interactions between creep damage and microstructure, it is beneficial to characterize this interaction over larger regions of an affected material, whilst retaining the high resolution structural, crystallographic and elemental information of individual microscopy images. In this work, we present a new methodology that combines these techniques with image processing to provide spatially-identified datasets of creep cavities, precipitation and grain structure with nanometre resolution, but across millimeter length scales of a component.
Methods
Type 316H austenitic stainless steel material was removed from a boiler component, initially service-exposed for 65,000 hours at 490°C–530°C in an AGR. Material was extracted away from high stress regions of the component and was characterized to ensure it had thermally-aged microstructure but no existing creep cavitation. The material was subsequently machined into a notched creep specimen with a gauge length of 40mm, a notch radius of 6mm and a notch acuity of 5. The creep specimen was subjected to 25 cycles of tensile stress relaxation at an initial net section stress of 390 MPa and a temperature of 550°C, and then allowed to relax in pure strain control. After testing, the crept specimen was sectioned axially, ground and polished using diamond slurry and vibropolishing to an EBSD-quality mirror finish.
An area of 3.2x1.2 mm across the centre of the sectioned specimen around the notch was imaged using 162 backscattered electron (BSE) images with a 30% overlap between neighbouring images

using a Zeiss SigmaHD FEG-SEM, as well as EBSD and FIB-XeF_2 imaging across the same region. The FIB-XeF_2 imaging approach used a ThermoFisher Scios2 focused ion beam instrument, and utilized a XeF_2 gas injection system to enhance contrast between the metal matrix and precipitates, as described in [2]. The software package Dragonfly (Object Research Systems Inc, Montreal, Canada) was used for post-image processing, segmenting the BSE images to identify cavities and the FIB-XeF_2 images to identify precipitates using an Otsu threshold selection methodology [3]. EBSD data was corrected using an in-house Matlab script and all three datasets were then overlaid to enable correlation between the cavity, precipitate and grain boundary information across the entire 3.2x1.2mm region to be characterized statistically. Further detail on the methodology can be found in [4].

Results

The graphic shows an example of this correlative workflow. Figure (a) shows a stitched FIB-XeF_2 image of a 3.2 mm x 1.2 mm region of the creep specimen, with the notch at the left of the image. The stiched image comprises 32 individual FIB-XeF_2 images, which along with the 162 BSE images were image processed to identify creep cavities, cracks and precipiates by grayscale contrast and morphology. Two example frames with image processing are shown in (b) and (c), where yellow represents identifed $M_{23}C_6$ carbide precipitates (verified by transmission electron microscopy diffraction) and blue represens creep damage. (d) shows the statistical overlay of the identified precipitates in yellow with the grain boundary locations obtained by EBSD in blue, across the entire sampled region. Similar maps of damage were also obtained. The statistical analysis of these data described in full in [4] showed that damage showed very little correlation with grain-to-grain differences in Schmid factor (which many computational models of creep assume to be a key factor in damage location), but in this material precipitation, grain boundary angle and localised strain (as indicated by the kernal average misorientation in the EBSD data) showed much clearer correlation with damage, indicating that in this material the trapping sites at grain boundary carbide precipitates are the primary initation sites for creep damage.

Conclusion

Creep cavitation is a complex degradation mechanism, which starts at the atomic or nanometre scale and over extended times can build to failure of entire components. The methodology presented here shows the effectiveness of advanced microscopy combined with image processing to statistically correlate microstructural features with damage locations in crept material, enabling much better understanding over large areas of the contributing factors to this process.

Poster Group 1

Lithium-ion batteries (LIBs) have dominated the market as preferred energy storage system since their commercialization. However, there is growing need to improve the system in order to accommodate the advancements in different sectors, with electric vehicles being the main driving force. Electric vehicles require high energy and power density, which translates to greater distances traveled and faster charging, respectively. In this respect high capacity and voltage cathodes are a promising path forward, and Li rich oxides (LROs) are amongst the most promising cathode materials for increasing efficiency of LIBs. In addition, the most widely studied composition of LROs, $Li_{1.2}Mn_{0.54}Co_{0.13}Ni_{0.13}O_2$, reduces the amount of nickel and cobalt, making it more environmentally friendly and less expensive. However, these cathode materials suffer from severe drawbacks of voltage decay, low initial coulombic efficiencies, transition metal migration and dissolution, oxygen loss etc. In order to target and resolve these issues, it is first important to understand the pristine structure of LROs, which is still under debate in the scientific community. There are two main hypotheses for its structure i.e., nano-domains of two phases or solid solution of a single phase. The two phases correspond to a rhombohedral $LiMO_2$ phase (space group R-3m) and a monoclinic Li_2MnO_3 phase (space group C2/m). These phases share a similar oxygen lattice, which increases the difficulty in distinguishing them from one another. As such, further studies on the structural and electrochemical properties of LROs are needed to reach its wide-scale commercialization.
In this study, we synthesized a series of LRO samples with the composition, $Li_{1.2}Mn_{0.54}Co_{0.13}Ni_{0.13}O_2$, through sol-gel synthesis. We used two different chelating agents; citric and oxalic acid, and the resulting foam was calcinated at two temperatures; 850°C and 900°C. We recorded X-ray diffraction (XRD) patterns at ~15keV (0.8265 Å), over the 2θ range of 8-60 degrees, at the MCX beamline at Elettra Synchrotron, Italy. The powder samples were measured in borosilicate glass capillary tubes (0.3mm diameter) in transmission mode. We analyzed the particles using a JEM ARM200CF, probe Cs corrected scanning transmission electron microscope (STEM), at 80kV. A GIFQuantum ER dual-EELS system (GATAN-AMETEK, Pleasanton, USA), was used for electron energy loss spectroscopy (EELS). Figure 1(a) shows the XRD pattern, in which the peaks correspond to that of a rhombohedral phase, excluding the weak reflections between ~11-15 degrees. These weak peaks correspond to a monoclinic phase and are highly asymmetric. The asymmetric peak shapes are related to the presence of stacking faults in the material. Figure 1(b) shows the STEM-High-angle annular dark-field (HAADF) image of the particle and the corresponding EELS spectra at O K-edge and Mn L-edge. Three spectra for each elemental edge are shown, moving from the center to the edge of the particle, as indicated in Figure(b). The white line of oxygen K-edge is seen to vary with depth; increasing towards the center of the particle. This change can be attributed to the change in valence state of the surrounding transition metals. On the Mn L-edge spectra, more prominent on the inner-most spectra, a shoulder appears which is similar to that seen in pure Li_2MnO_3.

By combining XRD and EELS in this study, we have shown the need to complement bulk probing techniques with local probing techniques, respectively. The weak reflection for the monoclinic phase in the XRD pattern make data analysis difficult but local EELS spectra indicate the presence of different environments within a single particle. Our findings contribute to a deeper understanding of the pristine structure of LROs and highlights the need for multiscale characterization.

Poster Group 2

Background
This work is focused on our recent improvements of 4D-STEM/PNBD method (Four-Dimensional Scanning Transmission Electron Microscopy/Powder NanoBeam Diffraction) [1-3], which provides a user-friendly way to use a modern SEM as a fast powder electron diffractometer. SEM must be equipped with a 2D-array detector of transmitted electrons (pixelated STEM detector). The pixelated detector yields standard STEM/BF images in the form of a standard scanning matrix. Moreover, each position within the scanning matrix is a 2D nanobeam diffraction pattern, which is captured thanks to the 2D-array of pixels within the pixelated detector. In 4D-STEM/PNBD method, the sum of the post-processed individual diffraction patterns is then used to obtain powder diffractogram.
The reduction of the 4D-STEM dataset to 2D-powder diffractogram and eventually to its 1D-radially averaged profile can be automated by means of our open-source Python packages STEMDIFF and EDIFF. The latest available versions support fast parallel processing on multiple cores, user-friendly Jupyter notebook interface and independence from any third-party software.
The current development aims to improve individual diffraction patterns so that even samples usually very challenging to study (such as specimens with high amorphous background and low diffraction power) can be processed satisfactorily. The 4D-STEM-in-SEM datasets of these difficult samples can be quite challenging to process and get the diffraction patterns that could compete with the quality of standard TEM/SAED diffractograms. Conventional image enhancement methods have failed because they cannot remove the background and noise without affecting the diffraction intensities. Therefore, deep learning methods were used to develop a model that would sufficiently suppress unwanted image deterioration. In this contribution, we introduce a U-Net Autoencoder (U-NAE) for noise and background removal in 4D-STEM-in-SEM complex datasets.
Methods
As the ideal target 4D-STEM-in-SEM data (clean, noise- and background-free diffractograms) were not available, an artificial dataset must have been simulated. The synthetic target data were derived from actual datasets of several different crystals (network input data) using multi-scale filtering, image transformations, thresholding, and manual corrections (a lengthy and inefficient procedure). After collecting the paired dataset (input/target data), each was split into 3 sub-datasets – 60% for training, 30% for validation and 10% for testing. Then finally, an architecture of a denoising neural network could have been designed. Given the limited dataset, the convolutional U-Net architecture was a suitable choice because it can find key features in the data from which it reconstructs the desired output. It consists of three parts – encoder (contracting path which captures contextual information), bottleneck (low-dimensional representation of the input), and encoder (extending path generating a clean image from the bottleneck representation).
The U-NAE encoding part consists of 3 blocks of convolutional layers that reduce the input image of size 256x256x1 to a feature map of size 32x32x64. This bottleneck-representation is then passed through the decoding part (3 blocks of convolutional layers which also work with the information

from the encoder transferred by skip connections and reconstruct the data to its original resolution). At the end, there are 3 fully-connected convolutional layers that fine-tune the output.
The model was trained using ADAM optimizer with mean squared error (MSE) as the criterial function. Additional metric to monitor for model performance assessment was mean absolute error (MAE). The validation loss after each epoch was the key score when assessing the network's learning state, as it is indicative of its generalization capabilities and how well it performs on newly introduced data. Training data was fed to the network in batches of 32 images, and the learning rate was adapting during training as it was designed to gradually decrease when approaching the global optimum.
Results
During training, the model's validation MSE dropped from 8135.73 to 25.31, and the MAE from 23.58 to 2.47. The model with the lowest validation loss was saved to avoid possible overfitting in the final training epochs. It was then tested on a test dataset that had not yet been introduced to the network and has shown to improve the quality of datasets acquired by our 4D-STEM-in-SEM technique, even for the challenging samples. Clear evidence of the functionality of U-NAE is shown in Fig. 1, where even for the most primitive method of obtaining a diffractogram (simple summation) the improvement in the quality of the output image is clearly visible, as well as the noticeable improvement of the radial distributions of the diffractograms.
Conclusion
The U-NAE has been proven effective on various challenging datasets, yet limitations arise in handling heavy noise levels, potentially leading to unsatisfactory results. Future efforts will prioritize optimizing the U-NAE architecture to address these challenges and explore alternative training strategies to enhance its performance. Incorporating domain-specific knowledge may further broaden its applicability in material science research. In addition, further work to refine the simulation of the target data could also improve model performance.

Anomalous effects of strain in selected area diffraction patterns due to boron doping in silicon

Miss Kaviyadharshini Dhamotharan[1], Dr Buddhika Mendis[1]
[1]Durham University , Durham, United Kingdom

Poster Group 2

Semiconductors have a significant impact on our lives due to their role in the fabrication of electrical devices. The sensitivity of its conductivity to temperature, illumination, magnetic field, and minute amount of impurity atoms make semiconductors one of the most important materials for electronic applications. It is important to study defects since it can significantly alter the electrical properties of a semiconductor. Microscopic lattice defects such as point defects, dislocations induce local electronic density of state changes and distort the surrounding lattice structure. The effect these interruptions of the crystal lattice have on the scattering of photons or charged particles such as electrons can be used to study the defect.

The effect of static atomic displacements associated with misfitting boron atoms in silicon (B-Si) has previously been studied using high angle annular dark-field (HAADF) imaging by Perovic et al (1). It was found that the HAADF contrast of the boron doped silicon (B-Si) layer is brighter than elemental silicon (Si), despite the decrease in atomic number. This could be due to static atomic displacements arising solely from the displacement of Si atoms from their equilibrium lattice sites adjacent to substitutional boron atoms (2). This type of contrast is called Huang scattering contrast. In addition, high concentrations of boron can also modify the phonon properties of the material (3), which affects the thermal diffuse scattering (TDS). Perovic et al. (1) had attributed the anomalous HAADF contrast to TDS, although the effects of Huang scattering were not considered.

We have used transmission electron microscopy (TEM) to analyse strain around point defects in silicon highly doped with boron, i.e., degenerate doping (B-Si). Fig 1 shows selected area diffraction patterns (SADPs) of elemental Si and B-Si from [100] and [110] zone-axis orientations obtained at room temperature. For [100] Si (Fig 1a) there is streaking arising from (largely acoustic) phonon scattering along [010] and [001] crystallographic directions around the Bragg reflections. The halo ring pattern around the unscattered beam is thought to be due to FIB specimen preparation artefacts. For [100] B-Si (Fig 1b), the streaking is reduced, which could be due to the smaller thickness of this sample. However, diffuse scattering in the form of a cross-shaped pattern between the unscattered and 040 Bragg beams is evident (dashed lines in Fig 2b). The diffuse scattering is not observed for elemental Si, suggesting modification of phonons due to boron doping. This is also consistent with our Raman results, which shows significant peak broadening upon degenerate doping. It should be noted that anomalous low angle scattering due to boron was not observed in other zone-axis orientations, such as [110] (Figs. 1c and 1d).

Radial intensity profiles from Si and B-Si are obtained from the [100] and [110] zone-axis diffraction patterns (Fig 2). The total intensity has been normalised for a direct comparison. For [100] the (t/□) specimen thickness ratio, measured using electron energy loss spectroscopy, was 0.75 for B-Si and 1.01 for Si. Therefore, at high scattering angles the intensity for Si should be higher than B-Si due to the larger atomic number (Z) and specimen thickness. However, the opposite trend is observed (Fig 2a), which is also consistent with the previous results of Perovic et al. [1]. The anomalous high angle scattering is also observed for [110], although its effects is smaller (Fig 2b; the (t/□) ratio for the two samples were similar, i.e., 0.71 for B-Si and 0.67 for Si).

The diffraction intensity at high scattering angles is due to localised scattering, and therefore we expect the intensity to be dominated by Huang scattering from the boron point defect atoms. On the other hand, the diffuse scattering in the zero order Laue zone pattern is likely to be dominated by phonons, and here we find evidence of changes in the phonon configuration due to boron doping. We acquired diffraction data of B-Si under liquid nitrogen cooling, which suppresses TDS but not Huang scattering, to investigate if the diffraction intensity at high scattering angles is solely due to Huang scattering, as boron doping in silicon induces local vibrational modes above the optical mode frequency of 16 THZ (4). Fig 3 illustrates the SADPs alongside a comparison plot detailing the radial intensities of B-Si at room temperature and -173 degrees Celsius. Due to nitrogen cooling, phonon modes above the frequency of 2.07 THz were supressed, which includes the TDS due to local phonon modes from boron doping. The radial intensity of B-Si at higher scattering angles in Fig 3b did not decrease; rather, it slightly increased upon cooling. This suggests that the intensities at high scattering angles were not predominantly contributed by TDS, as most of the phonon modes were suppressed. Hence, the intensity at higher angles is more likely to be contributed by Huang scattering, given that the vibration modes contributing to TDS were supressed.
In summary, the effect of strain due to point defects has been studied in boron doped silicon using SADPs from [100] and [110] zone axes. Anomalous diffuse scattered intensity is observed at both small and large scattering angles. It is concluded that boron gives rise large angle to Huang scattering due to the intrinsic strain in the lattice, as well as altering the phonon configuration, and hence thermal diffuse scattering.

Poster Group 2

Background
As Moore's Law starts to stagnate and the continuous pursuit of smaller and faster devices persists, there is a growing need for new approaches to further push the boundaries of nanofabrication. The modification and stacking of two-dimensional (2D) materials has significant importance in this context [1]. High precision structuring tools, such as a focused electron beam, can be employed to mill a wide range of structures into 2D materials [2], e.g., to modify their electronic properties. For example, creating a band gap in graphene [3] enables its use as a semiconductor in a variety of applications. By using customized sheets of 2D materials as building blocks, it should then become possible to produce almost any three-dimensional (3D) structure with properties that have been finely tuned to suit desired requirements [4].
Methods
2D materials are structured by using scanning transmission electron microscopy (STEM). Clean samples are essential to the quality of the resulting structures. Therefore, to minimize contamination on the sample, a micro-electro-mechanical system (MEMS) chip is used for its ability to provide in situ heating. Investigation of the manufactured structures is done by transmission electron microscopy (TEM).
Results
Atomically clean graphene samples have been successfully produced using the in situ heating of the MEMS chip. Furthermore, a wide range of structures using different STEM patterning parameters have been investigated. In order to open up a band gap within the graphene, large areas (600x600 nm) with small holes with a diameter of only 2-3 nm and a periodicity of 8 nm have been patterned. According to theoretical calculations, this introduced a band gap of approximately 0.6 eV into the graphene.
Conclusion
The ability to work with contamination free 2D materials and the consequent high patterning resolution of the structures is very promising. Smaller structures will be in reach soon and thus, the possibility of larger bandgap openings within graphene becomes available. Ultimately, novel van der Waals heterostructures will be created by stacking modified layers of various 2D materials.

Fabrication of electron transparent membranes and nanostructures in fluidic devices by NIL and “Flow-Through”-gas-phase deposition

Jeremy Teuber[1], Manuel Müller[1], Rukan Nasri[1], Dr. Irene Fernandez-Cuesta[1]
[1]University of Hamburg, Hamburg, Germany

Poster Group 2

Background incl. aims
Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) are invaluable tools for visualizing and analyzing samples with nanometer resolution. Integration of liquid cells with these microscopy techniques has expanded their capabilities, allowing dynamic imaging and real-time analysis under controlled liquid conditions [1,2]. However, existing liquid cells still face limitations such as high production cost, restricted geometries, and reliance on slit-like chambers formed by connecting two membranes with spacers.

Methods
We present a novel fabrication method for producing micro-, and nano channels and 3D structures, self-sealed with electron transparent thin Al2O3 membranes, as sketched in Fig. 1a), 1b) and 1c). For this, we make polymeric foils (<10 µm) containing micro-, and nanofluidic structures. Fabrication of the fluidic devices involves direct UV nanoimprint lithography (NIL) using a customizable and versatile stamp design adaptable to specific geometries [3]. Then, the channels are coated selectively from the inside with Al2O3 by using our self-developed gas-phase deposition [4]. These inorganic electron-transparent structures can be suspended by removing the polymer material around them, enabling their use as liquid cells for investigating dynamic molecular behavior within confined spaces, such as in TEM.

Results
Our method allows fabrication of liquid cells with a variety of lateral dimensions, even down to nanometric channels, and complex 3D structures with graded depths and widths. The fluidic device contains two microchannels which connect the inlet and outlet holes. These microchannels are interconnected by several nanochannels. For fluidic devices fabrication, a stamp is placed and aligned onto a polycarbonate plate which has been covered with a UV curable polymer containing pre-patterned holes. The assembly is then cured with UV-light, and the substrate and stamp are separated manually. Next, a polymer coverslip is used to seal the channel system of the fluidic device. The Al2O3 coating is achieved through a specialized gas phase deposition (GPD) reactor operating in a "flow-through" mode (ftGPD), providing conformal coating of the various structures [4]. The reactor's gas and vacuum ports align with the holes in the polycarbonate plate, facilitating connection to the imprinted fluidic system. By precisely controlling precursor gas flow across the microchannel, a controlled pressure gradient is established, enabling conformal deposition of Al2O3 onto various structures, including slits, chambers, and micro- and nanochannels. This method enables to tune the Al2O3 thickness, ranging from a few nanometers to hundreds of nanometers, allowing for adjustment of mechanical stability and electron transparency as needed. This strategy effectively circumvents existing constraints associated with liquid cell geometries, particularly those limited to slit-like chambers. In subsequent fabrication steps, the micro-, nanochannels or membranes can be selectively suspended by masking and reactive ion etching (RIE). Fig 1a) shows

hollow Al2O3 microchannel which are used for flow tests. Fig. 1b) shows an example of a suspended, hollow Al2O3 nanochannel with a cross section of 500 x 500 nm and a suspended length of 20 µm. To validate the electron transparency of the Al2O3 membrane, we created a TEM grid sample coated with an Al2O3 membrane fabricated in our GPD reactor. Subsequently, polystyrene beads were deposited both above and below the Al2O3 membrane, and imaged using SEM and TEM techniques (Fig. 1 d) e) and f), respectively). SEM images (Fig. 1 (d)) captured the same area with two different detectors, where polystyrene beads beneath the membrane were detectable solely by the secondary electron secondary ion (SESI) detector. In contrast, TEM imaging (Fig. 1 (e)) of the sample in transmission mode at a separate location demonstrated the feasibility of imaging beads through the Al2O3 membrane. We also made a sandwich, by placing another Al2O3 membrane on top, and imaged the beads in TEM at 200 keV, as shown in Fig 1 f). Furthermore, we also imaged gold nanoparticles placed below the Al2O3 membranes deposited and suspended from the top in one of our microchannels. The particles were visible in the SEM at an acceleration voltage of 8kV (Fig. 1 c)). All these results confirming the electron transparency of the membranes deposited using our method. To deploy this system as liquid cells in a TEM specimen holder, detachment of the structured and coated polymer foil from the substrate and subsequent cutting to a 3 mm total diameter are necessary.

Conclusion

This fabrication method offers a versatile approach for creating liquid cells with complex geometries, overcoming limitations of existing slit-like chamber designs. The electron-transparent Al2O3 membranes enable dynamic imaging of samples within confined spaces using SEM and TEM, with potential future applications in nanoscale research and analysis. Further investigations using these liquid cells inside SEM and TEM will be presented at the conference.

Poster Group 1

To increase the commercialization of solid oxide fuel cells (SOFCs), it is necessary to reduce their cost and extend their lifetime [1]. By operating SOFCs at temperatures below 650 °C, it is possible to make use of low-cost materials and reduce the performance degradation of SOFCs [2]. However, in the case of yttria-stabilized zirconia (YSZ) electrolytes, the electrochemical performance dramatically decreases at lower temperatures due to the low ionic conductivity of YSZ, leading to a high ohmic resistance [2]. The ionic conductivity of gadolinia-doped ceria (GDC) is significantly higher than that of YSZ at temperatures as low as 500 °C [3]. Ni/GDC fuel electrodes therefore provide superior properties compared to Ni/YSZ [4]. The microstructural integrity of Ni-based fuel electrodes is necessary for the long-term operation of SOFCs. Therefore, it is necessary to understand the structural and chemical degradation mechanisms of SOFCs to enhance and predict the lifetime of SOFCs [5].
In this work, the effect of operation temperature and duration on the structural and chemical degradation of Ni/GDC fuel electrodes was studied using (scanning) transmission electron microscopy ((S)TEM) and focused-ion-beam/scanning-electron microscopy (FIB-SEM) to correlate the structural and chemical evolutions with the results of electrochemical impedance spectroscopy. By using FIB-SEM, it is possible to reconstruct the 3D structure of the porous electrode to acquire structural parameters such as tortuosity, particle size distribution, specific active area, and triple-phase boundary length. The TEM sample preparation and 3D reconstruction of the Ni/GDC fuel electrodes were carried out using a Helios G4 FX dual-beam instrument (Thermo Fisher Scientific). STEM imaging and energy-dispersive X-ray spectroscopy were performed using a Tecnai OSIRIS ChemiStem (Thermo Fisher Scientific). TEM and SEM results of the Ni/GDC fuel electrodes at different aging states indicate a significant change in the microstructure, e.g. Ni agglomeration at higher operating temperatures, leading to an increase in polarization resistance.

Poster Group 2

Background
In the face of global energy and climate crises, the necessity for sustainable solutions has never been more pressing. Photocatalysts, which use sunlight to drive chemical transformations, offer hope in this quest. Among their many applications, one of the most promising lies in the conversion of carbon dioxide (CO2) into fuels, presenting a dual opportunity for reducing atmospheric CO2 levels and generating sustainable energy.1 However, the effectiveness of photocatalysts depends on the complex interaction of light absorption, charge carrier dynamics, and catalytic activity, particularly in the context of poorly understood steps such as charge carrier accumulation.1-3

Methods
Taking advantage of the fact that the accumulation of charge carriers in photocatalyst will induce local alterations in the atomic structure affecting parameters such as nuclear charge, atomic/ionic radius, and chemical bonding.3 These alterations, potentially originating from selective reduction of cations at a specific nanocrystal (NC) active surface facet,4 can manifest as local phase shift variations in transmission electron microscope (TEM) images. The goal of this study is to identify visible light-induced phase shift variations by extracting phase images from reconstructed exit wave functions corresponding to specific NC surface facets under various conditions. Advanced image simulations will provide valuable insights into the detectability of photogenerated charge carriers in TEM experiments.

Results
In this study, ab initio Transmission Electron Microscopy (abTEM) simulations5 was employed to assess the feasibility of detecting photogenerated charge carriers at the interface of photocatalysts under light irradiation, in the TEM. By creating a model photocatalytic system comprising facet engineered NCs, where photons are absorbed on the active facet during reaction, leading to the accumulation of photogenerated charge carriers. Simulating the structural and electronic properties of these photocatalysts under illumination, we aim to elucidate whether charge carrier accumulation at the interface is detectable in the TEM. I will present both high resolution TEM (HRTEM) and integrated differential phase contrast STEM (iDPC-STEM) imaging techniques and assess whether they are sufficiently sensitive to detect the potential difference arising from the slight change in nuclear charge.

Conclusion
This simulation study provides a crucial insight on the sensitivity of TEM techniques to subtle changes in potential and chemical reactivity induced by photogenerated charge carriers, providing insights into the feasibility of using TEM for monitoring photocatalytic reactions. This serves as a crucial step towards using advanced microscopy techniques for probing the dynamics of photocatalysis at the

nanoscale, ultimately facilitating the design and optimization of efficient photocatalytic systems for renewable energy generation and addressing environmental issues.

Poster Group 1

Oxygenic phototrophs perform carbon fixation through the Calvin–Benson cycle. Different mechanisms adjust the cycle and the light-harvesting reactions to rapid environmental changes. Photosynthetic glyceraldehyde 3-phosphate dehydrogenase (GAPDH) is a key enzyme in the cycle. Different photosynthetic GAPDHs exist in higher plants: the most abundant is formed by hetero-tetramers of A and B-subunits (AB-GAPDH), and the least abundant by A4 homotetramers. Regardless of the subunit composition, GAPDH is the major consumer of photosynthetic NADPH, and its activity is strictly regulated. While CP12 regulates A4-GAPDH, AB-GAPDH is autonomously regulated through a pair of cysteines located at the C-terminal extension (CTE) of B-subunits and by the substitution of NADP(H) with NAD(H) in the cofactor binding domain. Together, these conditions result in changes in the oligomerization state, thereby inhibiting enzyme activity. By combining small angle x-ray scattering coupled with size exclusion chromatography (SEC-SAXS) and cryo-electron microscopy (cryo-EM), we revealed the presence of several AB-GAPDH oligomers [(A2B2)n-GAPDH oligomers with n=1, 2, 4 and 5], co-existing in a dynamic system [1] (See Figure A). Moreover, the A8B8-GAPDH oligomer was present in two different conformers. Despite the sample's significant compositional and conformational heterogeneity, we solved the two A8B8-GAPDH hexadecameric conformers at around 3 Å (See Figure B). The other GAPDH oligomers were instead solved at intermediate resolution. In all GAPDH oligomers, we observed the same oligomerization/inhibition mechanism based on the mutual exchange between adjacent B-subunits of their CTEs, effectively preventing the binding of the substrate 1,3-bisphosphate-glycerate in the B subunits. The nearly atomic resolution we achieved allowed us to detail the molecular interactions among enzyme subunits at the tetramer interface, between the CTE and the active site residues, and between the CTE and the coenzyme.

Figure. A, AB-GAPDH oligomers cryo-EM density maps co-existing in the chloroplast leaf stroma. B, the cryo-EM electron-density map of the A8B8-GAPDH hexadecamer resolved at nearly atomic resolution (3 Å). The cryo-EM electron density maps are fitted by models derived from the crystal structure of oxidized A2B2 complexed with NADP+ (2).

Poster Group 1

Background and aims
Carbon Nitrides (CNs) attract great attention as promising materials for water remediation, gas sorption, energy storage devices and photocatalysis, among others. This variety of applications stems from a set of specific properties of CNs: chemical inertness, biocompatibility, high thermal and mechanical stability, and non-toxicity [1,2]. Tuning the functionalities of carbon nitrides requires precise control over their structure and composition. Many CNs are poorly crystalline or even amorphous materials, thus requiring specific methods to describe their local structure (short- and medium-range order). In this work, we explore the possibility of obtaining quantitative information about the local structure of CN-based compounds using electron energy loss spectroscopy (EELS) in (S)TEM. Element-specific radial distribution functions (RDFs) can be derived from the extended energy loss fine structure (EXELFS) of EELS spectra [3]. Taking into account that modern analytical microscopes are much easier to access than spectroscopic beamlines at synchrotrons, this method holds great potential for fast analysis and prescreening of high amounts of samples. Here we investigate two challenging CN systems to establish the limitations of RDF analysis from EELS spectra in application to polymeric compounds: (1) the heterojunction of two photocatalysts (poly(triazine imide) (PTI) and potassium poly(heptazine imide) (K-PHI)) is used to check the ability to distinguish between two structurally closely related polymeric materials; (2) Ce-doped CNs (Ce-CNs) are used to check the limitations regarding sensing the local environment around single-atom catalysts.
Methods
All samples were first investigated using high-resolution (scanning) transmission electron microscopy (HRTEM) and electron energy loss spectroscopy (EELS) using a double aberration-corrected Jeol JEM ARM200F equipped with a cold field emission gun and a Gatan Imaging Filter (GIF) Quantum spectrometer. HRTEM images were acquired on an Oneview (4k × 4k) camera, EELS spectra were collected on a US1000 (2k × 2k) camera. EELS spectra for the PHI/PTI sample were collected using a monochromated TFS Themis Z 80-300 microscope operated at 80 kV and equipped with a GIF Continuum 1065ER spectrometer (convergence and collection angles of 22 mrad) at energy dispersion of 0.15 eV/ch. For all EELs spectra, a power law model was used for background subtraction. Multiple scattering effects were removed using the Fourier-ratio method, implemented in the Gatan Digital Micrograph Suite (GMS), version 3.4. EXELFS data were normalized and Fourier-transformed using the Athena software package. FEFF9 was used for fitting of the experimental data.
Results
The results will be described in two sections following the scientific questions defined above.
(1) Samples of PTI, K-PHI and a heterojunction between them (PTI/K-PHI) were analyzed [5]. Our study confirmed the formation of a heterojunction between the PTI and the K-PHI phase. The RDF obtained from the EXELFS part of the N K-edge of the PHI/PTI sample shows five prominent peaks. The first peak at around 1.3 Å arises due to scattering from the nearest carbon neighbors in both PTI and K-PHI. The second and third peaks correspond to the N-N (2.1 Å) and N-C (2.75 Å) distances

within the aromatic rings. The fourth peak represents the summed contribution of the shortest N-N (3.3 Å) and N-C (3.58 Å) distances between adjacent layers of K-PHI. The fitting of RDFs obtained from individual phases and the heterojunction is in progress and should allow us to quantify the amount of each phase.
2. We investigated Ce-CNs employed in photocatalytic wastewater dephosphorylation. By varying the amount of Ce(NO3)3·6H2O precursor, samples with different concentration of Ce were obtained (9.5, 17.0, 30.5 and 39.8 wt.%). HAADF-STEM images of the samples showed that Ce is present in the CN matrix in different forms: single atoms, clusters and nanoparticles. To resolve the average coordination around Ce atoms and distinguish between the aforementioned types of structures, RDFs obtained from the EXELFS part of the M4,5-edge of Ce and from EXAFS at the Ce L2,3-edge were compared. The EXELFS signal obtained from the 9.5 wt.% doped sample was found to be too low in intensity to perform reliable RDF analysis. The position (~2.5 Å) and the high intensity of the first peak on RDFs obtained from the Ce-CNs samples with 17.0, 30.5 and 39.8 wt.% suggest that Ce atoms bind to C or N and that a considerable fraction of Ce forms single atoms. On the RDFs from the CeO2 reference the most intense peak, at 3.5 Å, corresponds to the Ce-Ce distance. Different structural models for Ce incorporated into the CN matrix were constructed and the refinement of these models is currently in progress. In addition, we collected X-ray absorption spectra from these samples in order to compare RDFs obtained from bulk samples and locally from EXELFS spectra.
Conclusion
The local structure in two soft polymeric systems utilized in energy-conversion (K-PHI/PTI heterojunction) and photocatalytic water treatment (Ce-doped CNs) was studied using element-specific RDFs obtained from EELS spectra. The results suggest that a clear discrimination between the structurally closely related PHI and PTI phases is challenging; accurate data fitting (which is currently in progress) is required to make a final conclusion. The formation of Ce single atoms manifests itself by considerably higher intensity of the C/N-Ce peak on RDFs. Conclusions about the possibility to quantify the amounts of co-existing phases (CeO2, Ce-clusters and Ce-single atoms) can only be made after accurate fitting of RDFs.

Poster Group 1

Background incl. aims
Primary parotid neoplasms necessitate specialized attention due to their diverse histological and clinical features [1,2]. Accurate classification and treatment selection rely on a thorough comprehension of both the phenotypic and molecular attributes of these tumors. Molecular markers and interactions within the tumor microenvironment critically influence their behavior. Therefore, identifying new markers using routine techniques such as needle aspiration to visualize tissue metabolism in vivo is essential for refining diagnostic accuracy and treatment strategies. Our study aims to preliminarily delineate the complex metabolic profiles of parotid gland tissues, especially focusing on distinguishing between healthy subjects and patients with squamous cell carcinoma, employing both Fluorescence Ratio (FRIM) and Fluorescence Lifetime (FLIM) Imaging Microscopy for precise quantification.

Methods
In our investigation, we conduct ex vivo analysis using advanced two-photon metabolic imaging techniques to examine the morphological, molecular, and functional aspects of parotid neoplasms. Fine needle aspiration biopsy is utilized to obtain cells for analysis, bypassing the need for invasive procedures and minimizing patient discomfort. Through this approach, we analyze metabolic markers such as NADH and FADH2, employing Fluorescence Ratio Imaging Microscopy (FRIM) and Fluorescence Lifetime Imaging Microscopy (FLIM) for precise quantification [3].

Results
Through the application of Metabolic Imaging techniques to analyze NADH and FADH2 levels in ex vivo samples, our objective is to complement traditional morphological assessments with a comprehensive evaluation of tissue metabolic states. We employed both microscopy imaging techniques to analyze the behavior of these two molecules in both healthy and diseased subjects. For instance, in the case of FRIM, we introduced an innovative workflow pipeline (depicted in Figure 1), which commences with autofluorescence imaging to derive redox ratio images by analyzing the blue and red channels. A redox ratio value approaching 0 indicates a state of reduction, while nearing 1 signifies oxidation. Subsequently, mitochondrial and cytoplasmic masks are applied to these images, enabling the assessment of tissue metabolic activity.

Figure 2 displays images in the blue channel, red channel, and the RR image generated by the analysis pipeline respectively for the healthy subject (top) and the subject affected by squamous cell carcinoma (bottom). These latter images feature a scale bar indicating areas of heightened metabolic activity within the tissue.

As shown in Figure 3, controls exhibit higher RR_mit values compared to patients, suggesting greater oxidative activity in healthy tissue.
RR_mit indicates the balance between reduced and oxidized pixels in relation to mitochondria, reflecting metabolic activity and cell viability. A higher RR suggests greater metabolic activity and more viable cells, while a higher RR low may signal metabolic alterations, as observed in squamous cell carcinoma. So, the higher RR_mit in healthy subjects compared to patients highlights significant disparities in tissue metabolic health.

We delved into metabolic dynamics by identifying the quantity of mitochondria exhibiting reduced and oxidized states within both healthy and diseased tissue, leveraging suitable algorithms for precise analysis.

Conclusion
Introduction of an innovative pipeline for autofluorescence image analysis has yielded significant findings. Notably, the results reveal a distinct contrast between healthy and diseased tissues. Moving forward, these insights are poised to influence diagnostic protocols and personalized treatments, with a focus on enhancing patient well-being. Such advancements hold promise for refining our understanding of tissue pathology and optimizing therapeutic strategies tailored to individual patient needs.

Using XeF2 FIB imaging to contrast and quantify precipitation in metal.

Mr Peter Thomas[1], Dr Mariia Zimina[1], Dr Lawrence Coghlan[1], Mr Aidan Gunn[1], Dr Siqi He[1], Dr Aya Shin[2], Dr Jonathan Pearson[2], Professor Peter Flewitt[1], Dr Tomas Martin[1]
[1]University of Bristol, Bristol, United Kingdom, [2]EDF UK, Gloucester, United Kingdom

Poster Group 2

Background incl. aims
Precipitation within a material is known to affect material properties, from mechanical to chemical [1]. Depending on the type, location, orientation, and distribution of precipitates, these properties can vary significantly [2]. In this study we utilize the XeF_2 gas injection system (GIS), a common feature on dualbeam microscopes, in combination with FIB imaging to drastically enhance the contrast of precipitates and therefore make image processing easier. By combining the FIB-XeF_2 technique with low magnification and high resolution, it allows the extraction of large amounts of statistical data using software such as Dragonfly [Computer Software] 2022.2.
Methods
The FIB-XeF_2 contrast mapping procedure and micrograph capture were collected using a ThermoFisher Scios 2 dual-beam FIB system, which contains a gallium ion source. A full procedure can be found in previous work [3]. We have completed this technique using three different materials, all of which had different initial conditions and reasons for evaluating. First, an experimental Fe9Cr1Mo steel exposed to high-temperature and-pressure CO_2 environments, second, a 316H steel that had undergone creep testing, and third, an Alloy 690 nickel-based alloy that has undergone a surface mechanical process.
First, the surface was initially exposed to a high current FIB beam (30kV:50nA) to remove the surface oxide layer and expose hard precipitates in the matrix. The GIS needle was inserted and XeF_2 gas was flowed across the area of interest. Once the GIS needle was retracted, the area of interest was then exposed to a much lower FIB current of 30kV:1nA. Under the influence of this FIB beam, the XeF_2 gas binds preferentially to the metallic matrix and less to the precipitates, resulting in an enhanced contrast effect. This imaging was continued until the maximum contrast between the precipitates and the metal matrix was obtained, following which a high-resolution image was taken. In this study, the final images were taken at a resolution of 6144 x 4096, integrated 4 times with a dwell time of 1 µs. This produced an image of significant quality for quantitative analysis without altering the contrast too much. The precipitates were also individually characterised with Transmission Electron Microscopy (TEM) diffraction, Energy-dispersive X-ray spectroscopy (EDS), and Transmission Kikuchi diffraction (TKD) to identify their crystal structure on elemental composition and diffraction pattern. Once a characteristic of a particular morphology was identified using TEM / EDX / TKD, precipitates of similar contrast and morphology in the FIB-XeF_2 images were labelled as this precipitate identity.
Results
FIB-XeF_2 images were processed using image recognition in Dragonfly [computer software] 2022.2. The features within each image were segmented according to greyscale contrast using an Otsu threshold selection method [4]. This allowed the separation of precipitate from bulk, voids, and subsequently segmented different precipitates into separate virtual objects. The graphic shows an example of this approach – top left shows the raw FIB-XeF_2 image of a region of Fe9Cr1Mo steel, showing a lighter metal matrix and several precipitates with different greyscale contrasts and morphologies. The subsequent subfigures show in pink, blue, and yellow the segmentation of these features into three distinct populations based on greyscale contrast and morphology that were

identified using TEM diffraction as $M_{23}C_6$, M_7C_3, and M_2C respectively. These segmented features are spatially located datasets, that can subsequently be parsed for the following statistical information: area fraction as a function of distance, distribution, size, orientation, and type. This enables quantification of microstructure over large areas with much greater confidence.
For 316H, precipitate locations were combined with grain boundary locations and compared with voids within the sample to obtain directional correlation information across the sample. Complete results for 316H steel can be found in previous work [5].
For the Alloy 690 sample, FIB-XeF_2 images provided clear microstructural information, such as precipitate pocketing along grain boundaries that was missed in other techniques.
Conclusion
Precipitation is an important factor when considering the chemical and mechanical behaviour of a material, especially for a material exposed to extreme environmental conditions. By re-utilising the XeF_2 gas module most dual beam FIB instruments have, it is possible to bring out the contrast of different precipitates against the bulk in such a way that image processing software can easily extract statistical information. This data will lead to a greater understanding of the behaviour of the material.

Towards Automation of the Transmission Electron Microscope

Kristian Tveitstøl[1], Magnus Nord[1]
[1]Department of Physics, Norwegian University of Science and Technology, Trondheim, Norway

Poster Group 1

The Transmission Electron Microscope is a powerful tool investigating samples at the nano-Ångström scale. Despite its increasing popularity due to its unmatched spatial resolution, operation of the microscope is time-consuming and tedious. At times, even trivial tasks may require hours of manual operation. Automation has thus become attractive in the field, as it would lower the threshold and workload for advanced material investigations.
Scanning TEM (STEM) differential phase contrast (DPC) is a technique utilizing movement of the centre beam to determine electric and magnetic domains. For a magnetic sample with domain formation, the beam will be deflected in different directions depending on the in-plane magnetic alignment in the sample, see graphic. This slight change can be measured using e.g. a pixelated detector. Nanomagnets with dimensions 225-75 nm are shown to have interesting monodomain properties, being currently widely studied for reservoir computing [1,2].
Problems arise when using the TEM as the magnetic field is typically too big for domain-formation. For this reason, the objective lens must be turned off, reducing the spatial resolution. With the objective lens turned off (so-called Low-Mag), the magnetic field can be estimated to be of the order of tens of millitesla. This is sufficiently low for ASI-samples to show hysteretic behaviour, and in-situ studies of the dynamics can be performed by either tilting the sample, increasing the magnetic field from the objective lens or rotating the sample.
Once the TEM is aligned, the STEM-DPC technique is rather trivial, that is: acquire data, then change the magnetic field, repeat. This experiment is typically referred to as “continuous-tilt STEM-DPC” and can take hours to complete. The task however, is trivial and using human operating time is both inefficient and prone to human errors. This procedure is easy to automate, and allows other in-situ experiments such as varying the temperature over critical regions.
ASI structures will be prepared from TEM samples with 20-50 nm Si windows with top layers of permalloy and aluminium using FIB, creating nano-magnets with mono-domain behaviour. Continuous-tilt STEM-DPC will then be performed with either a MerlinEM direct electron detector or a conventional ADF detector followed by procedural post-processing. This experiment will be a proof-of-concept, and the choice of detector will depend on access to the Merlin detector.
The project aims to gain complete control of both the microscope and the detector- and scanning systems and build a python-library allowing experienced microscopists to automate their own experiments. Creating possibility for feedback-controlled automatic decision-making will also be done. Even further, programmable input-output devices for in-situ experiments will allow scripted exploration of the parameter space of all TEM samples using custom in-situ chips.
Further, given control of the scanning system, random and quasi-random sequences for data-acquisition will be implemented, reducing the necessary acquisition time for sufficient statistic. This procedure will also in particular benefit samples prone to beam damage.

In situ SEM of slip localization and its relation to the onset of ductile fracture

Mr Antoine Ollivier, Dr Antonio Pereira, Dr Nicholas Blanchard, Professor Loic Vanel, Dr Döme Tanguy
[1]Universite Claude Bernard Lyon 1, CNRS, Institut Lumière Matière, Villeurbanne, France

Poster Group 2

We present surface deformation measurements by in situ SEM tensile tests. The surface displacement field is obtained by tracking gold nano-droplets formed by laser dewetting. A thin film of gold of a few nm is deposited on the sample surface. The laser fluence and the thickness of the deposit can be varied to modify the diameter of the droplets and their surface density, enabling a fine-tuning of the spatial resolution of the field measurement. Diameters in the range of 10 to 100 nm, densities up to 2000/µm2 can be obtained. The advantage of tracking the center of mass of the droplets with respect to digital image correlation using a correlation window is to limit the smoothing of the displacement discontinuities. Therefore, it is well adapted to the measurement of slip band thicknesses. The field of view of a typical SEM image is of the order of 3 µm. It is enlarged up to 25 µm by automatically acquiring a series of images and stitching them together (Fig. 1). Thus enabling slip system widths as thin as 50 nm to be measured. The tracking of the center of mass of the droplets along the tensile test is done by a homemade code based on the python libraries scikit-image, scipy and run on a computer cluster. It enables a real time image treatment and the acquisition of high magnification images in the regions of interest. For example, the change of shape of the droplets within the thick slip bands or the shearing of droplets by thin slip bands have been observed in situ.
The method is tested on Eurofer 97, a tempered martensite ferritic steel for nuclear application where slip localization might be important for the initiation of ductile fracture.

In-situ micro-mechanical tests under SEMs

Dr. XiaoMeng Sui[1]
[1]Chemical Research Support, Weizmann Institute of Science, Rehovot, Israel

Poster Group 2

Background
Materials exhibit varying mechanical behaviors and properties at lower dimensions, a phenomenon often termed as the size effect. Understanding this deformation mechanism and the relationship between structure and properties in nano- to micro-sized materials requires the capability to conduct in-situ mechanical tests under an electron microscope. In this study, we performed tensile and compression tests on synthetic and natural samples using our custom-built tensile tester.

Methods
To enable in-situ mechanical testing under SEMs, we developed a setup integrating a nano-manipulator for displacement control, load cells with various spring constants, and sample clamps mounted on a frame to create a tester stage. This configuration can serve as a plug-and-play accessory for conventional SEMs or environmental SEMs and can be easily adapted for use with optical microscopes..

Results
Our mechanical stage not only facilitates tensile testing but also enables compression testing when equipped with suitable sample holders. Examples such as tensile tests on carbon and cotton fibers, along with compression tests on silk needles, will be provided.

Conclusion
Through the integration of off-the-shelf components, we have built a micro-mechanical testing apparatus capable of conducting tensile, compression, and fracture toughness tests under both SEMs and optical microscopes. With appropriate design modifications to the sample holding fixtures, this device can be converted into a 3(4)-point-bending apparatus. Such a mechanical stage offers versatility in studying the micro mechanics of samples across material and life sciences domains.

Poster Group 2

Background incl. aims
Animals have the ability to generate a diverse array of minerals at various locations within or surrounding their cells. An example of this mineralization process is evident in the development of rigid skeletal structures. Especially skeletal hard parts like bones, teeth, shells, and exoskeletons are prime examples of biomineralization [1]. Carbonate apatite crystals constitute a significant portion of various mineralized tissues in vertebrates. In the mentioned structures, like bones and mineralized tendons, these crystals typically manifest as thin, irregularly shaped plates [2].
Electron diffraction experiments provide valuable insights into lattice parameters and symmetries and sometimes help uncover hidden crystals. Directing electron beams at these samples can explain their crystal arrangements, which helps to understand the mechanical properties of the materials, mineral composition, and integrity. A comprehensive understanding of the composition and characteristics of biomineralizations can be invaluable in diagnosing pathological calcifications, which are implicated in several severe diseases. Identifying and analyzing these crystals in tissues can provide crucial insights into underlying mechanisms and progression of such conditions, aiding in early detection, accurate diagnosis, and effective treatment strategies. Electron diffraction proves instrumental in diagnosing conditions such as Alzheimer's disease, which is characterized by abnormal accumulation of metals in the brain [3].On the bone samples, electron diffraction aids in identifying hard tissue calcification, which compromises elasticity, hardens these tissues and disrupts their function.
Electron diffraction offers a significant advantage in its ability to analyze a much smaller area, typically at the nanometre scale [4], compared to X-ray diffraction, making it feasible to detect locally ordered structures (nanocrystals).
This technique is also generally suitable for examining thin layers, such as 2D crystals. Consequently, this method proves particularly valuable for studying membrane proteins that readily form 2D crystals but face challenges in forming 3D structures [5].

Methods
Low Voltage Transmission Electron Microscopy (LVEM) is a valuable technique in life science and materials research. LVEM operates at lower voltages, typically below 25 kV. This lower voltage regime offers distinct advantages, especially enhanced contrast. When assessing micrograph quality, spatial resolution and image contrast are key criteria. Low voltage improves contrast mechanisms, which is particularly beneficial for samples containing light elements, such as biological specimens. Enhanced image contrast helps to identify suspicious crystal structures in tissues. Moreover, low-voltage electron diffraction has a distinct specific advantage yielding from the dimensions of the Ewald sphere, providing more information [6].
The Low Voltage Electron Microscopes (LVEMs) by Delong Instruments integrate TEM and STEM (including dark fields in both regimes) and SEM (BSE) imaging modes. The LVEMs offer Electron

Diffraction (ED) and eventually Energy Dispersive X-ray Spectroscopy (EDS), which makes them altogether highly versatile tools for material analysis.
The samples were sectioned with 35° diamond knives at a feed of 20-30nm using ultramicrotomy method.

Results
This study performed electron diffraction on selected biological samples, namely manganese-bound bacteria, bones, shells, and urea, and explored the advantages of analyzing biological samples using low voltage electron diffraction. The experiments were carried out using low-voltage electron microscopes LVEM 25E with an accelerating voltage of 25 kV and LVEM 5 operating at approximately 5 kV.

Conclusion
In summary, electron diffraction proves invaluable for analyzing biological materials, offering insights into crystal structures and tissue properties. Particularly, it aids in studying thin layers and 2D crystals, contributing to understanding membrane proteins and the structural complexity of hard biological materials like bones and shells. Additionally, it shows potential in diagnosing diseases such as Alzheimer's. This study highlights the utility of low-voltage transmission electron microscopy in such analyses, providing enhanced contrast and analytical precision for diverse biological samples.

Metal nanoparticles have attracted significant interest due to their distinctive properties which show significant potential in applications including drug delivery, chemical sensing, and biological imaging. A common method for synthesizing such nanoparticles is wet chemical synthesis; however, despite decades of development in synthetic methodologies, the precise mechanisms governing symmetry breaking and shape modification of these particles remains ambiguous and subject to debate. It is widely recognized that the introduction of different surfactants affects nanoparticle morphology.

In this work, we aim to study the influence of surfactants on the surface energies of nanoparticle facets. Our approach uses quantitative scanning transmission electron microscopy (STEM) to obtain a measure of surface mobility — as a proxy to estimate surface stability and hence energy [3]. We investigate the optimum set of parameters, including course sampling, for acquisition of a four-dimensional STEM dataset, such that the location and number of atoms in each atom column can be accurately determined while minimizing the electron dose. We quantify dose versus accuracy across these different parameter sets.

We apply these parameters to investigate the relationship between dose and atom mobility on a gold nanoparticle, with the use of double aberration-corrected microscopes (FEI Titan3 80-300 FEG TEM and a newly installed Thermo Fisher Scientific Spectra ϕ FEG TEM) (see Fig.1). We further apply this to measure surface mobilities on different gold nanoparticle morphologies.

This approach aims to offer insights into the fundamental processes underlying nanoparticle synthesis and shape evolution, paving the way for tailored nanoparticle design and optimization in various applications.

Poster Group 2

Background
Hydrogel is an organic-based material, which finds its use in various fields ranging from well-known employment in medicine (wound treatment, scaffolds,...) to rising involvement in agriculture (superabsorbents, controlled release of fertilisers,...)[1]. While hydrogels containing chemical fertilisers provide valuable nutrients directly, the unused nutrients remain in the soil, where they accumulate, which negatively influences biodiversity, soil fertility, etc [2]. An alternative approach relies on the use of biological fertilisers (bioinuculants) in the form of plant growth-promoting bacteria (PGPRs). PGPRs positively stimulate the growth of plants using several mechanisms (phytohormone production, nitrogen fixation,...), while simultaneously reducing the growth of pathogenic microorganisms or chelating heavy metals [3]. One of the PGPRs is Azotobacter vineladii, a microorganism interesting not only for its plant growth-promoting properties but also for its production of various polymers. Namely polyhydroxyalkanoates (PHAs), biopolymers praised for their properties similar to petrochemical plastics, or alginate, polysaccharide capable of forming a hydrogel. A. vinelandii releases alginate to form a capsule around the cells, which protects them from drying out and from other hostile environmental conditions. The production of alginate is a significant advantage of using A. vinelandii as bioinoculant since there is no need to add the hydrogel-forming polymers to the bacteria for encapsulation, the polymer already in the media is crosslinked and the resulting hydrogel is then processed into the final form of bioinoculant suitable for employment in agriculture [4]. This work aimed to study the morphology of hydrogel formed using different crosslinking agents (namely CaCl2 and glucono-D-lactone), a step necessary to determine the most suitable crosslinker. Since alginate hydrogels are composed of polysaccharides and a substantial amount of water, chemical processing for EM could severely alter the hydrogel ultrastructure. Therefore, cryogenic fixation followed by freeze-fracture and cryo-SEM was proposed to be the most promising technique to study the polymeric net the most closely to the native state.
Methods
Cultures of A. vinelandii were cross-linked using various agents (2% CaCl2, 1M GDL + 0,5M CaCO3). The resulting hydrogels were cut using a scalpel to fit into 6mm carriers for high-pressure freezing and fixed using EM ICE (Leica Microsystems). No cryoprotectant was added. Frozen samples were transferred under liquid nitrogen into a cryo-vacuum preparation chamber (ACE600 Leica Microsystems), where they underwent freeze-fracturing followed by sublimation at -95°C for 7min. Samples containing hydrogel-encapsulated bacteria were then imaged in a scanning electron microscope (Magellan 400/L, FEI) equipped with a cryo-stage, at −120 °C using a 1–2 keV electron beam.
Results
Cryo-SEM imaging revealed cells of A. vinelandii containing polymeric granules, consisting of polyhydroxyalkanoate (PHA). As was previously proved, PHAs in the form of intracellular granules stay elastic even at temperatures of liquid nitrogen. They can be seen as needles sticking out of the freeze-fractured cells, as was visible also for A. vinelandii. Hydrogel encapsulating the cells showed

different structures for both crosslinking agents. While hydrogel formed using CaCl2 showed a net of individually distinguishable fibres, the gel formed by GDL showed a dense mass surrounding cells. The changes in hydrogel ultrastructure seen in cryo-SEM support the difference in the macromorphological structure of the hydrogels visible immediately after cross-linking. Some polymer net was visible also for not crosslinked samples, possibly because of the trance concentration of Ca2+ ions in the cultivation media for the cells. However, the density of the net in the images as well as the overall amount of hydrogel was considerably lower. Similar results, supporting the hypothesis, were also obtained in the preliminary STEM experiments for freeze-substituted samples.

Conclusion

Cryo-SEM together with high-pressure freezing was proven to be a capable method for studying the structure of hydrogels. It was possible to determine the changes in the hydrogel structure based on the type of crosslinker used. Since the preliminary STEM data supported the cryo-SEM findings it is proposed to use the combination of these methods for the evaluation of other types of hydrogels.

The effects of B4C network microstructure on the thermoelectrical properties of spark plasma sintered SiC

Dr Salih Cagri Ozer[1], Ceren Korler[1], Prof. Dr. Servet Turan[1,2]
[1]Eskisehir Technical University, Department of Materials Science and Engineering, Eskisehir, Turkey,
[2]Ceramic Research Center, Eskisehir, Turkey

Poster Group 1

Thermoelectric (TE) devices convert waste heat to electricity and can be used in industrial waste heat recovery utilizing TE materials which may play a vital role in developing sustainable and renewable energy-harvesting technologies. TE materials should have high electrical conductivity and Seebeck coefficient as well as low thermal conductivity for a high dimensionless figure of merit, ZT, which represents the efficiency of TE conversion. Since these properties are related to each other, e.g. a high electrical conductivity results in a high thermal conductivity value, different composite approaches or doping must be maintained for optimization of these properties. Our recent studies explored the effects of transitional metal carbide/boride network microstructures on the TE properties of SiC and B_4C which revealed simultaneous improvement of electrical and thermal conductivities with conductive network and increased phonon scattering, but deterioration of the Seebeck coefficient due to the metallic nature of the network microstructure. To minimize this problem, a B_4C network microstructure was implemented to the SiC matrix in this study, aimed to increase the electrical conductivity with minimal Seebeck coefficient loss thanks to the semiconductor nature of B_4C.
Polycrystalline bulk samples of SiC with B_4C network structures were prepared by a simple dry particle coating method followed by spark plasma sintering (SPS). 1–8 vol.% B_4C-coated SiC granules were consolidated in an SPS furnace (HP 25D, FCT GmbH, Germany) at 2000°C by applying 40 MPa pressure under a vacuum atmosphere with a 5-minute holding time. Phase and microstructure analyses were carried out on polished surfaces of the sintered bulk samples. Electrical conductivities and Seebeck coefficients of the samples were measured simultaneously by the four-point probe method between 323 and 923 K. Thermal diffusivity and heat capacity values were measured by the laser flash analysis and differential scanning calorimetry, respectively, to calculate the thermal conductivity. Density values were obtained by using the Archimedes method at room temperature.
The implementation of the conductive B_4C network microstructures given in the figure (light phase is SiC matrix, dark phase is B_4C network) improved the electrical conductivity of SiC simultaneously with the decrease in thermal conductivity due to the increased phonon scattering with increased grain boundary concentrations. Optimization of B_4C content resulted in a minimal decrease in the Seebeck coefficient resulting in a composite with increased ZT values and TE performance.
To conclude, SiC granules were successfully coated with 1–9 vol.% B_4C powders and then spark plasma sintered to obtain conductive B_4C network microstructures to improve the TE performance of SiC by simultaneously increasing electrical and decreasing thermal conductivities while limiting the decrease in the Seebeck coefficient to a minimum.
This study was financially supported by the Scientific and Technological Research Council of Turkey (TUBITAK) (219M514) and The Eskisehir Technical University Scientific Research Project (23ADP195).

Revealing Nanostructural Dynamics: Exploring Inelastic Scattering in Electron Microscopy

Phd Caterina Chiari[1,2], Prof. Marco Beleggia[1], Dr Vincenzo Grillo[2]
[1]University of Modena and Reggio Emilia, Modena, Italy, [2]S3 CNR Nano, Modena, Italy

Poster Group 2

Background incl. aims:
Inelastic electron-matter interactions are pivotal for probing the dynamic behavior and electronic structure of materials at the nanoscale. Electron microscopy techniques like electron energy loss spectroscopy (EELS) and energy-filtered transmission electron microscopy (EFTEM) utilize inelastic scattering as a powerful tool for identifying chemical composition, mapping elemental distributions, and elucidating bonding configurations with exceptional spatial resolution [1,2].
A captivating consequence of inelastic scattering is that each electron beam, arriving at the sample after inelastic collisions, interacts with a different (e.g. excited) state. With inelastic processes like ionization, each collision contributes to the establishment of a plasma-like state within the sample. Consequently, it is pertinent to ascertain the final state of the sample after these interactions. Also, what is generally referred to as radiation damage, which may progressively change the very structure of the sample, is entirely a consequence of inelastic collisions. It becomes then extremely important to determine the state of the sample during and after electron irradiation, including, among many other effects, electron-hole recombination.
In this context, since that the relevant cross-sections are modified alongside the evolving sample, we aim to track the formation and dynamics of new molecules, molecular fragments and generated electrons resulting from inelastic scattering.
Additionally, exploring the effects of structured or shaped beams, adds another dimension to reveal the benefits and hindrances of inelastic scattering in electron microscopy. By employing beam-shaping techniques, it may become possible to modulate and control different scattering channels thereby driving the evolution of the sample.

Methods:
Our study commences with an analytical derivation of the wave function, decomposed in elastic and inelastic partial waves, originating from the electron-hydrogen atom interaction [2,3,4]. This choice has the unique advantage of providing analytical results from beginning to end. We present our findings with a set of plots describing visually the ionization of a hydrogen atom, and the subsequent formation of a secondary electron, highlighting the distinctions between elastic and inelastic scattering.

Results:
Representing the primary beam as a plane wave interacting with the hydrogen atom, we obtain scattered spherical outgoing waves modulated in amplitude and phase by the elastic and inelastic scattering factors. The latter (left side of Fig.1 a) shows a more pronounced forward-scattering angular distribution than the former, and, strictly speaking, should also exhibit a longer wavelength. This occurs because the primary beam loses momentum, transferring it to the hydrogen atom's electron. With an energy loss set at 20 eV in this example, the electron is expelled through ionization

and becomes a secondary. However, being proportional to the momentum transfer, the wavelength variation of the primary remains very small. The ejected electron is also depicted as a plane wave for simplicity, although it should be more correctly represented by a Coulomb wave function [3,4].

Conclusion:
In this preliminary study, we demonstrate how even a simple specimen as a hydrogen atom, undergoes modifications due to electron beam irradiation. The monitoring of any sample is fundamental in electron microscopy to track the alterations occurring in it and to control its behavior. This is crucial, as inelastic scattering leads to heating or damage effects, emphasizing the necessity of comprehending these interactions for proficient sample analysis and manipulation.

Figure caption:
Fig. 1 (a) Elastic and inelastic scattering processes representation. k_i and k_f are the primary initial and final momentum respectively, while q is the transfer one.
ksin is the initial momentum of the electron bounded to the hydrogen atom, while ksfin is that of the ejected electron according to momentum conservation: k_s^in+q= k_s^fin.
The angular distribution of the scattered wave function is broader for elastic collisions than for inelastic ones. This is reflected in the scattering factor f(θ) which appears narrower in the inelastic case (b).

Poster Group 1

Immunofluorescence microscopy (IFM) is the current "golden standard" in histopathology and biomedical research. IFM enables simultaneous imaging of multiple fluorescently tagged antibodies, but multiplexing beyond seven different fluorophores is impractical without photobleaching and re-staining, which it may cause sample degradation and difficulties with registering the separately-taken images. Other disadvantages are autofluorescence which can hinder detection of low-abundance proteins and signal bleeding. These disadvantages are absent in mass spectrometry-based approaches. Most mass spectrometry imaging (MSI) immunohistochemistry (IHC) is performed in “microprobe mode” which images pixel-by-pixel [1] and is limited to approximately 1,000 pixels per second, limiting the field of view. To overcome this limitation of typical MSI, fast mass microscopy (FMM) has been developed to acquire pixels, and collect many spectra, in parallel with a continuously moving stage, enabling orders of magnitude faster imaging [2]. Here we describe advancements in FMM for biomedical applications for the detection of multiple isotopically enriched metal tags that enable multiplex antibody panels, thus facilitating studies of multiple proteins in one imaging experiment.

Methods

MIBI staining with metal-conjugated antibodies (CD11b 155Gd, CD3 159Tb, Keratin 165Ho, α-SMA 164Dy) is performed similarly to traditional IFM. Flash-frozen tissue blocks were sectioned with a thickness of 12 µm using a Leica cryostat microtome. Serial sections from the same tissue block were obtained and collected on clean indium tin oxide coated glass slides. The stained human intestinal tissue and mouse tissue sections were analyzed with time-of-flight secondary ion mass spectrometry (ToF-SIMS) imaging using a PHI nanoTOF instrument II (Physical Electronics, Chanhassen, MN, USA) with tandem MS capability equipped with a liquid metal ion gun, C60 ion gun, and Ar cluster ion gun. FMM-IHC was done using an instrument based on the TRIFT II mass microscope (Physical Electronics, Inc. (PHI) Chanhassen, MN, USA) and equipped with a C60 ion beam (IOG C60-20S, Ionoptika, Chandler’s Ford, UK), with a Timepix3 ASIC-based camera (TPX3CAM, Amsterdam Scientific Instruments, Amsterdam, NL).

Results

The acquired ToF-SIMS and FMM mass spectral images of biological tissue show promise for antibody detection comparable to those observed using standard microscope-based workflows. Using IMS-IHC, it was possible to visualize elemental ions in fresh-frozen tissue sections with a high spatial resolution. The results were correlated with adjacent serial sections using optical microscopy and standard histological staining (H&E staining). A proof-of-concept study demonstrated the use of FMM as a tool for imaging by measuring the unfrosted part of a microscopy slide (23.5 x 40 mm) in under 4.5 minutes, at a pixel size of 900 nm.

Conclusion

The first steps of implementing FMM as a technique for MSI-IHC experiments instrumentation are presented. The elemental-mass-based multiplexed analysis, used to visualize protein expression on fresh frozen tissue, bypasses the limitation of both the traditional staining techniques relying on

optical absorbance or fluorescence signals and mass spectrometry imaging performed in "microprobe mode".

PS-06, Lecture Theater 1, august 29, 2024, 10:30 - 12:30

Background

The transmission of sound through the human middle ear is a complex process that relies on the biomechanical properties of the ossicular chain, comprising the malleus (hammer), incus (anvil), and stapes (stirrup). These ossicles are the smallest bones in the human body and are responsible for amplifying and efficiently transmitting sound vibrations from the tympanic membrane to the cochlea [1]. Their biomechanical properties are intricately linked to their structure, spanning from the molecular scale (e.g., collagen triple helix) to the millimetric scale (e.g., foramen).
In cases of conductive hearing loss resulting from an impaired ossicular chain, reconstructive surgeries are necessary to restore hearing function. In these procedures, the incus plays a crucial role as either a support for prostheses or as a material to be sculpted itself, serving as an autologous passive implant [2]. However, the optimal positioning of prostheses on the incus and the effects of the carving process on incus biomechanics remain largely unknown and would strongly benefit from an improved knowledge of the ossicles' organization across several length scales.
The ossicles display a hierarchical bone organization, beginning with collagen triple helices that further assemble into fibrils with a periodic d-spacing of approximately 67 nm. These fibrils are mineralized by hydroxyapatite (HA) forming mineral platelets that mostly align with collagen fibrils. However, the shape of these nano-mineral particles and the orientation of collagen fibrils across a significant volume of ossicle, as well as their interactions with the vascular and nutritional foramen network, remain largely unclear to date.
Recently developed Small-Angle X-ray Scattering Tensor Tomography (SAS-TT) has emerged as the preferred method for 3D nanostructural characterization of mineralized tissues like bone over extended spatial regions. SAS-TT combines principles from Small-Angle X-ray Scattering (SAXS), which provides insights into anisotropic non-crystalline structures at sub-um scales, with X-ray tomography, enabling 3D volume measurements. The complete 3D reciprocal space (scattering directions) is reconstructed for each voxel, leading to detailed information about the 3D main orientation and degree of orientation of the set of nano-structures within each voxel.
In this study, our objective is to elucidate the organization of nano- and micro-structures within the human incus, clinically the most crucial auditory ossicles in surgery, using SAS-TT. We aim to gain insights into the preferential orientations induced by sound propagation and identify potential sites of bone remodeling. Additionally, we aim to understand the effect of the sculpting process and erosive pathologies on the inner organization of the incus body.

Methods

Our study includes 5 human incudes in various conditions: 3 healthy, 1 sculpted during ossiculoplasty, and 1 pathological with cholesteatoma, obtained from anonymous donors. The samples were further cut and milled down to a size of approximately 2.5 x 1.5 mm2 each. In the end, the long crus of 2 healthy incudes, and 3 sub-volumes from the body of 1 healthy incus, 1 sculpted incus, and 1 pathological incus, were examined using SAS-TT. The experiments were conducted at the PXI beamline of the SLS (Swiss Light Source, PSI), using a focused beam of 25 x 25 µm² at 12.4 keV and a 4M EIGER detector enabling acquisitions at 300 Hz, resolving a wide energy range. Detector data were reintegrated into 32 azimuthal bins in the range of q = 0.014 – 0.36 Å−1 and symmetrically averaged to eliminate detector gaps. The remaining 16 azimuthal bins were used as input for the SAS-TT reconstructions using the mumott Python library (https://mumott.org).

Results

First results were obtained on the long crus of 2 human incudes. The samples comprised the long process followed by the lenticular process that articulates with the stapes, the last bone of the ossicular chain. We were able to extract the main orientation of the mineralized collagen fibrils and their anisotropy, enabling the identification of 3 regions along the long process that exhibit a higher degree of orientation. These 3 regions with anisotropic collagen arrangement are located along the main vascular channel in the center of the long process, and converge at the bony pedicle, the junction between the long and the lenticular processes.
Further q-resolved analysis revealed the presence of three distinct phases corresponding to various shapes and sizes of mineralized particles within the incus, specifically distinguishing the inner part of the long process from the annular shell around the lenticular process.
Subsequently, we conducted a comparison of 3 incus bodies in various conditions (healthy, pathological and sculpted). The distribution of orientations and anisotropy were extracted for each condition. While no significant differences were observed between the healthy and sculpted samples, the incus body affected by cholesteatoma exhibited a more isotropic collagen fibril organization, with a broader orientation distribution across the sample and lower local degrees of orientation. Additionally, we used the mean intensity as a measure of the mineral density to quantify the prevalence of low-density tissue in the pathological case, suggesting that bone remodeling occurred at different sites.

Conclusions

SAS-TT enables access to structural parameters at both nano- and micro-scales throughout the entire volume of samples. When applied to investigate human auditory ossicles, it revealed anisotropic pathways at the collagen fibril level, which may play a crucial role in guiding sound waves through the bone. Additionally, it identified regions with diverse nano-structuring, pinpointing sites of potential bone remodeling. Furthermore, it shed light on changes occurring in the bone in cases of erosive pathologies such as cholesteatoma. These findings could provide valuable insights for optimizing middle-ear surgery, with wide-ranging benefits for patients with conductive hearing loss.

Poster Group 1

Background incl. aims
Carbonic anhydrase (CA) is an efficient catalyst for CO2 absorption in solvent-based carbon capture. 1 However, replenishment of CA could be required, because the solvent regeneration temperature is often higher than the enzyme's thermal tolerance, leading to CA deactivation. Alternatively, immobilizing the enzyme on solid carriers can improve its stability and longevity, allowing for catalyst recovery and reuse, and reducing overall costs. 2,3 We are developing immobilization techniques to address this challenge, which calls for high-resolution visualization techniques to design the distribution of enzymes immobilized at condensed matter interfaces and optimize their accessibility with gases and liquids. 4

Methods
We use transmission electron microscopy (TEM) and fluorescent microscopy (FM) to investigate the interaction of the immobilized enzyme with the support nanostructure and substrate, with the aim of uncovering attributes that maximize the biocatalytic interaction.

Results
Various immobilization techniques were employed to achieve the desired surface coverage of the CA enzyme on carbon nanotubes. Two different methods were used - secondary π-π interaction and EDC/NHS covalent coupling. After fluorescent labeling and immobilization, the enzymes were found to be active. High-resolution TEM and fluorescent microscopy were used to further characterize the immobilization process, which showed a high enzyme coverage and activity on the surface.

Conclusion
With the systematic development of immobilization chemistry and imaging techniques, we would unlock new insights into the dispersion and structural aspects of immobilized enzymes.

Poster Group 1

Background incl. aims
Perovskite relaxor ferroelectric materials are very interesting for a variety of applications due to their extraordinary piezoelectric properties. However, understanding the complicated local order/disorder phenomena within these materials is crucial for optimizing their performance. Transmission Electron Microscopy (TEM) and Scanning Transmission Electron Microscopy (STEM) techniques were employed to study the local order/disorder phenomena in (1-x)$Na_{1}/_{2}Bi_{1}/_{2}TiO_3$-x$BaTiO_3$ (NBT-BT) compositions with varying $BaTiO_3$ concentration (x = 2.5, 7.5, and 15 mol%).

Methods
The samples with mol fractions of 0.025, 0.075, and 0.15 were prepared using conventional synthesis methods for mixed oxides. High-purity powders of Bi_2O_3, Ti_2O, Na_2CO_3, $BaCO_3$, and K_2CO_3 were combined in stoichiometric ratios and then milled in a planetary mill at 250 RPM for 2 hours. After drying, the mixture was calcined three times at 920°C for 5 hours to ensure the formation and purity of the perovskite-type phase. The resulting powder was ground again and passed through a 100 µm sieve. Afterward, the powders were compacted uniaxially and isostatically at 180 Mpa pressure into discs, then sintered at 1080°C for 10 hours in a powder bed of the same composition to minimize element volatilization. Cross-sectional samples were prepared using the ThermoFischer Scios 2 DualBeam in the Scientific and Technical Resources Service of the Universitat Rovira i Virgili.
Our research was aimed at understanding the chemical composition, domain configurations, and structural evolution of these materials. The crystalline structure was analyzed by selected area diffraction (SAED); local changes in lattice parameters were monitored using HAADF-STEM and the presence of polar nanodomains (PNRs) was assessed by iDPC imaging techniques. The samples were observed in a ThermoFisher SPECTRA (S)TEM 300 at 300 kV (ALBA synchrotron), in a JEOL 2010F TEM, and in a JEOL 2100 TEM, both working at 200 kV (Scientific and Technological Centers of the Universitat de Barcelona).

Results
Our findings showed the presence of various phases within the samples. For lower x value, R3c symmetry coexisted with Pm-3m, but higher BaTiO3 ratios resulted in a transition from Pm-3m to P4bm symmetry. For the sample with x=0.15 mol, only P4bm symmetry was observed. Conversely, for x=0.025 mol, R3c and Pm-3m symmetries were detected, and for x=0.075 mol, all three symmetries were observed in distinct grains. The analysis of the lattice parameters through HAADF and iDPC images also showed the transition from a rhombohedral phase for x=0.025, to a cubic phase

for x=0.075, and to the tetragonal phase for x=0.15 mol. Polarization maps from iDPC technique will highlight the presence of PNRs. Electron Energy Loss Spectroscopy (EELS) also exhibited particular features in the spectra when increasing the $BaTiO_3$ ratio. Low-loss energy loss spectroscopy was also conducted to observe variations in the optical response and to compare them with Density Functional Theory (DFT) simulated data of $BaTiO_3$, $BiTiO_3$, and $NaTiO_3$ using the Vienna Ab initio Simulation Package (VASP).

Conclusion
This study explores the general panorama of domain configurations and structural complexities in these materials, as well as the spectroscopic properties observed, including the dielectric function and ELF, as the $BaTiO_3$ ratio is incrementally increased.

Poster Group 1

Background incl. aims
Antibiotic resistance is a global health crisis with the ever growing need to develop novel antibiotics and strategies to treat resistant infections. Bacteriophage therapy is often highlighted as an alternative approach due to its high specificity to kill a certain bacterial strain. However, bacteriophage propagate through a replication cycle within the target bacterium, with the potential to generate mutations with detrimental consequences. Strains of Pseudomonas sp. produce phage tail-like bacteriocins (PTLBs) which have evolved from bacteriophage. Although sharing many similarities, they differ from bacteriophage lacking a capsid and therefore the ability to replicate. These unique features highlight the potential of PTLBs as an alternative therapy to treat bacterial infections as they can be tittered to a specific dose. However, for PTLBs to be implemented as a bactericidal treatment, further information is needed regarding their structure, mechanism of action and how they recognise their target strains. We have isolated a contracting PTLB from an environmental strain of P. veronii and determined its structure by cryo-EM.

Methods
The PTLB was purified by ammonium sulphate precipitation and visualised by cryo-EM. The structure of the PTLB was determined using a combination approach of single particle and helical analysis.

Results
The structure was determined of a new clade of contracting PTLBs in both its uncontracted and contracted states. We also identified the lack of a ‘ruler protein’ for the purified PTLBs, observing varying lengths in the collected micrographs.

Conclusion
We solved the structure of a novel contracting PTLB and show that it shares structural similarities with the previously characterised contractile nanomachine from P. aeruginosa. We also observe that inconsistent lengths of PTLBs does not appear to affect the lethality of the PTLB to its target strain.

Poster Group 2

Background incl. aims
Topological crystalline insulators (TCIs) belong to extensively investigated research area of topological quantum matter. The interest in TCIs stems from the presence of topologically protected Dirac states on high symmetry surfaces of TCI crystals. (Pb,Sn)Te solid solution is one representative of TCIs, with topological phase occurring above some critical Sn content. Since topologically protected states in TCIs are surface properties we have studied this material in quasi one dimensional nanowire (NW) geometry providing high surface-to-volume ratio. To further enhance the surface-related properties we have chosen to investigate core-shell NW heterostructures with wurtzite (WZ) GaAs cores and (Pb,Sn)Te shells instead of uniform NWs.
Methods
Core-shell NW heterostructures have been grown by molecular beam epitaxy using two distinct MBE systems dedicated to III-V, and IV-VI semiconductors. The interface structure of WZ-GaAs/(Pb,Sn)Te NWs is investigated using wide range of characterization techniques, such as high resolution transmission electron microscopy (HR-TEM), scanning transmission electron microscopy (STEM), geometric phase analysis (GPA) and energy dispersive x-ray spectroscopy (EDX).
Results
Misfit dislocations are observed as a direct result of the lattice mismatch between the core and the shell materials. Measured distances of moiré fringes match calculated spacings of misfit dislocations observed to be higher than the calculated values, suggesting the presence of a residual strain within the structures.
Conclusion
We have shown that (Pb,Sn)Te can be successfully grown as continuous full or half-shells on the sidewalls of GaAs NWs. This provides opportunity for investigation of topological surfaces of TCIs in the tubular geometry.

Poster Group 1

Background
Autism Spectrum Disorder (ASD), classified under neurodevelopmental disorders, is characterized by persistent deficits in social communication and interaction, along with repetitive behavioral patterns. Histomorphological changes occur in various brain regions in ASD. This study aims to investigate pathophysiological alterations in the cerebellum of rats with valproic acid (VPA)-induced autism model.
Methods
Adult female and male Sprague-Dawley rats were allowed to mate overnight. Rats with confirmed vaginal plugs the following day were considered pregnant, and embryonic day 0 (E0) was recorded. VPA (500 mg/kg) was injected intraperitoneally (i.p.) on embryonic day 12 (E12). On postnatal day 21 (P21) the genders of the offspring were determined and weaned. Rats were sacrificed at P46, and cerebellar tissues were collected. The sections were firstly stained with cresyl violet, and then random micrographs of the cerebellar cortex were captured from three serial sections at three different areas for each section. Afterward, the number of Purkinje cells was divided by the line measurement expressed as µm between the molecular and granular layers.
Results
In light microscopic examination, the number of Purkinje cells per unit length was significantly lower in the VPA-treated groups compared to the control groups in both sexes ($p<0.001$) (Female-control:0,0296±0,00263, male-control:0,0286±0,00365, Female-VPA:0,0224±0,00280, Male-VPA:0,0216±0,00254). There was no statistically significant difference between genders.
Conclusion
The number of Purkinje cells in cerebellum decreased in VPA-induced autism model. Additionally, there was no difference between genders. These results may consider that autism is also related with Purkinje cells.

Poster Group 1

Background incl. aims
We have previously presented novel optical autofocus modules that simultaneously provide extended range of operation (>100 µm) and high precision (<600 nm) using machine learning [1] in a 2-step approach or providing closed loop "single-shot" operation over up to ±37 µm with <50 nm accuracy [2]. These levels of performance are realised by focusing an infrared laser beam onto the microscope coverslip with the back reflection being imaged on a dedicated autofocus camera. We derive a metric that quantifies defocus from the size of the light distribution at the autofocus camera that can be independent of laser power and insensitive to drift in the optical alignment. The operating range and precision depend on the confocal parameter of the autofocus laser beam after being focused by the objective lens. This can be adjusted by changing the diameter of the autofocus laser beam incident at the objective lens. By contriving a different beam diameter in two orthogonal planes using either a rectangular aperture [1] in the collimated autofocus laser beam, or using different orthogonal cylindrical lenses [2] to collimate the autofocus laser beam emerging from the single mode fibre that delivers it to the autofocus module, we can maximise precision (with maximum beam diameter) and extend operating range (reducing orthogonal beam diameter), making both measurements simultaneously by resolving the autofocus camera image along orthogonal directions.
While these two approaches can provide months of stable operation, they each have their drawbacks. The machine learning approach with the rectangular apertured beam [1] requires a convolutional neural network to be trained to determine magnitude and sign of defocus from the autofocus camera image and we found it necessary to train it over ~10 days to make it independent of any system variations impacting the autofocus camera image. For the second approach [2], we slightly offset the collimation of the cylindrical lenses such that the measured defocus is different for the two planes defined by the orthogonal cylindrical lenses, and this enables the magnitude and sign of the defocus to be calculated from a single autofocus camera image following calibration of the system. However, while the system reported in [1] utilised a low-cost single-mode fibre (SMF)-coupled laser diode, we used a superluminescent diode (SLD) in the system reported in [2] since its performance was impacted by interference between the autofocus laser beam reflected from the coverslip and unwanted beam(s) reflected from other surfaces in the optical system. Using the SLD removed this interference. Unfortunately, SLDs are significantly more expensive than laser diodes, and availability can be intermittent. Accordingly, we are redesigning the optical system and analysis method to enable the closed-loop approach of [2] to be used with a simple fibre-coupled diode laser for implementation in slide scanning and automated multiwell plate microscopy.
Methods
We determined that the primary source of unwanted back reflections of the autofocus laser beam were from the microscope objective lens, and we modified the optical system such that the curvatures of the unwanted back-reflected wavefronts are different from the desired autofocus

beam reflected from the coverslip. Utilizing a modified background subtraction and signal processing algorithm we were able to achieve stable operation of this autofocus using a simple SMF-coupled diode laser implemented on an openFrame-based microscope [2] with a 100x oil immersion objective lens that was controlled using MicroManager [3]. To independently measure the performance of the autofocus system, we configured the microscope for brightfield transillumination imaging of a USAF test chart and imaged the edge of a bar to derive a metric of defocus from the steepness of the gradient of this edge. We are also working on a fluorescent bead image-based approach utilising machine learning to determine defocus from a single bead image for real-time monitoring.

Results

We were able to achieve stable operation of this autofocus using a simple SMF-coupled diode laser implemented on an openFrame-based microscope [2] with a 100x oil immersion objective lens. When imaging a test chart in transillumination, focus was maintained in closed loop within 200 nm over 5000 seconds – and within < 50nm over 500 seconds. The autofocus system can recover focus with single-shot operation within a range of ~60 µm and up to ~80 µm in a multi-step mode [2]. We are working to improve the autofocus precision and range and are cross-validating the measurement of defocus between the autofocus readout, the transillumination edge measurement and the machine learning approach applied to bead images. We will also explore using higher power multimode laser diodes that exhibit shorter coherence lengths [4] although these present additional laser safety considerations.

Conclusions

We have demonstrated that we can implement an optical autofocus using a low-cost diode laser that can provide closed loop “single-shot” operation and is suitable for multiwell plate imaging and slide scanning. This is important for the development of cost-effective instrumentation, including modular openFrame-based instruments for pathology and high content analysis. We will present the latest design together with methods to independently validate the correction of defocus.

Poster Group 2

Background incl. aims
Magnetic fluids, colloidal suspensions of magnetic nanoparticles (MNPs), exhibit intriguing self-assembly behaviors that are essential for numerous applications in biomedical, engineering, and artistic fields. Despite numerous simulations, experimental insights into the nanoscale self-assembly process in liquid phases remain scarce. The present study aims to address this deficit by employing advanced transmission electron microscopy (TEM) techniques to elucidate the intricate relationship between the self-assembly phenomena and the magnetic properties in magnetic fluids, in particular in those composed of iron oxide nanoparticles.
Methods
Our investigation involves a multi-scale approach using state-of-the-art TEM methods. First, in-situ observations of magnetic field-induced chaining are conducted using liquid cells, allowing real-time visualization of the self-assembly dynamics. Subsequently, advanced characterization techniques will be employed. These include off-axis electron holography to analyze the magnetic and structural properties of MNP assemblies, and precession-assisted 4D-STEM for orientation mapping. Quantitative measurements of magnetic property distributions based on first-order reversal curve (FORC) diagrams obtained by electron holography will also be performed. With a special focus on electron holography data, the development of software tools for automated data acquisition and analysis is described.
Results
Preliminary results show the successful characterization of self-assembly processes by cryo-TEM. The formation of diverse structures such as chains, rings and networks is demonstrated. Statistical analysis shows excellent agreement between experimental observations and Monte Carlo simulations. Electron holography measured on several assemblies suggests a competition between magnetic dipolar interactions and magnetic anisotropy energy, which deeply affects our understanding of the self-assembly process. In addition, we were able to establish a relationship between macroscopic magnetometry and nanoscale structural organization by combining experimental and simulated FORC diagrams. This is a promising approach for the measurement of magnetic nanostructures with different geometries and chemical compositions.
Conclusion
In summary, our study demonstrates the ability of advanced electron microscopy techniques to resolve the intricate dynamics of self-assembly processes in magnetic fluids. By studying magnetic interactions and structural organization at the nanoscale, our results provide insights that can aid in the efficient design and optimization of magnetic fluid-based technologies. In addition, the development of software tools for data acquisition and analysis offers potential improvements in the accessibility and applicability of advanced TEM methods in the study of magnetic nanomaterials.

3D reconstruction and temporal development analysis of dendritic spines

Mrs. Iva Svecova[1], Stepan Kortus[1]
[1]The Institute of Experimental Medicine CAS, Prague, Czech Republic

Poster Group 2

Background
Recent advancements in live cell microscopy have significantly improved our ability to study the dynamics of dendritic spines—membranous protrusions with a role in synaptic transmission (1,2). Even though several spine analysis tools have been published, it is still difficult to satisfyingly capture and analyze both spatial and temporal aspects of the data. To address this limitation, we developed Irbis, a new comprehensive software tailored for analyzing live cell fluorescence microscopy images of dendritic spines.
Methods
The software was designed to process 3D/4D fluorescence microscopy data. This data is used to create a 3D reconstruction, that is subsequently segmented into individual spines. To create the 3D reconstruction, several algorithms from 3D modelling, medical imaging and LiDAR technologies are utilized, among others Marching cube algorithm and Poisson surface reconstruction (3).
To be able to separate individual spines from the rest of the dendrite, we developed a method for approximation of the dendritic shaft. The approximation model is combined with the 3D reconstruction of the whole dendrite and used to separate the spines. Subsequently, individual spines are matched across time and their temporal dynamics can be analyzed.
The software was developed in Matlab with incorporation of Python libraries, such as PyMeshLab for 3D mesh processing (4).
Results
Irbis is a software tool capable of 3D reconstruction of the dendrites and subsequent separation and matching of dendritic spines over time. The resulting 3D model facilitates intuitive understanding of the biological system, as well as serving as a basis for subsequent quantitative analysis.
The software is designed as a standalone application with a user-friendly graphical user interface. Its design simplifies complex data analysis tasks, making it accessible to researchers without requiring any coding skills.
Conclusion
Irbis effectively bridges the gap in current analytical capabilities by providing robust tools for detailed 3D and temporal analysis of dendritic spines. This enables a deeper understanding of spine dynamics and their role in synaptic transmission. Its ease of use makes Irbis a valuable tool in neuroscience research.

Fast large-area EDS characterization of additive manufactured steels

Dylan Connor Bailey1, Christina Nicole König1, Joerg Jinschek1

1National Centre for Nano Fabrication and Characterization (DTU Nanolab), Technical University of Denmark, Kongens Lyngby, Denmark

Background

Powder Plasma Arc Additive Manufacturing (PLAAM) is a state-of-the-art approach for producing large-scale metallic samples with targeted geometry. One of this technology's defining features is its ability to produce samples with variable chemical composition.

However, further developments in novel additive manufacturing processes, such as PLAAM, require further development in characterization concepts and methodologies. Due to varying alloy composition, unknown process-microstructure-property relations and complex time-temperature-location profiles for each specimen, which result in evaporation, dilution and diffusion, there is a need for a method for time-efficient large-area characterization to become statistically relevant.

Methods

Steel samples were manufactured using the PLAAM process. A layer of steel with the length of 1 meter was welded onto a steel substrate. The chemical composition of the sample was varied gradually from a composition of a low alloyed Carbon Steel to a highly alloyed stainless steel (316L).

Using a Flatquad detector (Bruker®), a detailed energy dispersive spectroscopy (EDS) study was performed to investigate the varying chemical composition in the PLAAM steel samples. Thereby, the SEM electron beam scanning strategy was tested, and has been verified in respect to the results when characterizing the entire sample. In detail, the scanning strategy and parameters were optimized for analyzing for the varying chemical composition along and perpendicular to the PLAAM build direction as well as at the steel substrate interface with HT 20kV, current source 20 nA and dwell time 15µs. Additionally, the effects on diffusion from the thermal history of the build platform were analyzed.

Results

Optimization of the SEM beam scanning strategy and measurement system resulted in findings that were statistically consistent with large-area characterization of the samples using long dwell times (i.e., slow image acquisition).

The use of shorter dwell times, i.e. faster large-sample-area EDS mapping, significantly shortens the experimental time while introducing less significant statistical noise.

Further insights into the effects of local composition control were gained to further optimize the PLAAM process.

Conclusion

Using the Flatquad EDS detector allowed for a higher collection angle compared to normal angled EDS. Combined with an optimized SEM beam scanning strategy, we were able to significantly reduce measurement time required for large-area measurement of PLAAM samples and increased through-put to gain statistically relevant insights into the process-microstructure-property relationship of PLAAM structures.

Synaptic vesicles are important organelles in neurotransmission and their precise composition is essential for information transfer from neuron to neuron. While many aspects about their functions at the synapse are known, open questions remain regarding how these stoichiometrically highly-precise organelles are formed and maintained to mature to functional SVs that are able to release neurotransmitters at the synapse. To accurately study SV biogenesis, it is important to maintain the highly-precise stoichiometry of SV components in place and untouched. This renders experiments involving overexpression of a particular SV protein of difficult interpretation and instead requires endogenous expression.
One powerful approach to access endogenous localization, distribution and movement of proteins are intrabodies: small probes based on high-affinity nanobodies that can be expressed inside the cell. Here, I present the characterization of an intrabody against the SV Ca2+-sensor Synaptotagmin-1 (Syt1), that was named iNbSyt1. As shown in our recently published paper (https://doi.org/10.1002/smtd.202300218), this intrabody enables not only the direct live imaging of SVs (mScarlet-/mNeonGreen-iNbSyt1), but also allows to detect single action potentials thanks to a highly sensitive synaptically localized Ca2+-sensor, jGCaMP8s-iNbSyt1. Meanwhile, expression of iNbSyt1 does not affect vesicle mobility, synaptic localization, or fusion capacity, which makes this highly modifiable tool optimal to study synaptic processes in living neurons without genetic perturbation of the SV protein target. Likewise, we show that the underlying nanobody also is an ideal probe for several super-resolution imaging techniques, including STED microscopy, Structured Illumination Microscopy (SIM), DNA-PAINT and Expansion Microscopy.
Overall, the NbSyt1 is a versatile small imaging probe that offers adaptation to divers experimental requirements and will find a broad use in the microscopy field.

Background incl. aims
Visualizing the metabolism within its structural context is key to understanding the biological phenomena at stake. The microalga Sanguina nivaloides was recently identified as the responsible fopr the reddish color on snowfields, notably in the Alps. This organism is yet uncultivable in laboratory conditions, rendering most classical 'bulk' metabolomics analysis largely impossible. Time-of-flight secondary ion mass spectrometry (TOF-SIMS) enables the combined visualization of elements and molecules and is becoming more and more popular in the field of life sciences, especially for the investigation of tissue samples. Even though the ultimate lateral resolution of TOF-SIMS ought to be sufficient for subcellular imaging, very few studies have yet pushed the lateral resolution that far.
Methods
In this context, we have investigated how the subcellular architecture and molecular composition of Sanguina nivaloides is affected by the extreme environment it thrives in. For this purpose, we have performed TOF-SIMS imaging, combining both high lateral resolution (up to 100 nm) and high mass resolution (up to 9,000) over resin-embedded specimen using a NanoTOF II (ULVAC-PHI) instrument. We also performed over the same zone correlative SEM (10 nm) in order to identify subcellular compartments and used this image to segment the hyperspectral TOF-SIMS dataset. We are thus combining the strength of both techniques and increasing the resolution of TOF-SIMS imaging using SEM-derived information.
Results
In these algae, we have been able to locate proteins, carbohydrates, micronutrients, etc. across several subcellular features, including cell walls as thin as ~ 100 nm, nuclei, pyrenoid, starch and chloroplasts. High molecular weight molecules are being detected in the lipid droplets, however the sample preparation induced molecular damage does not allow for the identification of these species. Interestingly, the bacteria located around the cells display a higher phosphate content than the cells themselves. Our study also reveals the presence of cell wall specific compounds, while most of the micronutrients with the exception of phosphate and calcium are preferentially located in the mineralized particles located around the cells, hinting for a possible way that the alga collects micronutrients from its environment.
Conclusion
We have been able to perform molecular profiling of the microalga S. nivaloides at the organelle scale and revealed how this organism is allocating its resources to the different compartments so as to bloom in a cold and nutrient-deprived environment. We show that our approach of correlating high lateral and mass resolution TOF-SIMS with SEM is an effective manner to decipher the organelle content of microorganisms.

Innovative Microfluidic chip for Raman spectroscopy and advanced electron microscopy techniques

Ing. Tomas Laznicka[1], Jan Jezek[1], Kamila Hrubanova[1], Vladislav Krzyzanek[1]
[1]Institute of Scientific Instruments, The Czech Academy of Sciences, v.v.i., Brno, Czech Republic

Poster Group 1

Background
In microbiology research, there is a growing need for equipment that allows the study of biological samples with high resolution and preservation of their structural integrity. In this article, we present a new device, a microfluidic chip, designed for high-pressure freezing (HPF) of biological samples, freeze-fracture and their subsequent analysis using a combination of Raman spectroscopy and focused ion beam scanning electron microscopy at cryogenic temperatures (cryo-FIB-SEM). Microfluidic chips, created by microfabrication techniques, manipulate with a small amount of fluid volumes using intricately designed channels and chambers. Their precision and efficiency offer advantages over traditional methods, leading to the applications in bioanalysis, medicine, and environmental monitoring. Ongoing research focuses on enhancing chip design and integration with complementary technologies to extend their capabilities further [1]. Microfluidic chip technology has revolutionized fluid handling and analysis at a miniature scale, offering unprecedented control over fluidic processes through intricate networks of microchannels, chambers, valves, and pumps fabricated using advanced microfabrication techniques. This miniaturization enables precise manipulation of small fluid volumes, leading to applications in bioanalytical chemistry, biotechnology, medicine, and environmental monitoring.
The cryo-fixation of the microfluidic chips is very limited by a thickness of the material (sample) that must be frozen [2]. The only known microfluidics freezing system used for cryo-fixation of cells was published in 2014 using direct freezing in the optical microscope. The use of HPF presents the possibility of rapid freezing of even thicker samples (up to 600 nm) with subsequent observation by electron microscope under cryogenic conditions.
In our study, we present the application of a microfluidic chip in the research of microorganisms producing Polyhydroxyalkanoates (PHAs), which have the potential to serve as an alternative option to petrochemically produced plastics [3].

Methods
The microfluidic chip is designed primarily for frozen biological samples using a combination of Raman spectroscopy and focused beam scanning electron microscopy (cryo-FIB-SEM). This advanced chip allows the manipulation of biological samples that are either dissolved or mixed with liquid, providing the ability to perform detailed analysis and manipulation at the microscopic level. Biological samples are fixed using (HPF) and stored in liquid nitrogen. HPF is the only method used for freezing thick biological samples without the effect of ice crystalization. Fabrication of the structures that make up the microfluidic chip is done by soft lithography followed by the use of oxygen plasma to fuse the structures.

Results
The structure of the microfluidic chip consists of two thin layers of polydimethylsiloxane (PDMS). One of these layers contains channels for the flow of the sample liquid and a chamber for higher sample concentration (the chamber passes through the entire layer), while the other layer does not contain

these structures. These PDMS layers are then bonded using oxygen plasma, which provides a tight bond and allows the sample to move only within the channels. The microfluidic chip also includes a sapphire disk that allows the sample to be observed inside the chip and serves as a heat transfer medium for fast freezing processes. Ports are also attached to the inlets of the channels for easier introduction of liquid samples, which also allows for various manipulations such as mixing liquids. Once the chip is filled with the sample liquid, analysis is performed using Raman spectroscopy and the possible use of Raman tweezers to manipulate cells or particles. Subsequently, the chip is modified using a unique punch device to be inserted into the HPF. The sample is rapidly frozen using HPF and preserved in liquid nitrogen, allowing the sample to be studied in the state in which the biological material was at the time of freezing. The sample can then be inserted into a scanning cryo-electron microscope and analyzed using a focused ion beam.

Conclusion

Overall, this microfluidic chip represents an innovative tool for studying biological samples and using high-pressure freezing; high resolution is achieved by preserving their structural integrity. The combination of Raman spectroscopy and scanning cryo-electron microscopy enables detailed analysis and manipulation of biological samples, which has the potential to push the boundaries in microbiological research and biomedical science.

Electrons phase reconstruction using Kramers-Kronig relations

Dr. Yang Yin[1], Dr. Wenhao He[1], Prof. Changlin Zheng[1]
[1]Department of Physics,Fudan University, Shanghai, China

Poster Group 2

Background incl. aims
Phase imaging plays an important role in electron microscopy, particularly in mapping electric and magnetic fields at the nano and atomic scale. In this presentation we introduce a new electron phase imaging approach based on Kramers-Kronig (KK) relations, which is originally developed for optical imaging [1, 2].

Methods
According to the Kramers-Kronig relations, the real and imaginary parts of a complex function transform into each other when the function is analytical in the upper half-plane. This results in a clear link between the amplitude and phase of the exit wave. As a first attempt, we applied such KK method to reconstruct the phase of off-axis electron hologram. The experiments were performed on a Thermo Fisher Scientific Themis Z transmission electron microscope fitted with an electron biprism. An off-axis electron hologram of nano particles was then recorded using a CETA -S camera (see Fig.1). We applied the KK reconstruction on the electron holograms, the detailed reconstruction procedure is illustrated in Fig. 1. We also performed the conventional Fourier transform reconstruction for comparison.

Results :
The reconstructed amplitude and phase images based on KK relations are shown in Fig.1. Further comparsion with Fourier transform method reveals that the KK reconstruction results are consistent with Fourier transform method.

Conclusion
Here, we show that the Kramers-Kronig relation can be used to recover phase information from electron holograms. This method not only provides an alternative to conventional Fourier transform reconstruction but also helps surpass bandwidth limits when using a digital aperture in conventional Fourier transform reconstruction.

Compartmentalization of synaptic ER studied by correlative FLIP and FIB-SEM

Dr. Helena Vihinen[1], Dr. Leena-Stiina Kontturi[2], Asst. Prof. Juha Saarikangas[2], Dr. Eija Jokitalo[1]
[1]Electron Microscopy Unit, Helsinki Institute of Life Science, Institute of Biotechnology, University of Helsinki, Helsinki, Finland, [2]Helsinki Institute of Life Science and Faculty of Biological and Environmental Sciences, University of Helsinki, , Finland

LS-04 (2), Lecture Theater 4, august 29, 2024, 14:00 - 16:00

In hippocampal pyramidal cells, the endoplasmic reticulum (ER) comprises of small sheets connected with tubular network spreading to the tip of the axons and dendritic branches where it participates in the local protein synthesis required for synaptic transmission. The ER is known to be present in some of the dendritic protrusions called spines and it is highly dynamic in nature (Breit et al., 2018, Konietzny et al., 2023). In large spines, the ER forms a specialized organelle, the spine apparatus whereas in smaller spines the ER can comprises only one single ER tubule. Thousands of spines protruding from a single neuron differ morphologically and functionally from each other. To response to activation independently, each spine is supposed to have a distinct microenvironment e.g., the concentration of calcium ions differs from that in the dendrite and other spines (Breit et al., 2018). The spine morphology supports the compartmentalization, however other mechanisms are needed to obtain unidirectional diffusion and separated environment. The aim of this research was to substantiate whether the synaptic ER can be compartmentalized in the dendritic spines.

To study the compartmentalization of the synaptic ER, primary hippocampal neurons were cultivated on etched cover slips and transiently transfected with fluorescence markers for the ER and cytoplasm. The target dendrite was subjected to FLIP (fluorescence loss in photobleaching) where a part of the dendrite was bleached by pulsed light and the amount of fluorescence at the target spines after each pulse was detected. After FLIP the samples were chemically fixed and prepared for FIB-SEM (focused ion beam scanning electron microscopy). The target areas imaged with light microscope were correlated in FIB-SEM using a back scattered electron detector and the datasets were collected using 6 or 8 nm isotropic pixels. The dendrites in the FIB-SEM datasets were modelled using semi-automated segmentation tools in Microscopy Image Browser software (MIB, Belevich et al., 2016).

The FLIP studies indicated that the ER proteins may be in compartments closed off from the rest of the dendrite, preventing them from being affected by the repeated photobleaching. FIB-SEM applied to the correlated spines confirmed the results and revealed a subset of the non-continuous, compartmentalized synaptic ER. A single continuing ER tubule in a synaptic spine may have a diameter ca. 20 nm, however the volume-EM was required to enable the pinpointing the target spine in the complex neuronal network. In addition to compartmentalized synaptic ER, FIB-SEM data revealed variety of different shapes and size of dendritic spines as well as ER with two different densities. The ER with clearly different density joined and emerged throughout the whole volume of dendrites and even in some of the synaptic spines. No protein coat (possibly septin protein) could be detected around the spine neck, however, some of the spines with compartmentalized synaptic ER had a very long and narrow neck.

As a conclusion it can be said that correlative FLIP and FIB-SEM is a powerful tool to study temporally and spatially rare event in cell cultures and it allows to analyze the structures like a single tubular ER in a large neuronal network. Applying correlative FLIP and FIB-SEM verified the compartmentalization of the ER in a subset of synaptic spines. More studies must be done to further elucidate compartmentalization of the synaptic ER and its role in maintaining of synaptic strength and supporting neuronal function and plasticity.

Stromal cells remain the focus of research in tissue biology from past to present. It is known that the stroma hosts mainly fibroblasts, pericytes, neurons, endothelial cells and immune cells. These cell types also have various distinctive features due to their different morphologies and functional properties. In addition, other different cell types have also been described in the stroma, including the interstitial cells of Cajal and telocytes. Telocytes (TC), which are characterized with small cell bodies and long telopods, have been identified in the connective tissue of many organs and are strategically positioned between target cells, near nerve endings and capillaries. Telocytes coordinate tissue homeostasis by integrating information from multiple sources and their extracellular vesicles provide bidirectional communication between them and the other stromal cells. They are able to regulate stem cell proliferation and differentiation through their secretome and play crucial roles in embryogenesis, angiogenesis, and various diseases, including cancer. Human telocytes have so far beenidentified in the heart, lung, brain, eye, thyroid, skeletal muscles, skin, gastrointestinal tract and accessory glands, urinary system, and male and female reproductive systems. But there is no information about the relationship between the telocyte cells and the Infrapatellar Fat Pad (IPFP). The approach to serious joint diseases such as osteoarthritis (OA), which is highly prevalent in our society and causes significant morbidity in the population and treatment is currently limited to microfracture treatments, autologous chondrocyte transplantations and prosthetic surgery. The incidence of symptomatic OA in the obese and elderly population and the high costs of joint replacement surgeries are increasing every year. Therefore, in addition to current treatments, the search for tissue engineering and stem cell-based research continues to meet the needs for alternative treatment methods. In recent years, tissue engineering studies have emerged as promising methods in orthopedic treatment approaches. Difficulties that may be experienced in obtaining mesenchymal stem cells (MSCs) obtained from various sources may also lead to undesirable pathological conditions such as heterogeneity in the obtained stem cell populations and teratoma formation in new cartilage cell differentiation. For this reason, researchers are now focusing on different cellular sources. Infrapatellar fat pad (IPFP), also known as Hoffa; fat pad due to its proximity to articular cartilage, in recent years has been the focus of researchers working on the relationship between cartilage regeneration and the surrounding stem cells. Studies have shown that IPFP has a good stem cell reserve and is very suitable for studies based on cartilage retrieval. On the other hand, there are also studies showing that the use of IPFP-derived stem cells in repairing joint cartilage damage may be limited due to their heterogenity. In recent years, the presence of a unique cell group called telocytes, which is in close relationships with the stem cell niche, has been described in the stroma of many organs. These cells can stimulate stem cells with the microstructures they secrete called exosomes and induce tissue regeneration by creating cellular differentiation. The

existence of infrapatellar fat pad cells with surface markers same as telocytes have been reported in only one article in the literature. TC markers including CD34, vimentin, PDGRF-α and PDGRF-β, c-kit, and α-SMA are frequently used in telocyte studies and are regarded trustworthy. Double immunofluorescence is the most accurate and precise method for identifying these cells.

Aims: This research aims to advance our understanding of the heterogenity of IPFP cells and detect the presence of TCs by employing techniques such as immunohistochemistry and immunofluorescence. Through the investigation of their morphology and identification of telocytes in the IPFP stroma, this study endeavors to provide novel insights into IPFP architecture and its implications for regenerative medicine.

Methods: In this study, IPFP tissues were obtained from 5-10 patients preparing for knee replacement surgery at Sadi Konuk Training and Research Hospital, Orthopedics and Traumatology Clinic. After obtainiing the specimen one small piece of it underwent tissue preparation procedures for light microscopy and immunohistochemical staining was performed using CD34 which is the most common marker for telocyte identification. The rest of the specimen was used for cell culture from which these cells were isolated using tissue digestion agent such as collagenase II and cell strainers of different diameters in order to separate them from other stromal cells with the cell adhesion method and subculturing the media in which the telocytes were present during 96 hours. The cells were photographed at different incubation times such as at 24h, 48, and 96h and were examined under the inverted microscope. Finally the cells resembling to telocytes with their long projections were analyzed by double immunofluorescence staining used CD34/c- kit, CD34/vimentin, CD34/PDGFR- α and β, and CD34/ α-SMA markers for telocyte identification. This comprehensive approach aimed to illuminate telocyte presence and distribution in the IPFP stroma, offering future insights into IPFP physiology and pathophysiology.

Results: In this study, the existence of telocytes within the IPFP was identified by their different shape and immunophenotypes. We identified telocytes by immunohistochemical analysis, labeling with CD34, the most extensively utilized telocyte marker. We used immunofluorescence analysis with double labeling of CD34/c-kit, CD34/vimentin, and CD34/PDGFR α and β, CD34/α-SMA in order to distinguish these cells from fibroblasts and pericytes in cell culture.
We found out that TCs were strongly positive for CD34, PDGFR α and β, and vimentin and weakly positive for α-SMA. On the other hand fibroblasts and were found to be CD34 negative, while strongly positive for vimentin and PDGFR α and β. Notably, our findings delineate telocyte cells from fibroblasts and pericytes, underscoring their unique cellular identity within the IPFP microenvironment. TCs were recognized for their long and thin prolongations and small cell bodies primarily situated around blood vessels and dispersed throughout the IPFP stroma.

Conclusion: Our study adds greatly to our understanding of IPFP telocyte biology by shedding light on their presence, distribution, and morphological properties. As a result, these cells have the potential to be a unique progenitor cell source for cartilage regeneration, and they need full attention from researchers in the tissue engineering field.

Poster Group 1

EDS software often has the weakness that the (standardless) quantitative measurement result depends strongly on the energy calibration when peaks with evident overlap have to be deconvoluted. A typical solution is that the elements with the overlapping peaks are quantified using a WDS-analysis with much improved energy resolution and results are integrated into the EDS software via K-ratio values. Unfortunately, this WDS-analysis is then not standardless but standard based.
A combined EDS-/WDS-quantification method that is completely standardless is presented here. The novalty is that net-count ratios of the lines measured with WDS are taken into account in the Bayesian deconvolution for the standardless EDS-analysis. The by WDS measured net count ratios are used as additional boundary conditions of the probability theory based (Bayesian theorem) EDS spectrum deconvolution [1]. In this way, uncertain deconvolution of the EDS spectra is supported by additional real measured values. We use the software Benchmark-EDS and its standardless quantification model eZAF. In the latest program version Benchmark-EDS 2.01, an accuracy with relative result deviations of < ±10% was achieved (for 95% of all results) through dedicated model adjustments by empirical databases for ZAF method [2]. We will present additional EDS measurements on challenging samples on the poster, which are particularly suitable for evaluating the accuracy of standardless EDS-analysis.
The example of PbS (figure) shows how well the WDS supported deconvolution works. The spectra were measured with EDS and WDS spectrometers on a JEOL microprobe JXA-8530F. By varying the energy calibration from 5.00 eV/channel to 4.97 eV/channel, the pure EDS evaluation provides quite varying results (between 29 and 57 at% for S and 71 and 43 at% for Pb). The correct EDS quantification (50:50 at%) is achieved with 4.98 eV. With the WDS measurement support this influence of energy calibration can be eliminated. The normalised result (and at% then also) for this binary sample is determined exclusively by the deconvolution of the overlapping S- and Pb-lines. By taking into account the WDS measured line ratios, the quantification result is then stable at 50.64 at% / 49.36 at% . Uncertainties in the energy axis or other systematic errors of deconvolution of the pure EDS spectrum are then suppressed or, as in this case (binary sample, no other elements), no longer have any effect at all. It is worth noting that an EDS evaluation is still performed, but with additional WDS measurement knowledge and a probability-theory based deconvolution. The method works independently of different detection efficiencies of EDS- and WDS-detectors since peak-ratios are regarded only and the efficiency differences can be neglected since the line energies are similar. The method works even with more than 2 elements in the specimen and also if only a part of all elements is measured with WDS spectrometer, if applied only for selected EDS peak overlap problems. Additional application examples are included in the poster presentation.
In conclusion, the integration of standardless WDS-spectra acquired net-counts-ratios of lines that overlap in EDS spectra improves their peak deconvolution and makes the standardless EDS-quantification for EDS bad resolved line series independent from systematic peak deconvolution errors like the energy calibration.

Figure 1: EDS-/WDS-spectrum evaluation of PbS; a plot of deconvolution results [cps] depending on energy calibration w/wo WDS measurement support (the related quantitative results in at%)

Covalent organic frameworks (COFs) are a family of porous materials constructed through organic blocks connected by covalent bonds. Its versatility of functionality, its well-defined pores, and its high surface area / high porosity have cultivated many applications in gas storage, catalysis, and separation areas.
Determining the structure of three-dimensional COFs is important for understanding their structure-function relationships and enables the rational design of materials with better performance. The most trivial way to gather the structure information is through the single-crystal X-ray diffraction (SCXRD) method. However, the small crystal sizes of the COFs hindered the common routine of ab initio structure solution. Additionally, the poor crystallinity and polymorphism of COFs also make them difficult to analyze using powder XRD data.
Electron microscopy is widely used for structure characterization in material science and gained great success on the elucidation of many complex structures. It can investigate bulk structures of small crystals by three-dimensional electron diffraction (3DED) technique and local structures by imaging. Acquiring atomic-resolution images on 3D COFs remains challenging, especially due to the electron beam damage. In recent years, the development of electron detectors and image-acquisition methods have enabled high-resolution (S)TEM with ultralow electron doses, largely overcoming this challenge. The poor crystallinity, disorders, guest molecules, and flexible characteristics of COFs still undermine the determination of the COFs' structure.
We use the 3DED technique under cryogenic conditions to get the averaging atomic structure of novel 3D COFs. The accumulated electron dose is 6~15 e-/Å2. The structure is validated with corresponding low-dose high-resolution electron microscopy (HREM) images with relatively low position offsets. We hope this investigation will cultivate the further development of structure-solving on COFs and other organic materials.

In the development of on-chip electronics, group III/V semiconductor nanowires (NWs) hold great interest, due to their small footprint allowing compatibility with lattice mismatched substrates like silicon while greatly increasing the chemical flexibility.[2] Within this work GaAs-NWs with optically active axial InGaAs heterostructures and an AlGaAs capping layer are investigated. These spatially confined optical cavity structures facilitate low loss propagation of optical modes and show a high refractive index contrast.[3] We aim to create a better understanding of the exact structure and the resulting structure property relationship of the InGaAs heterostructure based on previously measured low-temperature photoluminescence spectra.[1]. As the functionality of these heterostructures, like efficient carrier confinement, is closely linked to their 3D structure and chemical composition, tomographic reconstructions employing STEM HAADF tilt-series were carried out. To this end a tilt series with a tilt range from -75° to 75° was measured on a probe corrected FEI Titan Themis electron microscope and reconstructed using a weighted SIRT algorithm as well as finite support correction after preprocessing and alignment. The resulting tomogram is shown as an isosurface in Figure 1a. It consists of six sidewall facets perpendicular to the main [111] growth direction terminating in aflat capping layer. Assuming Lambert-Beer's law, the obtained attenuation coefficients can be qualitatively correlated to atomic numbers by using two reference areas of the tomogram, here AlGaAs (Al and Ga assumed to be 1:1) and GaAs neglecting the very low Sb concentration. As the Z-contrast shows the average atomic number of the elements present, AlGaAs was set to Z = 27.5 and GaAs set to Z = 32 respectively. This assumes the small differences in crystal parameters between AlGaAs and GaAs are neglectable. The resulting element mapping corresponds well with the elemental compositions obtained from EDX, as can be seen by comparing Figure 1b and the corresponding EDX data acquired in the same projection direction in Figure 1c. While the facets are well measured some missing wedge artifacts and a slight density gradient based on the unaccounted carbon support are still present as seen in the slices along the growth direction shown in Figure 1e. The threefold faceted capping layers as seen in Figure 1e(i) show a truncated tetrahedral growth governed by the threefold symmetry of the ZnS type crystal structure of GaAs in combination with twinning defects. In order to validate the use of the Lambert-Beer-Law for STEM HAADF measurements, pytorch multi-slice simulations were conducted for GaAs at different tilt angles using the frozen phonon approximation to account for thermal diffuse scattering, and compared to the experimental results. Furthermore, the possibility to reducing the artifacts resulting from the missing wedge focus series are investigated by multi-slice simulations and experiments.

Figure 1: STEM tomographic analysis of the GaAsSb/InGaAs/AlGaAs NW heterostructure; (a) 3D isosurface rendering of the NW tip, illustrating the facet structure consisting of six sidewall facets perpendicular to the [111] growth direction. (b) Z-contrast volume rendering of the NW, (c) corresponding EDXS map of the same NW with comparable color code, (d) two central cuts parallel to {1-10} sidewall facets (as indicated in (a)), exposing the Z-contrast through the core. (e) Cross-

sections at different positions along the NW (as indicated in (d) by labels (i)-(iv)), revealing the Z-contrast in radial direction from top (GaAs) to bottom (GaAsSb) of the NW heterostructure.

Fluorescence emission anisotropy is the ratiometric measure of the polarization of fluorescence emission, which is used to provide insights into molecular organization. In the field of optical microscopy, the typical approach for multiwavelength emission anisotropy imaging involves either sequential imaging using a single camera [1] or simultaneous imaging using multiple cameras [2]. Given the limitations of the sequential imaging method, particularly in capturing sub-second dynamic processes in live-cell imaging, a viable option is the utilization of simultaneous imaging with multiple cameras. However, when accounting for multiple deformations or aberrations, the process of image registration for estimating anisotropy becomes more cumbersome. For facilitating simplified simultaneous imaging using a single camera, we engineered a novel multi wavelength, emission anisotropy image-splitter system. The measurement of point spread function (PSF) and dynamic range in emission anisotropy measurements served as critical parameters validating the potential of the constructed configuration for high-resolution cell imaging. We conducted simultaneous visualization and quantification of actin filament orientation using various actin labels, aiming to establish a benchmark for emission anisotropy measurements across three distinct excitation wavelengths: 488 nm, 561 nm, and 640 nm. Homo Förster Resonance Energy Transfer (Homo-FRET) assessments investigating the clustering behavior of Glycosylphosphatidylinositol-anchored proteins (GPI-AP) labeled with distinct fluorophores (GFP and mRuby) facilitated the realization of simultaneous multi-color anisotropy imaging through the utilization of a single camera system. We validated the capability of the system to accurately measure subtle changes in emission anisotropy during photobleaching of homo-FRET competent molecular species. This was demonstrated through a comparative study involving photobleaching of the trimeric VSVG-EGFP where VSVG-EGFP was diluted with a non-homo-FRET competent VSVG-tdTurboRFP, showcasing equivalent precision in anisotropy measurements. Simultaneous multi wavelength, emission anisotropy imaging of photoconversion of tetrameric Kaede and monomeric Dendra fluorescent proteins, transitioning from green to red fluorescence, provided a real time view of the interconversion dynamics inherent in the photoconversion process. Monte Carlo simulations were employed to provide an understanding of the intricate dynamics underlying the photoconversion process of the tetrameric fluorescent protein, demonstrating the power of this system. Simultaneous recording of Fluorescence Anisotropy Reporter (FLARE) sensors of PKA activity with cytosolic (mVenus-cpVenus-FLARE-AKAR, mCherry-mCherry-FLARE-AKAR) and membrane (LynmVenus- cpVenus-FLARE-AKAR) sensors [3], stimulated by G-protein coupled receptor activation, illustrates the optical splitter's capability to monitor the transfer of a second messenger signal from the membrane to the cytosol in real time. This substantiates the versatility of the setup, thereby unlocking a diverse array of applications within the realm of multiband emission anisotropy imaging.

1. Introduction

The development and construction of fusion reactor, such as ITER, have become very important in recent years, as has the development of new construction materials that can withstand the new requirements. Tungsten and tungsten-based alloys are considered as most promising candidate materials for these applications. Due to its favorable thermal and mechanical properties, such as high melting point, high thermal conductivity and low sputtering rate, the alloys were selected as the plasma facing materials in the ITER divertor.
Investigations of their radiation resistance, provide valuable information on the response of components to the fusion plasma. For this propose, tungsten samples were 20 MeV tungsten ion irradiated to create displacement damage and were subsequently loaded with deuterium. The aim of these investigations was to study the cause for the evolution of deuterium retention with damaging dose for samples where the displacement damage was created at a temperature of 1080°C.

2. Materials & methods

Pure W selected for this analysis was annealed at 2000°C so that the grain size increased to ~10 - 50 µm. The W-plates were W-irradiated with 20.3 MeV energy at different damage doses (0.1 dpa, 0.5 dpa and 2.3 dpa) at 1080°C. The thickness of the damaged layer formed in tungsten under these implantation conditions was ~2.5 µm. samples were loaded with deuterium at low energy and low flux (5 eV/D, $5x10^{19}$ D/m^2s) to decorate the existing defects without creating new ones. TEM lamellae preparation was carried out using the electron microscope Crossbeam Auriga, ZEISS. After preparation an electrochemical polishing process (flashing) of the lamellae was performed. The investigations were carried out using transmission electron microscopy (TEM) to determine the existence of voids and their distribution in the matrix over the cross-section, starting from the surface.

3. Results

TEM investigations of the prepared lamellae were performed using bright field imaging for the voids as well as scanning TEM dark field imaging to observe the formation of dislocation loops. The study demonstrates the homogeneous formation of voids in the depth up to 2.5 µm. The voids have a similar average size and a similar density over the whole thickness. The formation of inhomogeneities such as size peaks or number density peaks, which are typical for the implanted layers, was not observed. Figure 1 shows TEM cross-sections along the layers exposed to 0.1 dpa, 0.5 dpa and 2.3 dpa irradiation. The clearly visible fluctuations in the lamellae thickness are caused by the flash polishing of the film. The TEM images of all three tungsten samples clearly show the existence of voids of the nanometer size in the microstructure.

Figure 1: TEM image of the W irradiated to 0.1 dpa, 0.5 dpa and 2.3 dpa with finely distributed voids of different sizes.

4. Conclusions

The microstructure of tungsten irradiated to the damage dose of 0.1 dpa, 0.5 and 2.3 dpa at 1080°C were studied in detail using TEM. In all three samples, the existence of voids could be clearly demonstrated.

Background incl. aims
Large-scale and volume electron microscopy (EM) allow biologists to understand structural relations in biological systems from the nanometer up to the millimeter scale and beyond. However, EM data can be difficult and time-consuming to interpret and process due to a lack of biological specificity. Fluorescence microscopy (FM) can be used together with EM in correlative light and electron microscopy (CLEM) to add biologically relevant data to the EM images. CLEM does come at the cost of increased complexity and restrictions in sample preparation and measurement workflow. Furthermore, high-throughput EM methods like multi-beam scanning electron microscopy (MB-SEM) can be hard to combine with CLEM. We aim to develop a machine-learning model that can extract biologically relevant information from EM images, which is generalisable to different methods of EM.
Methods
Convolutional neural networks (CNNs) have been shown to perform well on various image-translation tasks in biomedical contexts. We explored the use of a CNN to extract biological information from EM images by imitating real fluorescence. We used a network architecture inspired by U-net, only with a truncated up-sampling arm to account for the resolution mismatch between EM and FM data. The network, named CLEMnet, was trained on CLEM datasets obtained using an integrated array tomography workflow. The dataset consists of rat pancreas tissue samples. The islet of Langerhans was stained with Hoechst, which binds DNA and RNA and immunolabeled for insulin using Alexa 594.
In regular EM, it can take a long time to acquire large volumes of EM data. To solve this, high-throughput EM methods have been developed. One of these methods is multi-beam optical scanning transmission electron microscopy (MB-OSTEM). In MB-OSTEM, contrast is generated by the number of transmitted electrons. As CLEMnet is only trained on data from one microscope, using only backscatter electrons as a detection method, it is not directly applicable to datasets imaged under different conditions like with OSTEM. To still be able to use CLEMnet with MB-OSTEM data, we propose to transform the MB-OSTEM data such that it appears as backscatter electron (BSE) SEM using another CNN. Imaging biological samples using EM introduces beam damage into the sample. This makes generating training data for a CNN by sequential imaging in both an SEM and MB-OSTEM unviable, as the damage would appear during the second acquisition. Using generative adversarial networks (GANs), a network structure called Cycle-GAN can perform image-to-image translation tasks without the need for paired training data. We thus trained a Cycle-GAN network to be able to transform MB-OSTEM data such that it becomes similar to BSE SEM images, like the ones CLEMnet is trained on. This could thus allow for the automatic extraction of biologically relevant data from high-throughput EM techniques.
Results
Network predictions of CLEMnet show a good qualitative agreement with the recorded fluorescence signal. By superimposing the recorded and predicted signals, we can see overlap between the

recorded and predicted signals. The Hoechst signal is localised to nuclei and the endoplasmic reticulum. The network trained on the immunolabeled insulin is capable of distinguishing between the different types of granules in the sample. Quantitative network performance was evaluated using the Pearson correlation coefficient (PCC). The Hoechst-based network achieved a PCC of 0.51, and the Insulin-based network achieved a PCC of 0.765. The PCC serves as an indication of network performance. Still, inaccuracies in the recorded dataset, like inaccuracies in the EM-FM registration and bleed-through from the different fluorescent stains, can result in a spurious reduction of the PCC.
The OSTEM training data for the Cycle-GAN contains numerous staining artefacts. Despite this, we can qualitatively see that Cycle-GAN is able to translate OSTEM data into BSE SEM-like data. Furthermore, when CLEMnet trained on the Hoechst dataset is applied to this translated data, we can see that the resulting signal is localised to the nuclei and ER as expected.
Conclusion
Preliminary results demonstrate our ability to use a CNN trained on BSE SEM data to extract biologically relevant data from OSTEM images. Future work will look into extending this to MB-OSTEM data. In this future work, we will acquire a CLEM dataset using MB-OSTEM to be able to quantitatively compare the predicted signal from CLEMnet to real fluorescence data when applied to translated MB-OSTEM data. This work could help to make the interpretation and analysis of large-scale EM data more approachable, as CLEMnet is able to provide biological context to EM datasets.

Background & aims
Electron energy loss spectroscopy (EELS) is a powerful technique, foremost allowing determination of the elemental composition, but furthermore investigation of electronic properties like chemical bonding and oxidation states. This information can be collected with high spatial resolution on today´s scanning transmission electron microscopes. Most common for the analysis of EELS data is the use of cross-section models. These are often sufficient for determination of the elemental composition, but to extract information like oxidation states, a different analysis approach is necessary: Spectra of well-known reference materials (standards) improve the quantification results and allow fitting of the edge shapes to investigate and map oxidation states. These reference spectra can either be obtained by measuring well-defined materials or by using EELS reference databases [1-3]. Since their content is mostly not exhaustive to provide a set of reference spectra for each element and oxidation state for a given material, the process of obtaining commercially available materials, evaluating them for their ability to be usable as standards and using the obtained set of standards to map the oxidation states of a Cu-based MeOH catalyst [4] post-catalysis is presented.
Methods
The investigated catalyst [4] consists of Cu, ZnO and Al_2O_3. The standard materials needed to cover possible oxidation states are Cu, Cu_2O, CuO, Zn, ZnO and Al_2O_3. Of each material a commercially available sample has been obtained and investigated for its purity and oxidation state via XRD and in the TEM using EDX and EELS. Storage and sample transfer under inert conditions are considered mandatory for all samples that could oxidise further. Sample parts suitable for the measurement of standard spectra are identified, measured and spectra extracted and then imported into Gatan GMS3 as references. An EELS map of the MeOH catalyst [4] after catalytic reaction, that has been transferred under inert conditions into the microscope to preserve the oxidation states, has been acquired. This map is evaluated for materials and oxidation states based on the measured standard spectra.
Results
First it was tested via XRD if the bought materials are as described, with a focus on additional phases that can result from trace metals or different oxidation states than expected. Two materials show a deviation, Cu showed ~5% oxidation and ZnO exhibited an additional unknown phase. EDX maps of each material led to the following results: We found ~3-5% O in Cu, non-homogeneous oxidation and a slightly less O content in Cu_2O, while CuO was homogeneous as described. Some oxidation of ~5-7% was found in the Zn sample and additional O in the ZnO. The oxidation layer on the Zn appears to be amorphous, otherwise it would have been detected in the XRD. Trace elements in all cases are Al, Si and Zn for the Cu-based materials, and Al, Si and Cu for the Zn-based materials, with each amount less than 0,2 at.%. They do not explain the additional phase in the ZnO, so additional bulk EDX has been measured in SEM at low magnification, again revealing no additional elements present. Due to

the O excess likely resulting from the production process, there is a high probability that this phase determined by XRD consists of zinc hydroxides.
In all EDX maps a region on the sample can be found, where the desired material in the specific state is likely to be present. Therefore, EELS spectrum images have been acquired and evaluated as elemental mappings, allowing to identify a region of this spectrum image where the material has the desired composition and oxidation state. Of this region the standard spectra for each element and oxidation state have been obtained, integrating over several single spectra. The concurrent standards fit using these spectra on the spectrum image of the MeOH catalyst is able to differentiate between elements and oxidation state, resulting in a detailed, spatially resolved map for each (figure 1).
Conclusions
By careful combination of analysis techniques, it is possible to obtain self-measured EELS standards from commercially available standard materials. These allow to evaluate EELS data also for oxidation states with high quality, allowing deeper insight in the properties of catalysts.

Figure 1: a) HAADF image of the MeOH catalyst, from the EELS spectrum image. b) Fit result for the O K edge using self-measured standards for CuO, Cu_2O, ZnO and Al_2O_3. Mostly ZnO is present, some Al_2O_3 and very few Cu oxides. c) Fit result for the Cu $L_{2,3}$ edges using self-measured standards for Cu, CuO and Cu_2O. It shows mostly pure Cu, slightly oxidised. The region from which the line profile in e) is obtained is highlighted in this image. d) Fit result for the Zn $L_{2,3}$ edges using self-measured standards for Zn and ZnO. e) Line profile across the calculated maps, quantifying the fit result.

Poster Group 1

Background incl. aims
Transmission electron microscopy (TEM) has become an important tool for characterizing the microstructure in materials [1]. However, to gain access to the underlying structure-property relationships, real-time observations in TEM experiments are required to study the material's microstructure under operating or process conditions, e.g. at elevated temperature in in-situ heating experiments. And, with the advent of TEM nanoheaters that utilize microelectromechanical systems (MEMS) technology [2,3], atomic-scale studies at elevated temperatures became feasible.
However, the exact local temperature of a TEM sample itself remains rather uncertain, limiting the interpretation of observed structural phenomena observed in in-situ TEM heating experiments. Here, we explored how accurately plasmon energy expansion thermometry (PEET) [4] can be used to determine the local temperature. .

Methods
As our model system, a tungsten (W) sample, prepared using a ThermoFisher Hydra plasma focus ion-beam (PFIB), was placed on a DENS Wildfire nanoheater [3]. For the PEET experiment, low-loss energy electron loss spectroscopy (EELS) was performed using ThermoFisher Spectra Ultra at 300kV with an energy resolution of 1 eV and a Gatan Continuum GIF with Dual-EELS functionality.
The site-specific temperature (T) within the W lamella was estimated by measuring the T-dependent energy shift of the W bulk plasmon in the low-loss EELS. The energy dispersion of 0.01 eV was used for an increased precision for detecting the plasmon energy shift.
To accurately estimate the temperature profile within the W lamellas with uniform sample thickness, we used the finite element method (FEM) in COMSOL. Further, the GPAW package [5] was used to simulate EELS spectra, based on the dielectric function. The temperature-dependent energy of the W bulk plasmon was estimated in the GPAW environment by implementing the temperature-dependent thermal expansion of the lattice constant.

Results
The COMSOL simulation models the heat flow and the temperature distribution in our W sample with increasing nanoheater temperature, providing an estimation to simulate corresponding low-loss EELS spectra. Our simulated EELS spectra using GPAW predicted a shift of the W bulk plasmon energy ΔE of ~0.236 eV when the temperature was increased from RT to 1000℃. The value of the simulated W bulk plasmon energy is at the same order of magnitude as our experimental PEET data (ΔE ~ 0.38 eV) when increasing the temperature from RT (25.11 eV) to 1000℃ (24.73 eV) in our in-situ heating TEM experiment.

However, the deviation between our simulation and experiments indicated that more details need to be considered. One approach in the simulation is that the precision of PEET has been evaluated in our simulated EELS data from the uncertainties of the coefficient of thermal expansion and of the lattice constant at the reference temperature. Another reason could be that we have to take varying sample thickness into account in our COMSOL simulations.

Conclusion
Our study shows that PEET with W is able to measure local TEM sample temperatures in a quantitative way. The COMSOL/GPAW simulation can be used to predict the T-dependent plasmon energy and estimate the uncertainties for spectra in such experiments. This advances our approach in determining the local temperature across the sample in in situ TEM heating experiments.

Corrosion of Alloys Suitable for Very High Temperature Systems (VHTRs) Exposed to High Temperature Helium

Dr Lawrence Coghlan[1], Dr Mariia Zimina[1], Dr Robert Burrows[3], Dr Aya Shin[2], Dr Tomas Martin[1]
[1]University of Bristol, Bristol, United Kingdom, [2]EDF Energy, Gloucester, United Kingdom, [3]National Nuclear Laboratory, Bristol, United Kingdom

Poster Group 2

Background and Aims
During operation of Very High Temperature Reactor (VHTR) systems, the temperatures will be operating at above 700°C where having a high creep strength and corrosion resistance to the high temperature atmosphere is of vital importance [1].

Helium is used within the VHTR systems as the gas is “inert” and helium, in comparison to other potential coolants, does not become radioactive when exposed to neutron radiation. Complications occur due to the presence of carbon (from the graphite in the reactor), any impurities within the helium gas and potential water ingress from the environment[2,3]. These factors, coupled with the very high temperatures of operation, can lead to complex interactions taking place between the helium coolant gas and the metal. These can include oxidation, carburization and decarburization [1,4] and in certain high temperature alloys, for example on Alloy 800 the surface corrosion layer can delaminate which will have a detrimental effect on the physical properties of mechanical components.

These interactions will affect the physical properties of the alloys as the chemistry is altered during exposure to helium at high temperatures and may negatively affect the physical properties of the alloys, for example decarburization will lead to a reduction in carbides which may affect the physical properties of the alloys.

The work here has characterized three high temperature nickel based alloys (Alloy 617, Alloy X and Alloy 800) using advanced microscopy techniques after exposure to high temperature helium (740°C) for various durations with the aim to better understand the interactions taking place within high temperature helium systems.

Methods
Various nickel based alloys have been exposed at 750°C to a helium atmosphere for various durations inside a high temperature tube furnace. These alloys (Alloy 617, Alloy 800 and Alloy X) were selected based on their physical properties and corrosion resistance. Upon removal from the furnace, samples were characterised using advanced microscopy techniques including Scanning Electron Microscopy (SEM) and Focused Ion Beam Microscopy (FIB). These techniques allowed for characterisation of the changes taking place during their exposure to high temperature helium. Elemental Dispersive X-Ray Spectroscopy (EDS) was used to characterise the elements within the corrosion layer and to highlight the elemental changes which take place at these high temperatures.

Results
Analysis of the samples shows differences in the oxidation/corrosion behaviour of the different alloys dependant on exposure duration. A comparison between three alloys exposed at 750°C to helium for

1000 hours is shown in the Figure where different morphologies can be seen across the surface of the alloys. The corrosion layer thickness and morphology varied for the different materials with precipitates and oxide nodes developing near to the surface of the exposed surface.

Conclusion
The corrosion behaviour of alloys exposed to high temperature helium is of importance to understand for use within VHTR systems. The work here has characterised three alloys and shown the differences in the oxidation characteristics for each alloy. This will help to better understand corrosion process taking place within a high temperature environment when exposed to helium.

Optimizing Soft X-ray Spectroscopy for Silicon Anode Lithium Mapping

M. Sc. Svenja Kalthoff[1]
[1]Fraunhofer ISE, Freiburg im Breisgau, Germany

Poster Group 1

Background incl. aims
Silicon has emerged as a promising candidate material for anodes in lithium-ion batteries due to its high theoretical capacity (about 10 times that of graphite). However, the practical use of silicon faces challenges related to its large volume expansion (~300%) upon lithiation, which leads to mechanical degradation and pulverization of the electrode over repeated charge/discharge cycles. This degradation results in loss of electrical contact, reduced cyclability, and capacity fading.
To address these issues and optimize silicon-based anodes, extensive research efforts are underway. One critical area of investigation involves understanding the distribution and behavior of lithium within silicon structures during battery operation. The distribution of lithium impacts the electrochemical performance and stability of the battery.
Various techniques are employed to study silicon-based anodes, including microscopy (e.g., scanning electron microscopy, transmission electron microscopy) for structural analysis, spectroscopy (e.g., X-ray diffraction, X-ray photoelectron spectroscopy) for chemical characterization, and electrochemical methods for performance evaluation. But the lithium distribution in the anodes cannot be found by these techniques.
However, soft X-ray emission spectroscopy (SXES) is a powerful technique that can provide detailed insights into the lithium distribution within silicon anodes with high sensitivity and spatial resolution. SXES allows researchers to map the chemical states of lithium in different states of charge (SOC) and investigate phenomena such as lithium trapping, where lithium becomes immobilized within the silicon structure, contributing to capacity loss and reduced battery efficiency over time.
By studying these fundamental processes, we aim to develop strategies to mitigate silicon degradation, enhance lithium utilization, improve battery cyclability, and ultimately advance the performance and lifespan of lithium-ion batteries. Furthermore, this study aims to establish optimal measurement conditions for SXES when analysing silicon-based anodes in lithium-ion batteries. By identifying and demonstrating the most effective measurement parameters and techniques, our goal is to streamline SXES procedures for battery research, facilitating broader adoption and use by other researchers in the field.

Methods
This research focuses on investigating silicon-based anodes derived from lithium-ion batteries fabricated in our laboratory using micrometer-sized silicon particles as the anode material. The batteries are assembled in coin cell half-cell format, featuring electrodes with a diameter of 18 mm. Assembly and subsequent disassembly for post-mortem analysis are meticulously conducted within an argon atmosphere glovebox to ensure controlled environmental conditions and prevent exposure to moisture and oxygen.
After disassembly, the electrodes undergo a thorough cleaning process using dimethyl carbonate (DMC) and are then dried under vacuum to eliminate any residual contaminants. For SXES analysis, a plane surface is essential. Therefore, a small portion of the electrode is extracted and a cross-section is meticulously prepared using the IB-19520CCP cross-section polisher from Jeol under a cooled atmosphere at -120°C. The transfer from the glovebox to the ion polisher and subsequently to the

scanning electron microscope (SEM) is carried out in an inert transfer vessel to ensure that the sample remains shielded from air or moisture throughout the process.
SXES investigations are performed using a JSM-IT800 SEM equipped with the JS50XL SXES detector from Jeol. This advanced setup enables high-resolution analysis of lithium distribution and chemical states within the silicon-based anodes.

Results
Our investigation revealed significant influences of probe current, excitation voltage, and exposure time on the spectroscopy results. Identifying optimal settings for these parameters is crucial, balancing high signal intensity with minimal sample degradation during measurements. Additionally, variations in lithium (Li) distribution within the analysed particles were observed. By employing mapping techniques, we were able to spatially resolve and identify regions enriched with lithium, providing valuable insights into its distribution within the silicon-based anodes. This detailed elemental mapping enhances our understanding of lithium behavior in battery materials and underscores the importance of precise measurement conditions in SXES for comprehensive battery research.

Conclusion
In conclusion, our study underscores the significance of SXES in elucidating the complex interplay between lithium distribution and silicon-based anode performance in lithium-ion batteries. The challenges associated with silicon's volume expansion upon lithiation and subsequent mechanical degradation highlight the critical need for advanced characterization techniques to optimize battery materials.
Through our investigation, we have demonstrated the pivotal role of SXES in mapping lithium distribution with exceptional sensitivity and spatial resolution. Our findings emphasize the impact of probe current, excitation voltage, and exposure time on spectroscopy results, emphasizing the importance of optimizing measurement parameters to balance signal intensity and sample integrity. The observed variations in lithium distribution within the anode particles provide valuable insights for developing strategies to mitigate lithium trapping and enhance battery cyclability. By enhancing our understanding of lithium behavior at different states of charge, we aim to contribute to the development of more efficient and durable lithium-ion batteries.

Background

The energy transition is nowadays a topic of huge attention, as a measure to face the global energy crisis and the more and more impacting climate change. In this framework, the production of carbon-based chemicals and fuels by exploiting anthropogenic CO2 is nowadays considered a way-out to leave the traditional oil-based technology. In fact, renewable and green approaches to CO2 valorisation are aimed at minimizing the worrying impact of its emission to the environment, and to drive the transition to a new circular economy approach in chemistry and energy production. A strategic method to reduce CO2 concentration in the atmosphere is to consider it as a valuable raw material, collecting it from industrials point sources and electrochemically reducing it into value-added products. This green approach can contribute to the development of alternative energetic vectors, or organic molecules normally derived from fossil resources. Among many products that can be obtained, which depend on the catalyst characteristics, reaction conditions and electrolyte, the CO2 reduction reaction (CO2RR) to carbon monoxide (CO) or formic acid (HCOOH) are up to now the most economically viable processes and can challenge conventional production routes [1]. In order to design efficient catalysts for CO2RR with high activity, selectivity and stability, it is important to understand the fundamental mechanisms involved in the electrochemical processes. In this context, in situ / operando characterization techniques provide insight into the correlation between physical-chemical properties and the electrochemical performance. Specifically, electrochemical liquid phase transmission electron microscopy (EC-LPTEM) yields temporally and spatially resolved morphological, structural and chemical information regarding catalytic materials under electrochemical stimulation [2]. Within this framework, in this paper, EC-LPTEM experiments on molecular Re@Cu2O/SnO2 catalysts for CO2RR are presented and compared to the lab-scale experiments.

Methods

EC-LPTEM experiments are typically carried out in miniaturized liquid cell TEM holders with controlled liquid flow, where the electrochemical functionality may be provided with different technological approaches. Poseidon liquid phase TEM holder and related electrochemical commercial and modified chips have been used to perform EC-LPTEM on a FEI TECNAI F20ST microscope. Molecular Re@Cu2O/SnO2 catalysts for the CO2 electroreduction to syngas have been prepared by wet precipitation of Cu2O/SnO2 followed two functionalization steps with vinyltriethoxysilane

(VTES), to form stable surface Si-O bonds, with electropolymerizations on the silanized Cu2O/SnO2-VTES NPs with vinyl-tagged Re complex.
For the EC-LPTEM, a dispersion of the catalyst in ethanol is drop casted on a Glassy Carbon working electrode in a microchip-based electrochemical set-up. This chip, together with an optimized prototype chip, provided by Protochips, are used to compose the electrochemical cell. The catalyst was studied in 0.1M KHCO3 saturated with CO2. The electrochemical activity for the CO2RR was tested by means of CV and Chrono Potentiometry (CP) analyses.

Results
One major challenge in conventional liquid cell TEM setups for CO2RR operando experiments in aqueous electrolyte is that the evolution of gaseous products at the electrodes causes the formation of gas bubbles. Due to the miniaturized volume of the liquid cell, in few seconds the cell is completely filled with gas, in electrochemical conditions which are relevant for CO2RR. Once the cell is filled with gas, the electrolyte-electrode interface is dramatically affected, resulting in uncontrollable experimental conditions and elusive data interpretation. In this work, we use a customised liquid cell geometry with optimized liquid flow configuration, which minimizes the formation of gas bubbles in the liquid cell and concurrently removes the gaseous products more efficiently in electrochemical conditions relevant for operando CO2RR studies in aqueous electrolyte [3], [4].
With this improved experimental capability, we investigated the morphological dynamics during the life cycle of Re@Cu2O/SnO2 catalysts for the CO2 electroreduction to syngas. What emerged is that the catalyst during electrochemical activity experiences dissolution and re-crystallization phenomena, that partially change the particle size and in turn can possibly change the catalytic performance.

Conclusion
In-situ EC-LPTEM helped to shed light on the changes the material undergoes during electrocatalytic activity, and thanks to improved cell we have been able to study this catalyst at relatively wide range of potentials for prolonged periods of time, which are close to those of interest for the applications. The obtained results on the catalysts hold significance from the fundamental point of view, and, in addition, the optimised design of the LP flow TEM cell allowed to perform stability tests, which are of huge interest for the future application of these catalysts in real devices.

CAR T cell dynamics in a 3D collagen matrix: migration and interactions with cancer cells

Nicoline Dorothea Daugaard[1], Mike Bogetofte Barnkob[2], Zelvera Ismetova Usheva[2], Torben Barington[2], Jonathan R. Brewer[1]
[1]Department of Biochemistry and Molecular Biology, University of Southern Denmark, Odense, Denmark, [2]Centre for Cellular Immunotherapy of Haematological Cancer Odense (CITCO), Department of Clinical Immunology, Odense University Hospital, University of Southern Denmark, Odense, Denmark

Poster Group 1

Background incl. aims
Chimeric antigen receptor (CAR) T cell therapy is a therapy in which T cells are engineered to target a specific antigen on a cancer cell and elicit a T cell response that ultimately leads to the death of the cancer cell. CAR T cell therapy has proven effective against blood cancers, but solid tumors are more difficult and complex targets due to their tumor microenvironment. In order to develop efficient CAR T cell therapies against solid tumors, we need systems in which we can study, challenge, and improve CAR T cells in extracellular matrix-like 3D environments. Here, we have developed a 3D model based on rat tail collagen to study CAR T cells and their interactions with cancer cells.

Methods
We used CD19 CAR T cells, i.e. T cells targeting CD19 antigen, and A375 melanoma cells engineered to express the CD19 antigen. CAR T cells and cancer cells were mixed into a rat tail collagen matrix and spinning disk microscopy was used to record 3D time-lapse videos of the cells. We developed a quantitative 3D analysis and analyzed the T cell tracks to elucidate the migration of T cells and their interactions with cancer cells. We furthermore conducted a 72-hour treatment of mature melanoma spheroids using CAR T cells to investigate the efficiency of the therapy in the 3D collagen matrix. In all experiments, we compared with untransduced T cells, i.e. normal T cells that do not express the CD19 CAR.

Results
Our analysis of CAR T cell migration in the collagen matrix showed that CAR T cells generally move slower compared to untransduced T cells. While they both have the same number of interactions with cancer cells, CAR T cells tend to interact longer.
72-hours treatment of melanoma spheroids with CAR T cells in the collagen matrix resulted in a substantial reduction in spheroid growth. Spheroids treated with untransduced T cells increased in size comparable to untreated spheroids. These results demonstrate the efficacy of CAR T cells in targeting cancer tumors in the 3D collagen matrix.

Conclusion
We have successfully employed time-lapse imaging and quantitative 3D analysis to study the migration of CAR T cells and their interactions with cancer cells. We propose that the 3D model and the quantitative analysis presented here can be used to test various CARs, antigens, solid tumor types, and matrix modifications.

Poster Group 2

Background incl. aims
Conjugated polymers have applications in organic, flexible electronics, with their mobility and conductivity largely dependent on parameters such as crystallinity, grain size, and chain orientation [1]. However, probing their structure at the nanoscale with electron microscopy remains challenging due to their radiation-sensitive nature. Development of fast direct electron detectors has helped open up the studies of these materials, with HRTEM and 4D-STEM data highlighting order and at the nanoscale not possible from x-ray approaches [2,3,4]. In this work we use low-dose scanning electron diffraction (SED), a variant of 4D-STEM, to investigate the nanoscale structure of conjugated polymers, with a workflow for determining chain orientation of conjugated polymers presented. We determine quantitatively chain orientation and grain size and compare to bulk experiments to observe how these quantities effect the underlying properties of the conjugated polymers.

Methods
TEM samples of a thiophene-based conjugated polymer – with potential to be used as an organic mixed ionic-electronic conductors (OMIEC) [4] – were prepared via spin-coating and a lift-off approach onto Quantifoil, amorphous carbon grids. SED data, comprised of diffraction patterns (256 x 256 pixels), acquired over a raster scan of 256 x 256 pixels was acquired on a Thermo Fisher Spectra at 200 keV, with a low convergence angle of 1 mrad and with 5pA probe current. Each diffraction pattern was acquired using a Quantum Detectors Merlin camera and analysed using the pyXem software suite. Polymer chain orientation is visualised using 'flowline maps' based upon the orientation of Bragg spots due to π - π stacking in the conjugated polymer structure.

Results
The results from one of the polymers studied, p(g0T2-g6T2), is shown in Figure 1 to illustrate the analysis now possible of conjugated polymer thin films. The bright field (BF) image results from using a 'virtual' aperture placed around the direct beam in each of the patterns acquired and plotting the summed intensity as a function of probe position. The annular dark field image is plotted similarly but using a virtual annular aperture with radius range 0.25 Å-1 – 0.3 Å-1. The mean diffraction map is proportional to the summation of all the diffracted intensity across the field of view, with a bright spot present in the bottom left due to a hot pixel on the detector during acquistion. The 'variance' map plots the variation in scattered intensity in a narrow annulus centred on the strong Bragg 'ring' (corresponding to π - π stacking) – in essence this highlights areas of strong crystallinity / order. The final map illustrates the variation in chain orientation across the field of view through the use of a colour wheel (to plot the local Bragg vector for π - π stacking) and flow lines to illustrate more graphically the local polymer structrure. In particular, here we highlight (see arrows) the appearance

of disclinations (with k = +1/2 topology), commonly seen in polymer liquid crystals. By careful analysis of the 'texture' around the disclination core, quantitative measurements of the splay and bend charcterisitcs may be determined.

Conclusions
The advent of 4D-STEM techniques, coupled with the progress in detector technology and the rise of computational power, provides an ideal platform for the study of conjugated polymers at lengthscales considerably smaller than is possible with other techniques such as x-ray diffraction. In the example we present here, chain orientation, grain size and the presence of disclinations have all been observed in the conjugated polymer p(g0T2-g6T2). The authors thank the EPSRC for funding under grant number EP/R008779/1.

Resolving single-electron and multi-electron distribution functions with event-based electron detectors

Alexander Schröder[1], Andreas Wendeln[1], Prof. Sascha Schäfer[1]
[1]University Regensburg, Regensburg, Germany

Poster Group 2

Background
The combination of electron probe pulses with a synchronized optical sample excitation as applied in ultrafast transmission electron microscopy (UTEM) has enabled the investigation of ultrafast dynamics on the nanoscale [1]. Besides the traditional optical-pump/electron-probe approach, sufficiently fast event-based electron detectors, based for example on the TimePix3 chip architecture [2], can detect electron events with a temporal bin width of about 1.6 ns. Due to the stochastic electron trajectories in the sensor chip the spatial and temporal resolution is often limited, in particular at higher electron energies [3,4], and requires further data processing to overcome these limitations. In addition to the nanosecond temporal resolution of event-based detectors, such a detection scheme gives access to spatio-temporal electron-electron correlations and has been recently applied to the investigation of Coulomb-correlation within a photoelectron bunch generated by femtosecond photoemission from a Schottky emitter [5]. In general, these new kinds of detectors in principal provide a measurement of multi-electron distribution functions both in electron beams and electron pulses containing additional information with respect to averaged micrographs traditionally recorded.
Methods
To gauge the potential of event-based detectors for UTEM, the temporal response of a TimePix3 detector (Cheetah T3, Amsterdam Scientific Instruments) was characterized utilizing 200-fs electron pulses (400-kHz repetition rate, 200-keV electron energy, 1.3 electron/pulse) as generated in the Regensburg UTEM. As a photoelectron source, both a laser-driven Schottky and cold-field emitter were employed. In a first experiment, we experimentally collected a dataset of electron detection events for up to 4 x 10^6 electron pulses (Fig. 1 (a)). For each event, the TimePix3 collects relative detector position, time of arrival (ToA) and time over threshold (ToT). The events are clustered depending on their ToA and position, resulting in an average of 6.5 events per cluster (Fig. 1 (b) and (c)). The data is synchronized by assigning a timestamp to each photoemission laser pulse. A fully connected deep neural network model is trained using event data from 1.6 x 10^5 time-scrambled event cluster, so that it becomes possible to predict the ToA of the primary electron.
In a second experiment, electrons are emitted by a cold-field emitter gun (CFEG) and around 5 x 10^7 electrons are detected with the TimePix3. To find Coulomb-correlated electron pairs, only clusters with a small mean ToA-difference (< 50 ns) from the dataset are selected. The electron pairs are statistically analysed and the influence of optical excitation, extraction fields and spatial distribution are examined.
Results
Using the non-clustered ToA events leads to a temporal spread of about 10 ns (Fig. 1 (d), grey curve). If a cluster algorithm is used and the mean ToA for each cluster is calculated, then the temporal spread can be reduced to 7 ns (Fig. 1 (d), red curve). The neural network reduces the predicted temporal distribution (for a part of the data not involved in the training) to 4.7 ns (FWHM) (Fig. 1 (d), green curve). In the case of the neural network the distribution is almost Gaussian while the ToA distribution in the previous cases shows a tail for larger ToA.

Applying closely spaced electron double-pulses with a temporal separation of 8 ns to TimePix3 detector (shorter than the intrinsic temporal resolution) shows a broadened flat top distribution (Fig. 1 (e), grey curve). With the implementation of the neural network, the two peaks can be distinctly separated (Fig. 1 (e), green curve), demonstrating the more general applicability of the approach.

Conclusion

In conclusion, we demonstrate, that the accurate prediction of the ToA by a neural network trained by femtosecond electron pulse data, resulting in an increased temporal resolution for the TimePix3 detector. This improved temporal resolution will also be helpful for the mapping of temporal correlations in the imaging of non-static nano-objects and non-trivial multi-particle correlations within electron pulses.

IM-03 (1), Plenary, august 28, 2024, 10:30 - 12:30

Background incl. aims
Ptychography measures a correlated matrix of interference or diffraction patterns with sufficient overlap between adjoining illuminated area, and reconstructs both the object and the probe with their amplitude and phase components. For a ptychographically reconstructed image, its image pixel size is determined by the detector sampling in the Fourier space rather than the scanning step size in the real space [1]. This would allow a coarser scanning sampling and therefore a larger field of view with reasonable number of scan pixels or a lower dose with a practical probe current. In order to boost the sampling efficiency further, which would enable much larger field of view phase contrast imaging (e.g. weak contrast cellular structures) or fast time-resolved phase contrast movies (e.g. electromagnetic field dynamics), we developed a new ptychography imaging mode called near-field electron ptychography [2]. This is based on the classic ptychography principle but adopts a full-field parallel beam illumination and measures Fresnel (near-field), instead of Fraunhofer, diffraction patterns. In this case, structured illumination is of vital importance. Otherwise, each near-field diffraction image carries the same information except for laterally shifted, and therefore the ptychography reconstruction reduces to a single phase retrieval loop. In addition, a properly structured illumination will bring in a mixed range of spatial frequency to the diffraction patterns and open up the contrast transfer function over a wider range of frequencies.
Methods
A variety of diffuser designs and optical setups have been tested for the structured illumination near-field electron ptychography. A silicon nitride-based phase plate with patterned local thickness variation were firstly used as a phase diffuser. This can introduce almost arbitrary phase patterns to the illumination but the profuse inelastic scattering from the silicon nitride thin film will add an incoherent background to the measured diffraction patterns, which becomes more severe when working with lower energy electrons. An amplitude mask diffuser, consisting of a few narrow but opaque, random oriented, curved lines within a round aperture (see the enclosed figure), was found to be also very effective for this application [3] because in the near-field “ptychograms”, the Fresnel fringes, which comes from the hard edges of those lines, carry exactly the additional frequencies that are required for structured illumination. In this case, the inelastic scattering from the diffuser becomes negligible. Such a diffuser can be placed in either selected area aperture plane or condenser aperture plane. The latter is preferred because then only the area that is going to be measured will be illuminated, and also this will allow variable size of structured parallel illumination if three condenser lenses are available on the microscope. In order to realise the “shift invariance” principle of ptychography, the stage shift was originally used, which is flexible enough for large distance travel but suffers from jigging unless waiting enough time for stabilisation. In the latest development, we implemented a parallel beam 4D STEM acquisition mode that drives instant beam shift and

synchronised fast detector readout for this application, which reduces the acquisition time by at least two orders of magnitude.

Results

We demonstrated, with as few as 9 diffraction patterns, near-field ptychography can already reconstruct micron square field of view phase images [2] and this can be easily extended to hundreds micron square field of view with a small number of diffraction patterns. Applying this method in magnetic field free TEM mode, we can visualise a permalloy magnetic domain structure using near-field ptychography [3] and the reconstructed phase image is almost equal to that measured by off-axis electron holography (see the enclosed figure). When switching to the parallel beam 4D STEM setup, ultralow dose phase reconstruction becomes possible (see the enclosed figure) with only second acquisition time and minutes reconstruction period.

Conclusion

A sampling efficient phase contrast imaging method is developed based on ptychography principle but with a bit adjusted optical setup including structured illumination and near-field diffraction measurement. It holds great promise to study large cellular structures with enhanced phase contrast or measure time-resolved dynamics of electronic or magnetic devices. Further discussions on how to push further its spatial resolution will be discussed in this presentation.

Poster Group 1

Magnetic skyrmions are, topologically protected, vortex-like magnetization patterns which can form a two-dimensional lattice. Skyrmion lattices, just as crystal lattices, can be deformed by both internal and external influences, resulting in dislocations or skyrmion grain boundaries. Understanding the rise of skyrmion lattice deformations is important to find the correlation between local and external influences on skyrmion lattice formation and stability. We apply geometric phase analysis (GPA), a widespread image analysis technique for measurement of deformation fields in high-resolution transmission electron microscopy images (TEM), to simulated Lorentz TEM images. Lorentz TEM images have been calculated by means of micromagnetic simulations based on FeGe chiral magnet which supports stabilization of skyrmion lattice. We have simulated Lorentz TEM images with and without the application of the spin-polarized current. The strain and dislocation maps were obtained by applying GPA to all simulated images. Our findings suggest that applying spin-polarized currents can lead to further stabilization of skyrmion lattice compared to ground state. We demonstrate that GPA can be successfully used for the analysis of Lorentz TEM images both at static and dynamic conditions. Strain analysis of skyrmion lattice in Lorentz TEM images can further enhance the knowledge of deformation mechanisms and skyrmion lattice dynamics.

Background incl. aims
Thermoelectrics are a group of semiconductors which generate electrical power by conversion of heat into electrical energy. A thermoelectric power generator requires a hot and a cold side to use the temperature gradient for this conversion of energy.
Microstructure engineering has been used in the thermoelectric material research community to reduce the phonon mean free path and thus led to reduction of thermal conductivity which is crucial for thermoelectrics. This can be done by grain refinement, i.e. reducing the grain size for more phonon scattering. The challenge remained to keep a high electrical conductivity since increasing the grain boundary fraction usually led to decrease of electrical conductivity. To achieve the desired properties in thermoelectrics, it is important to understand the dependence of the microstructure of grain boundaries and correlate it to the thermoelectric properties. For this, detailed electron microscopy investigations covering several length scales from the µm to an atomic scale need to be conducted.

Methods
Scanning electron microscopy (SEM) analysis including electron backscatter diffraction (EBSD) and energy-dispersive X-ray spectroscopy (EDX) has been done to observe the µm down to nm scale microstructure. The grain boundary characterization down to atomic scale was achieved with (scanning) transmission electron microscopy ((S)TEM). In addition, atom probe tomography (APT) was used to get a chemical analysis on the composition of the grain boundaries with highest accuracy and spatial resolution.

Results
EBSD analysis of the grain size of the Nb1-xTixFeSb based half-Heusler thermoelectric materials synthesized at two different temperatures and two different Ti contents of 5% and 20% replacing Nb revealed a significant difference related to the grain size while all samples showed a random Mackenzie distribution for the grain misorientation (see Figure 1a). The later observation means that specific low angle grain boundary types were not dominating.
To uncover this mystery and proove our hypthoesis of resistive and conductive grain boundaries, we combined APT analysis with STEM analysis at the grain boundaries. We observed a defect grain boundary phase at random grain boundaries (Figure 1b) with chemical composition and lattice parameters differing from the one of the matrix phase of the half-Heusler material. The parameters are close to an FeSb phase in all four samples (different doping content and grain size) but with an additional segragation of Ti content for the high Ti doped samples which was shown with APT (see Figure 1c). This defect grain boundary phase proved to be the reason for increased electrical conductivity by providing conductive pathways in the high Ti doped sample.

Conclusion
Scale bridging electron microscopy was key to understand the correlation between microstructure and thermoelectric properties of NbFeSb based half-Heusler p-type thermoelectric material.[1] We have revealed a way of decoupling the electrical and thermal conductivity to tune the properties for maximizing the materials performance. This way of grain boundary alloying will provide a new road map for microstructure engineering in the future and should also be applicable to other half -Heusler materials.

Background incl. aims
Extracellular vesicles (EVs) are biological nanoparticles found in biofluids such as blood. EVs have been suggested to play an important physiological role, and potentially serve as markers for various diseases. However, EVs are often confounded with other bio-nanoparticles, such as lipoproteins and protein complexes. Currently no method can detect and characterize EVs in a high-throughput manner. We present an optical instrument with spatial resolution to detect and characterize EVs based on light scattering measurements. The underlying technology relies on creating a standing wave of two interfering lasers, of which one is variably phase modulated to displace the interference pattern within the intersection of the two laser beams (Fig. 1A).

Methods
The core concept is inspired by amplitude modulation radio. Specifically, this optical instrument encodes spatial information in the illumination source, manifested as an interference pattern that can variably sweep in the interrogation zone. By phase delaying one of the laser beams, we can produce a sweeping interference pattern with a known scrolling frequency (Fig. 1A-B). As nanoparticles traverse the sweeping interference pattern, the light scattered by these particles oscillate with the scrolling frequency. This enables “locking-in” on the narrow bandwidth of the oscillating signal and exclusion of the majority of broadband noise (Fig. 1C). Hereby we can increase the signal-to-noise ratio (SNR) of these already dim scattered light intensities from nanoparticles, and thus improve the lower detection limit. Furthermore, it is possible to determine size of nanoparticles and extrapolate the refractive index from the measured signal. Thus, the inherent nature of this optical instrument allows us to distinguish between different classes of bio-nanoparticles in a label-free manner (Fig. 1D). To validate the presented optical instrument, a range of nanostructures with known sizes and refractive indices were fabricated and used to probe produced light field. This was done to characterize (1) the actual wavelength of the standing wave, and (2) the extent of the interrogation zone. We are further validating that scattered light from bio-nanoparticles can be expressed with Lorenz-Mie theory to develop an accurate model for extrapolation of particle refractive index.

Results
Currently, we have constructed a prototype of the optical instrument. This serves to prove the core concepts and demonstrate the feasibility of this instrument to (1) improve the SNR for dim light scatter signals, (2) distinguish between nanoparticles based on size and refractive index. To assess these features, we are fabricating a range of nanostructures with differing shape, size, and material properties, which we can use to characterize the performance of the optical instrument.

Conclusion
The complex bio-nanoparticle landscape is yet to be explored, and no methods have been demonstrated to have adequate sensitivity for high-throughput characterization and distinction between different classes of bio-nanoparticles. In this poster abstract we present an optical instrument that addresses these short-comings by utilizing a scrolling interference pattern to characterize bio-nanoparticles capable of measuring size and modelling refractive index. The project is still in an early stage, and the technology is yet to be fully demonstrated.

Background incl. aims
The use of PZT has continued despite the restriction of hazardous substances (RoHS) directives being passed by the European union (EU) to limit the use of hazardous materials – such as lead (PZT) – in electronic equipment. This is influenced by a lack of available substitutes that can be implemented and scaled in a reasonable time to eliminate the use of PZT (RoHS Annex III). The lead-free alkali-niobate, potassium sodium niobate (KxNa1-xNbO3, KNN), is a potential replacement for PZT, since it can exhibit equivalent, if not better, piezoelectric properties without compromise at temperatures >120 °C. The challenges in the synthesis of KNN, however, have hindered its use as an alternative. Notable challenges include difficulty in achieving the 50% K+ and Na+ occupancy required to make stochiometric KNN (i.e., K0.5Na0.5NbO3) and a lack of control in the formation of phase boundaries. Therefore, developing a reproducible method for synthesising stoichiometric KNN, bodes well for the implementing KNN as a commercial piezoceramic.
Methods
A simple and robust method for synthesis of the lead-free piezoceramic material KNN has been developed via an aqueous route. Stochiometric KNN (K0.5Na0.5NbO3) was prepared by combining alkali-nitrate solutions (NaNO3 and KNO3) with the nano-sized, water-soluble, niobium precursor hexaniobate ([HxNb6O19]8-x, Nb6), followed by sintering at elevated temperatures. Ex-situ studies on the formation of solid-state niobium oxides from Nb6 indicate formation of amorphous niobium oxides ca 400–500 °C. However, observing the dynamics accompanying this crystallization process are limited with conventional solid-state methods. We therefore probed the transformation of Nb6 in the presence of alkali-cations, to yield crystalline KNN from an amorphous oxide precursor. This was possible via in-situ heating with simultaneous selected area electron diffraction (SAED). Whereby, the amorphous Nb6-KNN precursor was mounted on a micro-electromechanical systems (MEMs) chip (Norcada Inc.), which is heated via a tungsten filament coil. In-situ heating experiments proceeded with heating from 400 to 1000 °C, at ramping rate of ca 0.25 °C s-1 in vacuum.
Results
KNN can be synthesised with heating NaNO3 and KNO3, with the water-soluble hexaniobate (Nb6) precursor. The results from SAED indicate the amorphous Nb6-KNN precursor becomes crystalline above ca 550 °C, without degradation after further heating up to 1000 °C. The SAED patterns at 800, 900 and 1000 °C, were acquired along the (101) axis, and agreed with the simulated diffraction pattern of stoichiometric KNN reported previously. The SAED patterns <800 °C exhibited sporadic spots which were incongruent with the simulated diffraction pattern. However, below ca 550 °C there were no obvious spots in SAED patterns, which is consistent with the presence of an amorphous oxide. These findings merit the use of a water-soluble niobium precursor, such as Nb6, as an alternative to accessing KNN in the solid-state.
Conclusion

In-situ heating with SAED is a suitable technique for monitoring the real-time transformation of amorphous precursor oxides, to yield crystalline lead-free piezoceramics. Formation of the lead-free piezoceramic KNN is achievable using the water-soluble, niobium precursor Nb6, which is advantageous compared to conventional solid-state methods. This makes it an attractive alternative approach for developing lead-free piezoceramic materials.

Background incl. aims

In scanning transmission electron microscopy (STEM) the image formation process requires the acquisition of convergent beam electron diffraction (CBED) patterns, at every position of the probe on the sample. Traditionally, disc or ring detectors capture only part of CBED signal within their area, enabling annular bright field (ABF) or annular dark field (ADF) STEM imaging. The center-of-mass (COM) of the CBED pattern provides an essential information on the sample, as the COM vector represents the projected electric field of the sample, the gradient (differential) of the projected electrostatic potential [1, 2]. In thin samples, the projected electrostatic potential is encoded in the phase of the electron wave passing through the specimen, and for this reason these COM-based techniques are referred to as differential-phase-contrast (DPC) techniques.

DPC-STEM techniques have emerged as a powerful tool, offering unprecedented insights into electric and magnetic properties of materials at nano and atomic scale. Integrated DPC-STEM technique (iDPC-STEM) [2] allows efficient imaging of light elements (including hydrogen) next to heavy ones, beam sensitive materials including Zeolites, Metal-Organic-Frameworks (MOFs) at sub-Å scale, as well as cryo-biological nanoparticles at near-atomic resolution [3].

DPC-STEM and iDPC-STEM are implemented in the simplest way by exploiting a four-quadrant detector [1], as this is sufficient for obtaining a good representation of the COM vector. At the other extreme, cameras with larger number of pixels can be used to record the full CBED patterns. This approach is known as 4D-STEM and enables additional reconstruction techniques such as ptychography. However, due to readout limitations, the acquisition speed of cameras (10 to 100µs dwell-time) is much lower than of single/multi-segment detectors (100ns dwell-time). While the precision of 4D-STEM methods benefits from larger number of pixels, many practical applications require dwell-times of 1µs, or smaller, making the use of cameras not an ideal choice.

In this work, we propose an intermediate solution based on a 48-segment detector, called Quarantotto. With this approach, the acquisition speed can be as fast as with a single segment, while, at the same time, the larger number of segments improve the COM measurement. This leads to contrast transfer improvement for DPC-STEM and enables implementation of new applications, such as aberration measurements [4] and segmented ptychography.

Methods

Although four segments provide very accurate results for most applications, there are cases (e.g. thicker samples and heavy atoms) where the effects of the 4-fold symmetry of the detector is

reflected in the corresponding contrast-transfer-function (CTF). The CTF improves by increasing the number of detector segments as the COM vector can be precisely computed and an ideal version of iDPC-STEM, called iCOM-STEM, can be obtained. When a smaller number of larger segments is used, the positions of their geometrical-gravity-centers are used (the DPC mask in Fig. 1a-d bottom) to map their integral signals and compute COM of the CBED.

Quantification of the atomic electric field based on COM was used to demonstrate how the number of segments in segmented-STEM detector affects the accuracy of the measurement compared to cameras [5].
Quarantotto, the newly proposed solid-state detector, Fig. 1a-d top row, consists of 48 segments arranged in 3 rings of 8, 16 and 24 segments of equal area. All 48 segments can be simultaneously read out at a speed of 100ns dwell-time. The improvement in the CTF for the DPC-STEM and iDPC-STEM techniques with the 48-segment detector, is demonstrated against the three sub-configurations of the detector. The first two sub-configurations are two orientations of a regular 4-quadrant detector (Fig 1a and b), the third one is an 8-segment detector consisting of 8 pie-pieces (Fig. c).

In addition to DPC-STEM and iDPC-STEM, the 48-segment STEM detector enables efficient implementation of new techniques, such as segmented-ptychography, where the reconstructed CBED patterns are matched with the measurement segment by segment, and fast probe aberration measurements, where the shifts between the 48 segment images based on the aberration function are matched with the measured segment image shifts. In the past, these techniques have not been fully explored because of the lack of a detector featuring both enough segments and high speed, but now possible with the 48 segments detector.

Results

Quarantotto was used to demonstrate a more rotationally symmetric CTF when compared to four quadrant detectors. Figure 1 shows a direct comparison between iDPC-STEM images of gold islands on amorphous carbon, acquired at 300keV and convergent semi angle of the beam of 30mrad, obtained with the two possible 4-quadrant configurations (Fig. 1a-b), 8-segment azimuthal segment configuration (Fig. 1c) and the full 48-segment detector (Fig. 1d), respectively. For each image, the bottom row shows the FFT where the bottom-left insets show the DPC mask (x-direction), while the bottom-right insets show the theoretical CTF [1] using given detector configuration.

The FFTs of the iDPC-STEM images reflect the corresponding symmetry of the CTFs. The possible undesired effects of the noncentral symmetrical CTFs of 4-quadrant configurations are largely mitigated with 8-quadrant configuration and eliminated using the 48-segment configuration. The CTF of the 48-segment configuration is practically indistinguishable from the ideal rotationally symmetric situation of a camera.

The detector has been successfully utilized to measure and tune the aberrations of the microscope. This was achieved by measuring the shifts between the 48 segment images and fitting them to the expected shifts based on the aberration function. The image in Figure 1 was obtained after correcting for these measured aberrations.

Quarantotto has also been benchmarked against EMPAD to validate the precision of the electric field measurement across a GaN-GaAlN nanowire structure.

Conclusion

The 48-segment detector was used to demonstrate an improvement in (i)DPC-STEM performance when compared to the 4 and 8-quadrant detectors. It has been successfully used to measure the electric fields across a GaN-GaAlN nanowire structure and to tune the optical aberrations of the microscope. Overall, the Quarantotto detector represents a significant advancement, offering improved imaging at ultimate speed, larger field of view measurements, and the implementation of new techniques.

PS-06, Lecture Theater 1, august 29, 2024, 10:30 - 12:30

Background incl. aims
The application of Atom Probe Tomography (APT) to geological materials has recently disclosed new possibilities into the nanoscale characterization of these systems, yielding important results in the interpretation of the processes that characterize their growth and the subsequent modifications [1, 2]. APT may indeed be exploited because of its 3D nanoscale resolution within a multiscale approach including a set of microscopical and microanalytical techniques. Optical emissions in some minerals have been related to the presence of impurities and defects within a matrix, and can be used in correlative nanoscale analyses targeting both chemical – possibly structural – and optical properties. In this framework, cathodoluminescence (CL) has already been applied as a spatially and spectrally resolved technique [3].
Zircon is a robust geochronometer and one of the most widely used minerals across the geosciences to quantify the nature, timing, and duration of geological processes. Zircons exhibit a strong CL signal and a significant optical emission with spatially varying luminescence properties, also due to the presence of luminescent quartz inclusion within the zircon matrix. In this work we aim to provide more in-depth nanoscale information on such luminescent systems using correlated analysis obtained by coupling APT with in-situ optical spectroscopy, using the recently developed Photonic Atom Probe (PAP) [4].
Methods
As a model system, zircon ($ZrSiO_4$) grains from Jack Hills were embedded in resin, then carbon coated to enable SEM imaging. CL and EDX were carried out to reveal chemical and optical properties, and help determine suitable regions of interests. The samples were then prepared into sharp needles using the standard site-specific FIB lift-out method followed by annular milling to enable subsequent APT analysis. The APT and photoluminescence (PL) analyses were performed simultaneously in the PAP, where a deep-UV laser was used to trigger both the field-evaporation of the surface atoms and the optical emission.
Results
Following CL and EDX analysis, samples from several zircon grains were analyzed and compared using the PAP. Data collected from different phases highlight varying PL signals that were correlated to the measured chemistry, thus demonstrating the capability to discriminate microscale features. Our exploratory results indicate the possibility to obtain different types of correlation at different scales: (a) the correlation of CL or EDX hyperspectral maps with the APT analysis of tips whose location is controlled on the crystal surface (b) the correlation of optical PL spectra and 3D APT reconstructions within the in-situ approach enabled by the PAP (c) the multi-scale correlation of CL and PL spectra providing a useful insight on the optical properties of the samples.
Conclusion

The optical properties of zircons at the micron and nanoscale were exploited to carry out multi-scale correlative chemical and structural analysis. Varying PL spectra obtained in-situ from different phases were correlated to CL and APT data, demonstrating the photonic atom probe as a new correlative nanoscale analysis characterization technique for the geosciences.

Poster Group 2

Background
Solid-state nanopores are an emerging technology for single molecule sensing of biomolecules including DNA, RNA, and proteins [1]. They provide a more resilient alternative to tradition biological nanopores, which are sensitive to temperature, pH, and other environmental factors. Specifically for solid-state nanopores, 2D materials provide a good foundation that is easy to modify, robust, and reusable [2,3]. 2D materials have unique properties that only appear when bulk materials are reduced to the nanoscale. Specific attributes can be generated in the 2D material and alter the dynamics of molecules travelling through the nanopores. Materials of interest include graphene, hexagonal boron nitride (h-BN), and transition metal dichalcogenides (TMDCs).
Methods
Different techniques for manufacturing solid state nanopores are investigated. These include transmission electron microscopy (TEM), scanning transmission electron microscopy (STEM), and helium ion microscopy (HIM). From these microscopy methods, nanopores are created in SiNx membranes as well as in 2D materials.
Results
Pores in the range of tens of nanometres are milled into SiNx using the HIM. Single nanopores as well as arrays of nanopores were created to investigate various milling parameters (Figure 1. A, B). DNA translocations were observed by ionic current measurements, validating the presence and function of the nanopore. For 2D materials, a scaffold of SiNx must be used to create freestanding 2D materials. Graphene and h-BN are transferred onto HIM milled or gallium focused ion beam (FIB) milled holes in SiNx membranes. The resulting membranes are imaged with high resolution TEM (Figure 1.C).
Conclusion
Electron microscopy and ion beam milling are promising techniques for the production of solid-state nanopores. Various pore geometries will continue to be explored and methods will be developed to create novel nanopores in 2D materials. The combination of 2D materials results in unique properties in nanopore structures which would otherwise be difficult to achieve without the use of electron microscopy and nanostructuring.

Microstructure of light-emitting phosphor of (Sr, Ca)AlSiN3:Eu2+

Hajime Matsumoto[1]
[1]Mitsubishi Chemical Corp., Yokohama, Japan, [2]National Institute for Materials Science, Tsukuba, Japan

Poster Group 2

If the peak half-maximum width of the emission spectrum is wide, the emission of light at wavelengths far from the target emission peak wavelength may increase, and the emission color indicating the desired chromaticity coordinates may not be obtained. In addition, in the case of red phosphors, the emission of light increases in wavelength regions with low specific visual sensitivity, such as 700 nm or more, which contributes to a decrease in the conversion efficiency of the light-emitting device. For this reason, phosphors with a narrower peak half-maximum width are required.

(Sr, Ca) AlSiN3:Eu2+ (SCASN) is a red phosphor [1] with a narrower peak half-width in the emission spectrum than CaAlSiN3:Eu2+ (CASN). These phosphors are highly reliable because they replace the Al site of AlN with Sr, Ca, and Si. In this study, we present the first microscopic results obtained for this type of materials.

SCASN and CASN have the same crystal structure, space group: Cmc21, which was investigated by the convergent beam electron diffraction (CBED) technique and the integrated differential phase contrast STEM (iDPC-STEM) technique. In the case of SCASN, the structure of the spatial group: Pcbn was also confirmed in the selected area of diffraction pattern, which was found to be due to the local atomic arrangement of the stacking fault. It was found using scanning moiré fringe imaging [2] that the higher the amount of Sr added in SCASN, the more dislocations and stacking fault co-exist, and that the disturbed stress distribution settles through the stacking defects in the region with high dislocation density. In addition, in SCASN manufactured by the high-pressure method, the distance between the stacking fault was far apart, and the stress distribution was stable.

These experiments have allowed the achieving of understanding of the close relationship between the ratios of Sr and Ca and the stress distribution and the extraction of significant features like the dislocation in the crystal, the stacking fault that it expanded, and the first neighbourhood distances between defects.

Molecular dynamics simulation of the Brownian motion of biomolecules in liquid phase electron microscopy

Mr Xiaopeng Wu[1], Dr Peng Wang[1]
[1]Department of Physics, University of Warwick, Coventry, United Kingdom

Poster Group 2

Background incl. aims
Liquid phase electron microscopy (LP-EM) revolutionizes our ability to observe dynamic processes within liquids at nanoscale resolution. It allows for the direct observation of biological, chemical and physical phenomena in their native liquid environments which was not possible with conventional or cryogenic electron microscopy (Cryo-EM). While previous successes of the technique have predominantly been demonstrated with rigid materials such as gold nanoparticles [1], it is anticipated that the application of the technique on soft materials such as biological macromolecules may yield novel insights into the functioning mechanisms from the observed dynamics [2].
In this work, we aim to investigates the behaviour of biomolecular samples in a liquid environment and consider the effect of the Brownian motion.
Methods
We employed molecular dynamics simulations to study the behaviour of the biomolecules in liquid at the nanosecond scale. The structure of the horse liver alcohol dehydrogenase (ADH) enzyme was used for this study [3], as shown in figure (a). We simulated multiple trajectories of the ADH enzyme using the OpenMM library [4], and the ff14SB force field along with the TIP3P water model was used for all simulations [5].
Results
As expected, the diffusivity of the protein is found to be increasing with temperature from the simulations. The protein exhibits significant deviations due to Brownian motion, which can be characterised by a random walk model, in figure (b), we have shown a snippet of the trajectory of the centre of mass of the ADH at 300 K to confirm that the global motion of the protein is indeed random. When the thermal energy of the water molecules is low but still above the freezing point, the diffusive motion of the protein tends to favour the direction with the smallest solvent accessible surface area, this was due to the irregular shape of the ADH protein. Upon further increase of temperature to 300 K, this anisotropy diminishes, as the protein diffuses more isotopically potentially due to more frequent interactions between the solvent and itself.
The protein exhibits thermal vibrations across all temperatures, which collectively influence the overall deviation of its structure. These vibrations are temperature-dependent and exhibit a relatively stable magnitude throughout the period of observation. Additionally, higher temperatures can induce further localised deviations within the protein structure, particularly in regions with higher flexibility, such as the sequence termini, where deviations can be notably pronounced compared to the rest of the protein.
Conclusion
Overall, this study enhances our understanding of the effect of Brownian motion inherent to biomolecules in liquid and may inform the development of more effective experimental designs for LP-EM. Future studies could extend this analysis to samples of different configurations, as well as longer simulation times for more robust estimations over larger timescales. The authors would like to acknowledge funding from the BBSRC International Institutional Partnership Fund.

Multifunctional hybrid nanocomposite films: linking inorganic nanoparticles using α-synuclein as molecular linker

Prof Patrizia Canton[1], Prof Adolfo Speghini[2], Dr Emil Milan[2], Dr R Tira[2], Dr. M. D'Onofrio[2], Dr M Assfalg[2]
[1]Department of Molecular Sciences and Nanosystems, Ca' Foscari University of Venice , Venezia, Italy, [2]Department of Biotechnology, University of Verona, Verona, Italy

Poster Group 2

Background incl. aims
Organic-inorganic hybrid nanocomposites can combine mechanical properties and particular functionalities exploiting organic macromolecules and inorganic nanoparticles. Inorganic nanoparticles can induce peculiar properties that can be exploited in several technological fields. For instance, luminescent nanomaterials are useful in nanomedicine as contrast agents, while proteins can act as stealth agents.
Methods
The interaction of inorganic nanoparticles with proteins is a matter of particular interest when studying their behaviour in a biological environment, especially for the development of new hybrid materials. Recently, investigation on hybrid monolayers of gold nanoparticles and α-synuclein, an intrinsically disordered protein associated with some neurodegenerative diseases such as Parkinson's disease, have appeared in the literature. Due to particular variations of the chemical environment, α-synuclein undergoes structural changes from a disordered state to a β-sheet conformation that leads to the formation of fibrils, useful for the formation of hybrid films. This behavior makes α-synuclein suitable for the development of nano-biocomposite nanomaterials such as nanofilms and filaments.
Results
Hybrid films composed of inorganic nanoparticles and α-synuclein have been developed. The hybrid films have been prepared, using a wet chemistry procedure, using various types of inorganic nanoparticles, as lanthanide doped alkaline-earth fluorides, to obtain nanocomposites with strong emission in the optical range. In particular, the structure of the inorganic nanoparticles and the α-synuclein monolayer is under study by means of STEM and HREM; the nanoparticle upconversion emission, a particular process involving emission of light (e.g. in the UV-visible range) upon excitation with electromagnetic radiation of lower energy (e.g. in the Near InfraRed, NIR, range) of the nanocomposites is described. The peculiar emission of the lanthanide ions in the optical range can be very useful for applications in nanomedicine, working in the so-called biological windows, exploiting the transparency of biological tissues in certain NIR ranges. Moreover, combination of different kinds of nanoparticles (e.g. gold and luminescent fluoride based nanoparticles) have been considered to develop multifunctional films with luminescence and thermometric capability for possible applications as biosensors.

Quantitative EMCD analysis of Fe thin films on MgOx substrates
Sharath Kumar Manjeshwar Sathyanath1, Anna L. Ravensburg2, Vassilios Kapaklis2, Björgvin Hjörvarsson2, Klaus Leifer1
1Department of Materials Science and Engineering, Uppsala University, Box 35, 751031, Uppsala, Sweden,
2Department of Physics and Astronomy, Uppsala University, Box 516, 75120, Uppsala, Sweden

Background

The structure and electronic structure of interfaces determine their magnetic properties in many modern materials. Yet, X-ray and neutron-based analysis techniques, albeit their fantastic contributions to the field, cannot give the real space image of magnetization. And among the TEM techniques, the close-to-atomic scale analysis of magnetic interfaces remains a challenge. All three magnetic analysis techniques in the TEM, electron holography, Lorentz microscopy, and electron energy loss magnetic circular dichroism (EMCD) have now established the first results demonstrating that with TEM techniques, we can obtain magnetic information at this length scale [1-4]. In the EMCD technique, magnetic information originates from the interference of electrons inelastically scattered into different beams. This interference giving rise to the EMCD signal is appearing at well-defined and conjugated q-vectors called C+ and C- positions. It bears an intensity that can be interpreted as resulting from the orbital and spin magnetic moments of the involved magnetic atoms. The technique can address both ferro- and antiferromagnetic materials.
Here, we present EMCD measurement on thin Fe films on MgOx substrate and show how accurate alignment and experimental parameters like convergence and collection angles modify the EMCD signal and interpret this change in magnetic signal to obtain magnetization and orbital/spin magnetic moment ratio in the Fe and at the Fe/MgO interface.

Methods

Fe films were grown on MgOx (001) substrate by sputter deposition. The cross-sectional and plan view samples were analysed using the EMCD technique in STEM mode. Spectra of the L3 and L2 edge of Fe corresponding to the C+ and C- positions were acquired at 2 beam condition using a Titan/Themis probe corrected TEM at an acceleration voltage of 200 - 300 kV with Gatan energy filter and a CEFID energy filter equipped with a direct electron camera ELA. The q-selection of the EELS spectra was carried out by using a custom-made script to shift the diffraction pattern and by placing a slit aperture into the EELS entrance aperture holder, see schematic Figure below. Each acquisition contains between 2000-10000 spectra which enables the treatment of individual spectra or sum spectra as well as the use of statistical methods in data analysis.

Results

Refinements of both, EELS analysis conditions as well as the sample quality enables us to improve the EMCD signal strength from the original paper of around 4 % to 17 % as shown in the figure below,

which was taken at small convergence angle and using the conventional circular EELS entrance aperture. Though, aiming to approach atomic resolution in magnetic measurements, high convergence angles in the EMCD analysis are needed, which will be typically larger than 5 mrad. The other limit of such EMCD analysis is beam damage. We analysed the EMCD signal as a function of convergence angle and optimized acquisition conditions in view of limiting beam damage. With those conditions, we analyse EMCD signals at the Fe/MgOx interface with down to 2Å resolution [4,5].

Conclusion
In summary, we have optimized and analysed signals in EMCD measurements on Fe/MgOx . An excellent EMCD difference signal as well as improvement in the signal-to-noise ratio is evident due to the crystalline quality. We have obtained interfacial profiles of EMCD signals with down to 2Å resolution.

Poster Group 2

Background incl. aims: Soft X-ray microscopy is a powerful tool for three-dimensional investigation of biological material [1]. The water window energy range between the absorption edges of carbon (284 eV) and oxygen (543 eV) provides a strong natural contrast for aqueous samples and offers the possibility for both a high resolution of a few tens of nanometer and a high penetration depth of up to 10 µm. Within the Collaborative Research Center 1340 (CRC) “Matrix in Vision” funded by the German Research Foundation, we use soft X-ray microscopy to investigate the role of the extracellular matrix (ECM) in diseased tissue, as the components and properties of the ECM play a major role in the regulation of cell and tissue function.
Methods: Alteration of the ECM plays a pivotal role in the progression of inflammatory diseases such as atherosclerosis. Understanding the underlying processes contributing to ECM alterations can aid in early detection during the initial stages of development. The ECM of cryofixed model cells (THP-1 cell line derived from an acute monocytic leukemia patient) has been studied with a laboratory soft X-ray microscope (L-TXM) located at the Berlin Laboratory for innovative X-ray Technologies (BLiX) at TU Berlin. A correlative workflow was developed by integrating a visible light microscope into the L-TXM setup [2], allowing a fast transition between the two modalities, and facilitating sample localization to accelerate 3D cell imaging. Additionally, various upgrades have been performed on the L-TXM setup to enhance stability and increase sample throughput in order to streamline the workflow and address the specific demands of the samples investigated within the CRC.
Results: The upgraded L-TXM at TU Berlin offers enhanced stability and increased sample throughput for biomedical research within the CRC, resulting in consistent imaging quality over extended acquisition times. Laboratory-based soft X-ray microscopy was able to resolve the THP-1’s glycocalyx – an intricate fragile extracellular structure. Nevertheless, different sample preparations resulted in different thicknesses and lengths of the glycocalyx’s interlocking meshy structure.
Conclusion: Laboratory soft X-ray microscopy provides unique flexibility and access to high resolution 3D imaging. Recent upgrades of the laboratory setup now enable a more streamlined workflow. The resulting higher sample throughput will help to establish suitable preparation techniques for various cell types for soft X-ray ECM research within the CRC. Combining results from X-ray based analytics with clinical diagnostics adapted for ECM research will help to better understand the role that the extracellular matrix plays in (inflammatory) diseases.

Poster Group 2

Background incl. aims
Devices whose operation is based on the field emission phenomenon are widely used and continuously developed. Among the numerous categories, vacuum microelectronics stands out. In previous decades, the fabrication of field emitters based on the Spindt method was developed[1]. This is a multi-step method based on etching and deposition of selective areas on a volumetric substrate. The extremely attractive topic of integrating field emitters with microelectromechanical systems (MEMS), acting as nano- and picometrology sensors, has now emerged[2]. However, the fabrication of multicomponent micro- and nanodevices in a single process line is a challenge. Therefore, combining different manufacturing technologies should be considered. A method that enables the creation of planar and three-dimensional nanodevices is a combination of focused-electron-beam-induced deposition (FEBID) and focused-ion-beam-induced deposition (FIBID)[3]. This is a one-step, so-called direct-writing method. The material of the deposited nanodevice is defined by the precursor used. Its shape is determined by the scanning motion of a focused beam with nanometre and sub-nanometre cross sections. The equipment that enables the fabrication of ultra-sharp field emitter tips is the scanning electron microscope (SEM) with a focused gallium ion beam (Ga-FIB) and the helium ion microscope (HIM). A commonly used material is tungsten[4] due to its good thermal and electrical conductivity, low work function and the ability to sustain high current densities. However, platinum is also of interest due to its high chemical inertness[5]. In this work, nanowire platinum and tungsten field emitters fabricated by the FEBID and FIBID (Ga and H) process will be shown for the first time. The field emitters will be integrated into microcantilevers manufactured by photolithography, acting as nanosensors of their deflection. The field emission phenomenon will be studied and the operation of the nanosensors will be evaluated.
Methods
A Helios Nanolab 600i SEM with FIB equipped with MeCpPtMe3 precursor and a Zeiss Orion Nanofab HIM containing W(CO)6 precursor were used for microcantilever modification and deposition of nanowire field emitters. During the FEBID and FIBID process, precursor molecules are injected into the vacuum chamber of the microscope. The primary focused electron/ion beam induces secondary electrons from the sample surface, which have the required energy to decompose the precursor molecules. Hence, in the vicinity of the scan area the material grows, leading to the fabrication of the field emitter nanowire. In order to prepare the microcantilever for field emitter deposition and eliminate the risk of short-circuiting the electrodes due to the existence of the halo effect, the microstructures were modified by milling with a focused gallium/neon beam. Leakage currents between the electrodes were measured before depositing the field emitters on them. The field emission phenomenon was characterised in the vacuum chamber of the microscope, using a self-designed electronic setup, a source measurement unit Keithley 2614 and software written in the

LabVIEW environment. Analysis of the nanowire material composition was conducted with an energy-dispersive X-ray detector attached to a transmission electron microscope.

Results

Calibration of the growth of platinum and tungsten nanowires was performed using SEM-FIB and HIM, respectively, for specific values of beam current, accelerating voltage, dwell time, beam spacing, and precursor pressure. Field emission enhancement factor calculations were made to optimise the emitter shape. Microcantilever modifications were performed using a focused gallium and neon ion beam (Figure 1a). Spatial holes were milled between adjacent electrode paths dedicated to the integration of field emitters on the microcantilever. The aim was to separate them permanently, minimising the risk of short-circuiting due to the halo effect associated with the FEBID and FIBID process. Leakage currents between adjacent electrode paths were measured in the range of +/-100 V. Measurement values oscillated in the pA regime. Planar nanowires, as field emitters, were then deposited with a distance of about 100 nm between them (Figure 1b,c). In situ field emission measurements were conducted for the fabricated structures. Field emission from 50 V was recorded for the platinum field emitters with a distance of 150 nm between the electrodes. For tungsten field emitters and a cathode-to-anode distance of 120 nm, the threshold voltage of field emission was equal to 70 V. The stability of the emitter operation over time was verified, together with an analysis of the emitter material composition before and after operation.

Conclusion

This work presents a fabrication technology for nanowire field emitters by the FEBID and FIBID process, using two different precursors - MeCpPtMe3 and W(CO)6. The technique of integrating FEBID/FIBID nanodevices with microcantilevers produced in photolithography steps was developed. The characterisation of the field emission phenomenon was undertaken as a basis for investigating the usability of a microcantilever deflection sensor.

Poster Group 2

Background
Two-dimensional (2D) materials have the potential to transform semiconductor technology. Their rich compositional and stacking diversity, especially when deposited as heterostructures, allows tailoring of material properties to enable a wide range of device applications [1]. A prominent class of these 2D materials are the transition metal dichalcogenides (TMDs). With improved synthesis and fabrication capabilities, heterostructure concepts have been developed that show promising material properties for ultrathin optoelectronic devices. While these heterostructures can be fabricated by mechanical pattern transfer for small areas with high precision, these approaches are difficult to scale up. Therefore, alternative approaches such as metal organic chemical vapor deposition (MOCVD) have been developed to fabricate 2D materials and their heterostructures. Depending on the process parameters, several growth modes can dominate and thus a variety of structure combinations can be created. Since optical and electronic properties typically depend on the orientation, high-resolution measurements of the number of layers and feature sizes of each material can help to understand macroscopic optical measurements and guide the optimization of growth processes towards desired layer structures.
Methods
The MOCVD grown WS2/MoS2 heterostructures were transferred using a PMMA transfer process with successive cleaning and baking steps. Scanning transmission electron microscopy (STEM) measurements were performed using a JEOL JEM-2200FS. By tuning the convergence angle to less than 2 mrad, we obtained scanning diffraction data leading to nanoscale resolved alignment information. In addition to these diffraction measurements, we use energy dispersive X-ray spectroscopy (EDX) to resolve the chemical composition of the few-layer heterostructures. The structure is further resolved by conventional quantitative annular darkfield STEM image simulations and 4D-STEM measurements.
Results
We find evidence for both vertical and lateral heterostructures of MoS2/WS2 and a homogeneous but complex 2D film with few layers and pronounced island growth. The number of layers can be deduced by quantitative EDX mapping supported by image contrast simulations (Figure 1a). We find a nearly coalesced WS2 monolayer with additional multilayer island growth. The MoS2 layer grown on top can be shown to form either from facets of the multilayer WS2 (Figure 1b) or from nucleation without facets on top of the tungsten TMD. Figure 1c shows an example of a presumably vertically stacked MoS2/WS2 heterointerface. It can be seen that the contrast is dominated by the tungsten columns of the underlying film, which highlights the need for quantitative image simulations.
Conclusion

We can show the microscopic orientations of the TMD heterostructures in the case of MoS2 and WS2 grown by MOCVD. The combination of analytical techniques such as EDX and quantitative image simulations helps to unambiguously identify the complex layer structure of this few layer material system. We are also exploring the possibility of identifying relevant material domains by large area scanning nanobeam diffraction using 4D STEM imaging.

In-Situ microscopy study on self-healing process of vitrimers

Tobias Krekeler[1], Siraphat Weerathaworn[2], Matthias Hemmleb[3], Volker Abetz[2], Martin Ritter[1]
[1]Hamburg University of Technology, Hamburg, Germany, [2]University of Hamburg, Hamburg, Germany, [3]point electronic GmbH, Halle (Saale), Germany

Poster Group 1

Vitrimers are reprocessable and recyclable polymers with a wide range of adjustable properties. One keypoint of the reprocessability is the thermoreversible associative dynamic exchange mechanism which makes a vitrimer behave like viscoelastic fluid at elevated temperatures and like a thermoset at low temperatures. This change in behavior also has the potential to design polymers with "self-healing" characteristics where scratches or fractures are removed by applying heat. In this work we track this self-healing mechanism of a scratched vitrimer surface with in-situ microscopy and surface reconstruction using a segmented backscatter electron detector. The vitrimer used in this study is a tailor-made vinylogous urethane vitrimer with self-assembling binary and ternary block and random copolymers.[1]
The surface height of the sample is obtained with a shape-from-shading algorithm that uses the angular dependency of backscattered electrons and the orientation of the surface inclination to the detector. This technique does not need sample tilting and allows for live in situ topographic view of sample surfaces.[2]
The topographic view of the scratch show the displaced material as a 2 µm high ridge on both sides right next to the 5 µm deep scratch. After heating the sample to 115 °C for 2 minutes the ridges have flattened to a large extent due to the transition of the polymer to a fluidic state.
This initial result show the great potential of topographic imaging in in-situ experiments as conventional SEM imaging only result in 2D-images without or only obfuscated height information.

Poster Group 2

Background and Aims:
Soft X-ray microscopy within the water window spectral range offers non-destructive imaging capabilities with nanometer resolution and a penetration depth of up to 10 µm. This enables the investigation of biological samples in a near native state in three dimensions. The interpretation of X-ray microscopy images of biological cells can be challenging due to the similar absorption characteristics of carbon-based structures within these samples. To address this challenge, we have developed a contrast enhancement protocol, to improve the interpretability of the acquired images. Subsequently, an efficient segmentation technique based on deep learning is deployed for the extraction of biologically relevant information from the large amount of data generated by fast tomogram acquisition.
Methods:
We employed a laboratory-based soft X-ray microscope operating within the water window (500 eV photon energy). To enhance the contrast in acquired images, we developed a contrast enhancement protocol incorporating an adaptation of the Paganin filter as well as an unsharp masking filter. Additionally, we deployed a neural network model utilizing a U-Net architecture for the segmentation of THP-1 cell tomograms. This approach leverages the natural higher contrast of lipid membranes to facilitate segmentation.
Results:
The implementation of the contrast enhancement protocol resulted in improved contrast-to-noise ratios, thereby enhancing the interpretability of acquired images. Moreover, the neural network-based segmentation technique efficiently extracted biologically relevant information from tomograms, as confirmed by organelle volume calculations that align with tabular data. This segmentation can enable quantitative insights at the subcellular level, including the location and distances between different organelles, as well as their concentrations.
Conclusions:
Our study offers a comprehensive approach to soft X-ray microscopy analysis, addressing challenges in image interpretation and data segmentation. The developed contrast enhancement protocol and segmentation techniques facilitate efficient and accurate investigation of biological samples at the sub-cellular level. For the generalization of the segmentation process, increasing both the volume and quality of the data, as well as refining sample preparation, is necessary. Nevertheless, our advances contribute to analyse soft X-ray microscopy data more efficiently.

Poster Group 2

Background incl. aims

ZnO, and Ga2O3 nanostructures are the subject of interest in many research groups. In particular, ZnO and Ga2O3 nanorods (NRs) have considerable potential for applications in gas sensors, piezoelectric nanogenerators, photovoltaic devices, and pressure sensors. Most applications require position-controlled ordered arrays of physically identical nanorods (NRs). Position-controlled nanorod arrays can be obtained by selective-area epitaxy (SAE) on a suitable seed layer (SL) [1].
The size, shape, and preferential orientation along the c-axis, as well as the in-plane orientation of the crystallites within the SLs, are crucial for successful nucleation, good alignment, and crystallinity of the NRs. Crystallographic, morphological, also optical, and electrical properties of the crystallites and nanocrystals can be influenced and enhanced by heat treatment [2, 3].
The impact of the SL on the orientation of the NRs is even more significant and visible during the SAE, where the NRs do not nucleate and grow in close proximity, and the geometrical selection is suppressed. Every deviation from the preferential orientation of crystallites along the c-axis causes a visible misalignment of the grown NRs.
Another property of wurtzite ZnO crystals, which not only influences the optical and electronic properties but also affects the nucleation and growth of ZnO and NRs, is the polarity of the crystals. Spontaneous polarization in the ZnO and GaN wurtzite structures is present because of the missing center of symmetry; therefore, the [0001] direction and [000-1] direction are not equivalent.
We provide novel insights into the formation and investigation of the properties and quality of SLs used for the growth of ZnO and Ga2O3. We utilize SAE-grown arrays of single NRs to scrutinize the misalignment of crystallites within SLs prepared under different conditions without the influence of geometrical selection. By enhancing the crystal quality, controlling the Ga2O3 phase, and understanding of the ZnO polarity, we are moving the ZnO and Ga2O3 nanostructures closer to the applications.

Methods

ZnO and Ga2O3 arrays were prepared by chemical bath deposition (CBD) on sol-gel-deposited SLs patterned by EBL. The SEM provided the first morphological characterization of the nanostructures. With the assistance of machine learning during SEM image processing, dimensional changes were evaluated in nanostructures prepared under different growth conditions.
The crystallographic structures of ZnO and Ga2O3 were further investigated using TEM and HRTEM. Plane and line defects, which significantly influence the electronic and optical properties of the nanostructures, were examined using HRTEM, DF, and WBDF.
The epitaxial relationship between the NRs and SLs was investigated in more detail by automated crystal orientation mapping in TEM (ACOM/TEM-ASTAR), where a high spatial resolution map of the

crystallite lattice orientation was obtained [2]. The interfaces between the NWs and SLs were investigated not only crystallographically but also chemically using EDX in the TEM.
Piezo-force microscopy (PFM) was used to examine the polarity of the crystallites within the ZnO SL. PFM is an AFM mode that can map the piezoelectric and ferroelectric properties of a material. The polarity of ZnO polar wurtzite NRs was investigated using convergent beam electron diffraction (CBED) and annular bright field (ABF) measurements.
In situ TEM heating experiments were performed on polycrystalline ZnO SL (Fig. 1) and Ga_2O_3 NRs to provide insight into the phenomena that occur at elevated temperatures.

Results
The SAE-grown arrays of NRs showed the expected behaviour. When the NRs showed significant misalignment on the non-patterned SL, the NRs in the arrays exhibited the same behaviour. In addition, the NRs showing good alignment on non-patterned SL sometimes grew well aligned in the arrays. However, a discrepancy was observed on a significant number of ZnO SLs, where the alignment of NRs from patterned and non-patterned SLs was not in agreement. This discrepancy was caused by geometrical selection during nonpatterned growth on SLs with a low texture.
Generally, the alignment of crystallites within ZnO SLs improves with elevated temperatures at the expense of reproducibility. The results of the ZnO SL sintering experiments in different atmospheres and on various substrates indicated the simultaneous occurrence of oxygen and zinc diffusion and preferential alignment. Depending on the conditions, this phenomenon occurs at different temperatures. Surprisingly, preferential alignment was also observed in the in-situ TEM heating experiment, where the substrate was not present. Furthermore, PFM investigation of the crystallite polarity evolution during the heat treatment of the ZnO SL suggests the unification of ZnO crystalline polarity at Zn-polar at elevated temperatures.
To move towards applications and achieve monocrystalline SAE-grown ZnO NRs on ZnO SL, the correlation between the size of an opening in the patterning mask and the size of crystallites in the SL was crucial. If the size of the opening was equal to or smaller than the average size of the crystallites in the SL, the probability of nucleation and growth of monocrystalline NR from a single crystallite increased significantly. The requirements for SL were still a good crystalline preferential orientation along the c-axis, maximum crystallite size, and minimized dispersion of crystallite sizes within the SL. Investigation of the crystal polarity dependence between the ZnO SL/ZnO NR indicated a hereditary relationship between the ZnO SL/ZnO NR polarities.
Although Ga_2O_3 has several polymorphs, the monoclinic β-Ga_2O_3 phase was mostly observed in the Ga_2O_3 nanostructures. SAE of β-Ga_2O_3 NRs on SnO SL showed no preferential alignment and uncovered a significant role of the geometrical selection. Furthermore, no epitaxial relationship was observed between the SnO SL and the β-Ga_2O_3 NRs during the in situ TEM heating experiment.

Conclusion
Using microscopy techniques and SAE, we delved into the behaviour of ZnO SLs during heat treatment. We break the common belief that vertical orientation of NRs on polycrystalline SLs can be directly linked to the quality and preferential orientation of the SL. With the help of SAE, we showed that this conclusion can be made only on arrays where the distances between the NRs are high and geometrical selection affecting the growth is not involved. We further demonstrated that the development of the preferential orientation of the crystallites in the SL during heat treatment is not related to the presence of the substrate.

SoftGrids: towards disease modelling in CryoEM

Abstract Submission Asena Oelschläger[1], Prof. Dr. Stefan Raunser[1], Dr. Sebastian Tacke[1]
[1]Max-Planck-Institut für molekulare Physiologie, Dortmund,

Poster Group 1

Background incl. aim
In vitro cells derived from pluripotent stem cells (iPSCs) show some changes in their phenotype compared to their adult counterparts in vivo. Studies have shown that the application of external stimuli to provide a more natural environment has a major impact on many characteristics of cultured cells. Of particular interest is mechanical stimulation with a material whose stiffness is adapted to the tissue in which the cell type naturally occurs. Typical electron microscopy substrates such as EM grids do not offer this possibility. These usually consist of a combination of very hard grid bars and a very soft film and therefore do not offer the optimal conditions for some cell types. The aim of this work is to offer a workflow for cryo electron tomography (CryoET) that closes this gap by coating grids with a material whose mechanical properties can be easily modified.

Methods
In order to show the influence of the stiffness of EM grids coated with substrates of different stiffness, mesenchymal stem cells (MSCs) are seeded onto the grids and then examined for the quantitative expression of specific markers proteins using fluorescence microscopy. The markers selected were those that are usually expressed to a high degree in cells with strongly differentiated natural stiffness domains. They are categorized into neurogenic, myogenic and osteogenic markers. In addition, control cultures are created from progenitor cells that express the specific markers to a particularly high degree. The stiffness of the respective substrates is measured using atomic force microscopy.
For the integration into the CryoET workflow, iPSC-derived neurons and iPSC-derived cardiomyocytes are seeded on the grid and plunged after 7-10 days. With the help of a FIB, thin lamellae of about 200 nm are prepared. In a transmission electron microscope, tilt series are generated by gradually tilting the stage, from which tomograms are then generated.

Results
The measured intensities from the marker expression in MSCs show a maximum for a certain stiffness and a decreasing signal for cultures on grids whose stiffness leads further away from the ideal value.
The generated tomograms show vitrified content. The lamellae can be produced in a comparable time compared to non-coated standard grids. By using stripe grids for the topological stimulation of cardiomyocytes, the cells can be polarized efficiently. This configuration allows a very high slat density per grid.

Conclusion
We have shown that the cultivation of cells on our grids has an effect on the phenotype of certain cell types compared to standard EM grids and that this effect depends on the stiffness of the material. This behavior has been sufficiently proven for non-grid substrates in many studies. With the provided workflow for CryoET, the possibility has been created to perform model-based research

with iPSC-derived cells in structural biology. This opens another door, particularly for desease research on neuonal and cardiac model systems.

Room temperature viscoplastic response of amorphous olivine films revealed by ex/in-situ TEM nanomechanical testing

Dr Armand Béché[1]
[1]IMAP/LACaMi - UCLouvain, Louvain-La-Neuve, Belgium

Poster Group 2

Olivine is a silicate which controls the rheology of the Earth's mantle down to ca. 410 km depth. Recently, we have discovered a new deformation mechanism of olivine where grain boundary sliding involves amorphization of grain boundaries under high stresses and further plastic flow along this amorphous layer [1]. We are convinced that this mechanism has a fairly general application to hard materials under conditions of high stress. This idea has been previously advocated by Idrissi et al. [2]. In the present case of olivine, the implications are mainly in the lithosphere in a ductile brittle context and at the boundary between the lithosphere and the asthenosphere. This led us to characterize the mechanical properties of amorphous olivine, but this material is mostly available in the form of thin films. It is therefore necessary to employ nanomechanical techniques: nanoindentation, in-situ TEM deformation and Lab-on-Chip (Figure 1). These tests have in particular the capacity to extend the solicitations to very low deformation rates relevant in geodynamics. Advanced TEM characterizations have allowed to identify the underlying microscopic mechanisms either in-situ or in ex-situ deformed samples. These data will allow in the future to feed mesoscopic mechanical models of olivine-rich rocks of the upper mantle. We also observe a significant influence of the electron beam on the viscoplastic behaviour of amorphous olivine. Special attention was paid to elucidate the origin of such feature.

Low-dose 4D-STEM cryo-tomography of biological samples

Dr. Shahar Seifer[1], Shai Kiriati[1], Dr. Peter Kirchweger[1], Prof. Michael Elbaum[1]
[1]Weizmann Institute of Science, Rehovot, Israel

Poster Group 2

Background incl. aims
4D-STEM provides a copious amount of information that must be reduced for interpretion. The challenge is compounded in the context of low dose exposure in beam-sensitive specimens. We describe several data processing approaches for tomographic reconstruction that result in improved 3D mapping of biological samples.

Methods
4D STEM collects a 2D diffraction pattern at each pixel in real space. Summation of electron counts over masked areas define virtual detectors in the form of annular rings and azimuthal sectors. A tilt series of projection images provide data for tomography, from which 3D reconstructions are generated for each virtual detector individually. Principal component analysis (PCA) of annuli yields a separation of amplitude and phase contrast. Alternatively, center of mass (COM) and differential phase contrast (DPC), generated from azimuthal segments, reveal phase gradients. By manipulation of parallax corrections, which appear as image shifts, the phase contrast extracted by integrated virtual differential phase contrast (iDPC) can be separated into parts that originate from distinct contributions of the contrast transfer function, aiding in interpretation. Finally, by collection of a large scattering range, information accessible in the virtual rings in the dark field is also interpretable as a differential cross section, which decomposes to elastic and inelastic scattering contributions depending on the scattering angle.

Results
3D reconstructions are applicable on either the virtual rings or sectors. Applying parallax manipulation over the virtual DPC is particularly useful and shares common aspects with ptychography techniques. The differential cross section data fits predictions in elastic scattering and plasmon generation in several amorphous non-metallic materials.

Conclusion
4D-STEM in tilt series can be applied routinely to generate 3D imaging that demonstrates improvement over simple dark-field or incoherent bright-field STEM. In parallel, the direct measurement of differential scattering cross section provides indications on atomic composition.

Ultra-low-cost, high-dynamic-range, additively manufactured CMOS spectrometers with UV, visible, and NIR sensing functionality

Mr. Hironori Kondo[1,2]
[1]John A. Paulson School of Engineering and Applied Sciences, Harvard University, Cambridge, USA,
[2]Department of Chemistry and Chemical Biology, Cambridge, USA

Poster Group 1

Background incl. aims
Ultraviolet (UV)-Visible and infrared (IR) spectroscopy are widely used to characterize material and chemical samples. Inexpensive and high-performance spectrometers would broaden the impact of these tools. Educational spectrometers often lack accuracy, resolution, and repeatability, whereas industrial spectrometers are often expensive and hard to customize. We used consumer microprocessor development boards, image processing, and additive manufacturing (AM) to create an ultra-low-cost spectrometer platform, capable of modularly converting between UV, visible, and near-IR (NIR) measurements. The system can also track reaction progress via tandem temperature monitoring, with the possibility of further General Purpose Input/Output (GPIO) channels. This device offers high precision and flexible customization within a simple and inexpensive package.
Methods
This work comprises 1) hardware, 2) electronics, 3) firmware and software. The hardware architecture uses design for AM (DfAM) principles to minimize the part count, while achieving high performance, and low cost. We explored Fused Deposition Modeling (FDM) and stereolithography (SLA) manufacturing strategies. The electronics are based around an ESP32S3 development board from Seeed Studio, which has a high pseudostatic random-access memory (PSRAM) capacity that enables long-term data-gathering and GPIO expansion. The board is paired with complementary metal oxide semiconductor (CMOS) OV2640 and OV5640 camera modules from Seeed Studio, with the former offering low costs and the latter's backside-illuminated (BSI) construction enabling UV sensing. Temperature sensing is via a thermistor. The firmware is written in C/C++ using ESP32 camera libraries. The control software and user interface are written in Python using standard serial communication, image processing, time series analysis, and graphical user interface libraries. Features include automatic wavelength calibration using curve registration algorithms and an option for manual exposure control. Debvec's algorithm constructs a camera response curve from the bracketed exposures to produce a high-dynamic-range (HDR) reading.
Results
Using these inexpensive CMOS arrays, rapid data collection with high-precision sensing is achieved. Camera module and development board costs are less than USD 15 combined, and each scan takes on the order of 10 milliseconds (excluding HDR processing, on the order of seconds). For a 500-nanometer detection range, the 1600-pixel CMOS array width corresponds to approximately three pixels of data per nanometer. Practical resolution is limited by the choice of diffraction grating. NIR functionality relies on the intrinsic NIR sensitivity of CMOS arrays. UV functionality requires the removal of the Bayer filter from a BSI sensor, increasing fabrication cost and complexity. Software calibrations correct for color casts (i.e., intrinsic tints from the sensor) and uneven black levels. Raw RGB sensor data is not accessible due to poor library and hardware support, but raw grayscale data yields low noise (70dB peak signal-to-noise ratio for non-HDR data). JPEG compression is available given resource limitations. Tandem temperature monitoring successfully tracks reaction progress. SLA manufacturing requires fewer parts, while FDM achieves similar performance with simpler post-

processing. Further quantification of usable resolution, noise performance, dynamic range, and wavelength limits is ongoing.

Conclusions

Desktop AM systems, low-cost development boards, and library support for CMOS sensors enable the design of ultra-low-cost and compact spectrometry systems that can be tailored to specific experimental needs. With appropriate image processing and hardware, these systems achieve the repeatability and precision of commercial solutions that are more expensive and less modular. The approaches presented here enable low-cost, high-performance, agile spectrometry solutions that experimentalists can tailor to their specific needs, including in distributed IoT and other non-laboratory systems.

Background incl. aims
Spintronics is an expanding field in nanoscience, attracting attention in the last decade due to its potential to revolutionize CMOS based logic and data devices by utilizing the spin of electrons. Spin manipulation via spin current generation, propagation, and spin injection and detection, are key steps for the realization of fast, non-volatile, and low power computational devices. The successful achievement of these goals is challenging as it requires atomic level control of interfaces and thin film structures in multi-layered heterostructures. The 100% spin polarization in ideal L21 structured Heusler alloys is very sensitive to both extended defects (i.e. dislocations) due to strain effects, as well as anti-site defects, and which results in variety of lower symmetry ordered Heusler phase, like B2, DO3, and A2. Hence methods that can detect differences between phases in nano-volumes is critical for optimizing performance of spintronic devices based on Heusler alloys.

Methods
We have investigated the nano-grain structure of Co2FeSi films using correlative microscopy, fusing simultaneously acquired Energy Dispersive X-ray (EDX) spectroscopy and 4D-Scanning TEM datasets, on a Thermo Fisher Talos F200X operated at 200kV. The convergence angle achieved was 1.5 mrad, using a 10 µ C2 aperture. A Thermo Fisher Super-X SDD detector, with 0.9 srad collection angle, was used to acquire EDX. CBED patterns were recorded using a Quantum Detectors Merlin Quad detector with 512x512 pixels. For the scans used in this study a dwell time of 2–25 ms was used to scan regions with a step-size of 1–2 nm. Unsupervised machine learning algorithms have then been employed to identify nano-grains in the Heusler Co2FeSi thin films. Fuzzy C-means clustering, using a Gustafsson-Kessel approach allowing for elliptical clustering, was applied to a robustly scaled and dimensionally reduced combination of CBED and EDX data. The dimensional reduction was achieved using Principal Component Analysis. Density Functional Theory (DTF) studies were performed using the Vienna Ab-inito Simulation Package (VASP) using the SCAN functional with PAW pseudopotentials. A k-point mesh of 8 x 8 x 8 and planewave cut-off of 700eV were used for geometry optimisations with a finer density used for spectral calculations.

Results
Clustering of individual signals from the 4D-STEM and EDX of Co2FeSi thin films was unable to identify any higher ordering within the Heusler structure. However when the signals were combined the finer details of the film texture became apparent. Specifically, the correlative acquisition has allowed the unsupervised clustering algorithm to separate regions inseparable via noncorrelative techniques. The analysis of the clustered nano-grains, of differing structural and chemical composition, revealed a novel phase of CoFeSi that has been confirmed via further HAADF imaging. The structure has been optimised using DFT calculations and shown to be more stable than other

known CoFeSi phases, emphasising the structure's relevance. Further computational calculations have predicted the structure to be a semi-metal rather than a half-metal and as such it's inclusion in a Co2FeSi is potentially a, previously hidden, defect compromising spin polarisation.

Conclusion
By combining Energy Dispersive X-ray (EDX) spectroscopy and 4D-Scanning TEM datasets, we have a unique structure and chemical composition that is invisible when the data is treated independently. Subsequent analysis of the identified nano-size secondary phase shows that it contains ordering peaks that overlap with the full-Heusler L21-ordering, making it difficult to detect via standard characterization techniques (e.g. X-Ray Diffraction). Furthermore, we show that this new phase has unique ordering nor reported for Heusler phases in current literature. Additional magnetic measurements and density functional calculations have shown that the secondary phase is not fully spin polarized, has lower magnetic moment per unit cell, which can be detrimental when films with such inhomogeneities are incorporated in a device structure.

Background, Motivation and Aims

The incidence of Osteoarthritis (OA) is increasing across the world with an expected 1 billion individuals suffering from it in the year 2050 [Lancet Rheumatol. 2023 PMID: 37675071]. OA is the most common degenerative joint disease, which presents as degradation of articular cartilage that results in pain and limited mobility. There is an unmet need for patient friendly paradigms for clinical assessment that do not require ionizing radiation (CT), exogenous contrast enhancing dyes (MRI), biopsy, and/or invasive instrumentation approaches (arthroscopy or endoscopy). Hence, techniques that use non-destructive, near- and shortwave infrared (NIR, SWIR) light may be ideal providing for providing non-invasive, label-free and deep tissue interrogation. NIR and SWIR spectral regions (700 nm to 2500 nm) are well suited for deep tissue penetration given the reduction in scattering with an increase in wavelength and decrease in absorption by tissue components. This results in 'biological transparency windows' in the NIR and SWIR that can be used for deep tissue penetration of light. With this motivation we utilized the chemical 'fingerprinting' techniques of NIR Raman scattering and NIR-SWIR absorption spectroscopy to develop a new approach to tissue diagnostics. We aimed to develop the multimodal 'spectromics' approach, wherein we carry out low-level abstraction data fusion of Raman scattering and absorption spectroscopy data to provide an enhanced, interpretable 'fingerprint' for diagnosis of OA in human cartilage.

Methods

Articular cartilage samples, obtained with full ethical approval and patient consent (REC reference 18/NW/0231), were excised from human femoral heads. Cartilage tissue slices were taken parallel to the femoral head surface, as deep as the subchondral bone. Cartilage slices were fixed in 4% paraformaldehyde (PFA) for 72 h and stored, refrigerated, in phosphate buffered saline before spectral analysis.
Raman spectroscopy measurements were carried out on a Renishaw InVia microscope system with samples excited using a 785 nm laser focused through a Leica 50x (0.75 NA) short working distance (~200 µm) objective. NIR-SWIR spectroscopy of the cartilage samples was carried out on a homemade benchtop system. Incident excitation light was provided by a broadband halogen lamp (HL-2000-FHSA-LL, Ocean Insight) emitting as a blackbody across the NIR-SWIR range, and signal collected via an OceanOptics NIR Quest 2.5+ spectrometer. Hyperspectral mapping of each sample was achieved by moving the sample stage and for each position, a mean average spectrum of 3 acquisitions with exposure time of 5 s for Raman and 10 ms for NIR-SWIR absorption spectroscopy were recorded. A modal average of 3 samples were investigated for each patient.
Raman spectra were preprocessed (baseline corrected, denoised and normalised). NIR-SWIR absorbance spectra were first treated with a 1st-derivative transformation and subsequently

smoothed, baseline corrected and normalised. A rubber-band baseline correction was applied to both spectra before concatenating them. The spectromics 'fingerprint' was created by concatenating the mean average pre-processed Raman spectra to the mean average pre-processed NIR-SWIR data from a given patient. Multivariate data analysis and classification was carried out using principal component and linear discriminant analysis as well as supervised machine learning using support vector machine.

Results
Under multivariate statistical analysis and supervised machine learning, tissue was classified to high precision: 100% segregation of tissue classes, and a classification accuracy of 95% (control) and 80% (OA), using the combined spectroscopic data was obtained. There was a marked improvement (5 to 6-fold for multivariate analysis) in classification performance using the spectromics fingerprint compared to results obtained solely using Raman or NIR-SWIR data. Furthermore, discriminatory spectral features in the enhanced fingerprint elucidated clinically relevant tissue components (OA biomarkers). Clinically relevant spectral features from the tissue allowed interpretable feedback from the enhanced fingerprint.
In order to take tissue heterogeneity into account we further created a new setup and performed automated 3D goniometric hyperspectral mapping of OA cartilage on whole human femoral heads post hip arthroplasty for spatially correlated spectromics of OA and age-matched controls. Spatially resolved spectral analysis highlighted morphologically relevant regions and chemical signatures with potential to aid early diagnosis, using spectromics-based OA biomarkers.

Conclusions
This proof-of-concept study examined Raman scattering and NIR-SWIR absorption spectroscopy for chemometric assessment of articular cartilage tissue in an elegant low-level abstraction data fusion approach termed spectromics. The improved classification potential of the enhanced spectromic fingerprint was shown. Our study demonstrated the potential of the spectromics approach for OA diagnosis with significant therapeutic diagnostic implications for an aging demographic. Our results lay the foundation for label-free chemometric diagnosis of OA and potentially other diseases that can be implemented in the clinic in a minimally-invasive or completely non-invasive ways.

Simultaneous nanoscale mapping of strain and electric field in semiconductor heterostructures using 4D-STEM

Yucheng Zou[1], Dr. Lei Jin[1], Peng-Han Lu[1], Prof. Dr Rafal Dunin-Borkowski[1]
[1]Research Center Jülich, Jülich, Germany

IM-06 (1), Lecture Theater 1, august 29, 2024, 14:00 - 16:00

Background incl. aims
High-performance semiconductor devices are the basis of modern electronic equipment and have a very important impact on the processing, transmission and storage of information and energy fields. In many of those devices, the built-in electric field, depending on the distribution of dopants, plays a vital role in their performance and operating characteristics. On the other hand, introducing strain in the semiconductor structures, either during epitaxial growth or by external stresses, has been often used to optimize the functional properties of the semiconductor materials. Therefore, how to measure the electric field and strain at the nanoscale accurately and ideally simultaneously is crucial to the development and improvement of miniaturized semiconductor devices. Transmission electron microscopy (TEM) would be able to offer such a spatial resolution, but it is usually required to adopt different imaging modes to measure the strain and electric field. This would make it particularly difficult when measuring them during in situ straining experiments as the measured strain and electric field may not correspond to the same state over serial measurements.
The emergence of four-dimensional scanning transmission electron microscopy (4D-STEM) has enabled an alternative solution to measuring electromagnetic field and strain at the nanoscale. 4D-STEM, employing a pixelated electron detector for recording 2D images of convergent beam electron diffractions over a 2D grid of beam positions, offers a wide range of applications. Its resolutions in high-precision strain measurement and electromagnetic field determination can be up to the sub-nanometer scale. The technique allows nanoscale field mapping by measuring the center-of-mass (CoM) shift of the bright-field (BF) disk which is linearly proportional to the field, and the integration of CoM (iCoM) leads to the projected phase shift comparable to other techniques such as electron holography. For strain mapping, the variation of the reciprocal distance between a pair of diffraction disks is typically quantified to measure the strain.
Methods
Precession-assisted 4D-STEM dataset including both dark field disks and bright field disks were acquired. Precession was used to overcome the effect of dynamic diffraction. The long range electric field will cause a physical shift of the whole disk rather than the intensity redistribution inside the disks. In view of this, an edge detection method was used to determine the position of the diffraction disks, in contrast to the traditional CoM method. In theory, the shift of the bright disk is only caused by the electric field (EdgeBF), while the shift of the dark disks contain the effects from both electromagnetic fields (EdgeD¬¬¬¬_field) and the strain (EdgeD_strain). Since the EdgeD_strain in a pair of diffraction disks are equal in magnitude and opposite in direction, we can add the vectors of a pair of diffraction disks together and divide by two to obtain the pure contribution from the electrical field.

Results
Applying this method with semiconductor, the electric field and strain result are obtained simultaneously in a same 4dstem data. In principle, one pair of dark field spots are enough if they are the zone axis we want and uniform and bright enough, but if we can get 3 pairs of diffraction spots

edge results respectively and average them up is also credible. In second figure, there is a demo experiment result with this method, the EdgeBF, from bright disk, is compared with the average EdgeD¬¬¬¬_field, especially the profile and the difference in (d), the dark field is same direction of (b) and (c) in vertical, the (e),(f) and (g) is the strain along x and y direction.

Conclusion

In this contribution, we describe the procedure for decouple the influences attributed to strain and electromagnetic fields from the observed edge detection of a pair of diffraction patterns within a same 4D STEM dataset, as shown in the Figure. This procedure is applied with semiconductor samples to ensure the perfect correspondence between electric field and strain data acquired under identical conditions. After comparing with electric field from bright disk, the EdgeD_strain result is credible to some extent.

Novel In-situ TKD Nano-tensile Testing: Insights into Nanoscale Crystal Plasticity and Grain Boundary Mechanics

Dr. Tijmen Vermeij[1], Dr. Amit Sharma[1], Dr. Xavier Maeder[1], Prof. Johann Michler[1]
[1]Laboratory for Mechanics of Materials and Nanostructures, Swiss Federal Laboratories for Materials Science and Technology (EMPA), Thun, Switzerland

Poster Group 2

Background

Advancements in nanoscale characterization techniques are crucial for understanding the complex deformation mechanisms of metal alloys, coatings and nanolaminates. Traditional post-mortem Transmission Kikuchi Diffraction (TKD) and Transmission Electron Microscopy (TEM) analyses, although powerful, often fail to capture the complete sequence and nature of deformation mechanisms as they occur [1]. This limitation is due to their inability to observe the initiation, progression, and interaction of deformation features such as dislocations or twins, leading to potential misinterpretations involved in material deformation.
In-situ TEM and in-situ EBSD nano- and micromechanical testing are both well-established techniques that offer detailed characterization of evolving crystal plasticity [2-3]. However, in-situ TEM is technically challenging and is limited in its scale. In contrast, In-situ EBSD is more feasible and allows larger field of views, yet its spatial resolution is typically limited to ~50 nm, which can miss finer structural details critical in nanoscale materials. In-situ TKD, on the other hand, would offer a significantly enhanced spatial resolution down to ~5 nm [4], while still performed inside a relatively accessible SEM.
Given these challenges and opportunities, this study introduces in-situ TKD integrated into nano-tensile testing as a novel methodology designed to provide comprehensive insights into the evolution of twinning, dislocation plasticity, and grain boundary mechanics under applied loading. This method will bridge the gap in understanding the intricate behaviors of complex nanolaminate metal/ceramic structures, while also providing an ideal platform to study phase transformation and twinning in advanced alloys.

Methods

A specialized experimental methodology was devised, combining (i) focused ion beam (FIB) processing for specimen preparation, (ii) a push-to-pull device for in-situ tension application, and (iii) an SEM configured for in-situ TKD with an Alemnis indenter. As proof of concept, we investigate deformations of advanced Cu1-x–Alx (X=0-12 at.%) multi-layers with interlayer interfaces of 2-5 nm amorphous Al2O3 for improved microstructure control and strength. These were synthetized in a novel deposition chamber from Swiss Cluster AG (https://swisscluster.com/), combining physical vapor and atomic layer depositions (PVD and ALD) without breaking the vacuum.
Specimens were prepared through site-specific FIB lift-out, subsequent fixation to the push-to-pull device using Pt deposition [5], a dedicated procedure for thinning to ~150 nm, and creation of a precise gauge section of several µm2. We designed and employed a custom configuration of an Alemnis nanoindenter frame inside a Tescan SEM, configured to fit with an Oxford Instruments Symmetry 2 EBSD detector for in-situ TKD and simultaneous STEM detection. Specimens are loaded with the push-to-pull device under continuous in-situ STEM observation, with intermittent loading pauses for detailed TKD mapping.

Results
In-situ STEM and TKD nano-tensile testing provides detailed and rich insights into the microstructural behavior of nanolaminate CuAl/Al2O3 films. We observe the development of twinning, dislocation plasticity and interactions at grain boundaries from the undeformed state all the way to the formation of a localized shear band. Thereby, we demonstrate the capability of this methodology to analyze complex mechanical interactions at the nanoscale on a specimen of several micrometers in size.

Conclusions
This study establishes in-situ TKD nano-tensile testing as a valuable approach for analyzing nano- and micromechanical deformation mechanisms of complex metallic specimens. The integration of TKD with nano-tensile testing offers a new perspective for exploring deformation mechanisms, providing insights essential for the design and improvement of nanolaminated metallic materials, as well as advanced alloys that show phase transformation and twinning. The findings emphasize the utility of this method in advancing materials science and engineering.

Background incl. aims.

Alloying is a key step towards the fabrication of advanced nanomaterials with multiple and unique properties demanded by the most innovative nanotechnology solutions. In particular, the interest in Au nanoalloys is expected to increase with the capabilities in tailoring and modelling new compounds, such as bimetallic NPs containing the sp-metals, which have appealing plasmonic and electronic properties for a wide range of applications in optics, catalysis, nanomedicine, sensing and quantum devices. However, for these systems little is known about the thermodynamic and synthetic factors leading to successful alloying at the nanoscale.

Methods.
Laser ablation in Liquid (LAL) is currently one of the reference techniques for the green and straightforward preparation of colloids of nanoalloys with conventional (e.g. Au-Ag, Au-Cu) or unconventional composition (e.g. immiscible elements such as Au-Fe, Ag-Fe, Ag-Co, Au-Co); LAL has, in addition, several advantages such as being a green, low-cost and self-standing process.
In this work, Au-M nanoalloys, with M = Al, Ga, In, or Pb, have been synthesized by LAL using anhydrous (acetone) and not-anhydrous (ethanol) liquid environments to delve deeper in the key parameters leading to the successful alloying in the typical operating conditions of LAL.
Electron Microscopy Techniques, SAED, NBD and HREM, have been applied to the study of the synthesized systems together with a multiparametric analysis that was performed considering the mixing enthalpy from DFT calculations and other alloying descriptors like the Hume-Rothery parameters.

Results.
The series of prepared four alloy nanosystems (Au-Al, Au-Ga, Au-In, and Au-Pb) by laser ablation in liquid (LAL) has the purpose to move along the 13th group for studying the effect on the products composition, structure and morphology. In case of Al, Ga, In, and Pb, these are either miscible with Au at some proportions or form intermetallic phases, but they also form stable oxides with a strongly negative standard formation enthalpy. Therefore, oxidation and passivation at the surface of NPs, as well as segregation due to oxidation of the sp metal during the synthesis, may occur. To confirm that the sp metals are alloyed with gold and identify the alloy phase among the various possibilities (substitutional SS, intermetallic compound, or phase-segregated), the XRD patterns of the ten dried colloids were collected and the phases were identified through the Rietveld refinement. In all samples, at least one substitutional alloy or intermetallic phase was detected, confirming the presence of the nanoalloys. The composition of each Au sp metal alloy was different in anhydrous acetone and in ethanol. It is worth noting that the NPs obtained by LAL have a relatively broad size distribution; hence, the composition obtained from the XRD analysis is the average composition of the sample, and it does not give information about the possibility that the chemical composition

changes with the size of the NPs. Therefore, alloying was also assessed at the nanoscale using SAED, NBD and HRTEM (see Figure) on the samples obtained in anhydrous acetone, which are those with the highest fraction of Au–sp metal phases. HRTEM analysis evidenced the polycrystalline structure of the NPs, which is also systematically observed in single-element metal particles obtained by LAL. Consequently, the SAED patterns on groups of NPs are rich in reflections coming from different crystalline domains, even inside the same particle. Nonetheless, it was possible to identify the reflections of the various Au–sp metal alloys previously identified using XRD analysis, where there is no ambiguity about the discrimination from the pure Au FCC reflections. This includes the AlAu4 phase with space group P213, the Au7Ga2 phase with space group P-62m, and reflections compatible with both the Au3In phase with space group Pmmn and the Au9In4 phase with space group P-43m. In the case of the Au–Pb sample, the very low abundance of the alloy compared to that of pure Au and hydrocerussite does not allow for the unambiguous identification of the Au2Pb phase in the SAED and NBD patterns, but it was possible to find a match with HRTEM of a single Au–Pb NP, exhibiting the interplanar distance and the Hanning masked FFT pattern of the Au2Pb phase with space group Fd-3m. Overall, the NBD and HRTEM results, along with the Hanning masked FFT patterns on selected nanometric regions, further confirmed, at the single NP level, all results obtained by SAED on groups of NPs and by XRD on the powder samples.

Conclusion.
The physical and chemical parameters determining the formation of gold–sp metal nanoalloys were studied as a function of the sp metal period, moving from Al to Ga, In and Pb, and under real synthetic conditions involved in the nanosecond laser ablation of bimetallic targets in two different liquid environments (anhydrous acetone and ethanol). The successful formation of Au nanoalloys with sp metals has been demonstrated in most cases and the LAL is confirmed to be a versatile approach for the production of innovative nanoalloys, provided that appropriate synthesis parameters are adopted. Especially relevant is the oxidizing capability of the solvent which must be balanced with the tendency of the metals to undergo oxidation, to avoid phase segregation and byproduct formation. The physical and chemical parameters leading to the formation of alloyed versus phase segregated NPs were analyzed systematically. Good agreement with the typical rules for alloying is found only in the absence of remarkable chemical interactions with the metals; otherwise, the tendency to undergo oxidation prevails. These findings lead to an immediate and deeper understanding of the phenomena that affect the composition of nanoalloys under real physical synthetic conditions. This will provide a crucial support for guiding the realization of next-generation multifunctional metallic nanostructures with remarkable applicative potential in optics, catalysis, nanomedicine, sensing and quantum devices.

Sample holder design for TEM in-situ straining experiments on 2D materials

Carmen Rubach[1], Dr. Xin Zhou[1], Tobias Dierke[2], Robert Kammel[1], Michael Sommerschuh[1], Prof. Janina Maultzsch[2], Prof. Erdmann Spiecker[1]
[1]Institute of Micro- and Nanostructure Research (IMN) & Center for Nanoanalysis and Electron Microscopy (CENEM), Friedrich-Alexander-University Erlangen-Nürnberg, 91058 Erlangen, Germany, [2]Institute of Condensed Matter Physics, Friedrich-Alexander-University Erlangen-Nürnberg, 91058 Erlangen, Germany

Poster Group 2

Background incl. aims
Two-dimensional (2D) materials consisting of single- or few-layer atoms such as graphene, transition metal dichalcogenides (TMDs, e.g. MoS2, MoSe2, WS2, WSe2) and hexagonal boron nitride (h-BN) show unique physical, chemical and mechanical properties owing to their planar atomic and band structures making them promising candidates for future device applications. For the fabrication of stable and reliable nanodevices such as for example energy storage and memory storage devices, optical switches, nanofilm displays and superconducting devices, it is crucial to understand the deformation behavior of the 2D materials used as building block of the respective device. In situ TEM tensile testing can give insights into the mechanisms of nanomechanical deformation, cleavage and sliding of the strained 2D material at the atomic level. [1]
For uniaxial in situ TEM tensile testing of freestanding 2D materials, either commercially available push-to-pull devices or custom-designed straining holders are needed. The custom fabrication of straining holders allow for the flexible adaptation of the utilized design to the needs of the transferred 2D material and/or the employed TEM techniques.
2D flakes mechanically cleaved from the bulk material are typically very small in size, but the exposed sample surface is very clean. To preserve this clean sample surface, a transfer process not involving stabilizing polymer layers (for example polymethyl methacrylate (PMMA) or polyvinyl alcohol (PVA)) should be used. For the Polydimethylsiloxane (PDMS) mediated dry stamping transfer of mechanically cleaved 2D materials a sample holder with a small central “viewing window” is required because the transfer small flakes is facilitated if they span over the whole central window. Furthermore the material surrounding the central window must be sturdy enough to withstand the slight pressure applied during the stamping transfer.
For the transfer of PMMA stabilized CVD grown 2D materials it can beneficial to have a longer viewing window (length about 20 µm) allowing the determination of the layer number of the 2D material by tilting the flake in Darkfield-TEM [2].
In this work, we report the design and fabrication of Cu support, which was used as substrate for the transfer of both mechanically exfoliated MoS2 and CVD grown bilayer graphene in situ TEM straining combined with 4D scanning transmission electron microscopy (4D STEM) were carried out to study the mechanical properties of 2D materials.

Methods
As substrate material for in-situ TEM tensile tests on 2D materials using a single-tilt Gatan straining holder 50 µm thick copper foil (Karl Schlenk AG) was chosen. As the transfer of 2D materials on the substrate requires a very smooth surface, the Cu-foil was polished to a surface roughness of 0,25 µm using diamond paste. After polishing, custom-designed dog bone shaped sample holders were sculpted from the Cu-foil, tailored to fit the Gatan straining holder 654, using a microPREP PRO laser

ablation system (3D micromac). The sample holder design, measuring 12,0 mm in length, 2,4 mm in width and 1,0 mm width in the center, was generated using AutoCAD software (Autodesk). A small window with a length of 5 µm or 20 µm (depending on the transferred material) was cut into the middle of the dog bone-shaped Cu-holder for the transfer of desired 2D flake. Two longer lateral slits (length 300 µm) were added to the design close to the central window to prevent exceeding the force limit of the Gatan straining holder 654 during tensile testing. To eliminate residual debris from the rim of the laser ablated central windows and to adjust the shape of the windows, the central area of the Cu support underwent precise ion beam refinement using a FEI Helios NanoLab 660 instrument (scanning electron microscope-focus ion beam, SEM-FIB). [3]
If the Cu-holder was used for straining molybdenum disulfide (MoS_2) the polished copper surface was coated with a thin gold film (thickness 30 nm) to facilitate PDMS mediated dry transfer. The MoS_2 flake to be transferred was first exfoliated to a PDMS stamp attached to a glass slide using wafer tape. The glass slide was then mounted into a micromanipulator which was used to align the flake under a stereomicroscope with the central windows of the sample holder and then to bring it in contact with its surface. To prevent slipping and deformation of the Cu-holder during the transfer process, the holder was attached on both ends with 2 strips of thermal release tape (RA-95LS(N), Rephalpha, release temperature 100-105 °C) to a glass slide prior to transfer. Once the MoS_2 flake was in contact with the rim of one of the central small windows of the Cu-holder, the PDMS stamp was gently peeled off and the glass slide was placed on a hot plate at 100°C for several minutes to detach the thermal release tape.
CVD grown bilayer graphene (ACS materials, Trivial Transfer Graphene) was directly transferred to the customized Cu support by a “fishing” method. The PMMA coated CVD graphene was first immersed in deionized (DI) water, collected on a piece of filter paper and sectioned into tiny rectangles. One of these rectangular PMMA/ graphene films was then detached from the filter paper by once again immersing the filter paper in DI water and was fished out covering one of the central windows of the custom-designed Cu-holders. After drying for one hour, the PMMA was removed using acetone. [3]

Results & Conclusion
We designed straining holders tailor made for both the PDMS mediated transfer of mechanically exfoliated MoS_2 as well as the polymer-assisted transfer of CVD grown bilayer graphene. After successful transfer, in situ straining experiments combined with 4D STEM were performed on both materials giving insights into the mechanisms of nanomechanical deformation at atomic level (for more details on this straining experiment on bilayer graphene see Zhou et al.- A twist to superlubric sliding in bilayer graphene uncovered by in situ TEM) .

Background incl. aims
Coronavirus Disease 2019 (COVID-19) pandemic is severely impacting the world, and tremendous efforts have been made to deal with it. Despite many advances in vaccines and therapeutics, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) variants remains an intractable challenge. We employed non-antibody protein binder called repebody and designed a dimeric form of repebody A6 which can effectively neutralizes viral infection.
Methods
Using a library of non-antibody protein binder called repebody, and rational maturation, we have produced an A6 repebody that binds RBD (KD of 2.2nM) and blocks its interaction with ACE2. By using both cryo-EM and X-ray crystallography, we successfully determined A6 repebody mode of action. We utilized ITC, SPR to measure the binding kinetics and FRNT to test A6 neutralizing ability. In-vivo neutralization test was conducted on the mouse model expressing human-ACE2.
Results
We present a bivalent Receptor Binding Domain (RBD)-specific synthetic antibody, specific for the RBD of wild-type (lineage A), developed from a non-antibody protein scaffold composed of LRR (Leucine-rich repeat) modules through phage display. We further reinforced the unique feature of the synthetic antibody by constructing a tandem dimeric form. The resulting bivalent form showed a broader neutralizing activity against the variants. The in vivo neutralizing efficacy of the bivalent synthetic antibody was confirmed using a human ACE2-expressing mouse model that significantly alleviated viral titer and lung infection.
Conclusion
In the present study, we have demonstrated that a bivalent repebody, specific for the SARS-CoV-2 RBD, effectively neutralizes the SARS-CoV-2 virus and its variants. Despite their small size, target-specific synthetic antibodies developed from the repebody scaffold through phage display offer larger interface areas. The present approach can be used to develop a synthetic antibody showing a broader neutralizing activity against a multitude of SARS-CoV-2 variants.

Poster Group 2

Background
A catalyst's stability and longevity under operating conditions is key for their long-term application in industrial processes. This calls for an understanding of deactivation mechanisms to advance catalyst design strategies that can counteract such mechanisms.
Here we focus on gold (Au) nanoparticles (NPs) as a catalyst for the CO oxidation reaction (1). Specifically, we demonstrate that NPs formed by titanium (Ti) and Au alloying enables the development of an anchoring shell over the Au NPs, that suppresses sintering during operation. This new design strategy could be generally applicable and offers a higher degree of flexibility in preparing sinter-resistant catalyst nanoparticles.
Here we report the synthesis, structural characterization and stability testing of colloidal core-shell AuTiOx nanoparticles, displaying improved stability under thermal CO oxidation conditions on silicon nitride and TiOx supports (2).
Method
An Au0.5Ti0.5 alloy target was used to synthesize mass-selected nanoparticles of 160k amu under high vacuum conditions onto material supports that were used for the present characterization. Ion Scattering Spectroscopy (ISS), X-ray Photoelectron Spectroscopy (XPS) and High-Resolution Transmission Electron Microscopy (HRTEM) were used to elucidate the structure and chemical composition of the synthesized NPs. The catalytic characteristics of the AuTiOx NPs were then studied by performing comparative studies of the NPs and reference Au NPs under CO oxidation conditions. The NPs deposited on silicon nitride were studied by HRTEM under reactive conditions, by introducing a few mbar CO and O2 at various sample temperatures in a FEI Titan ETEM operated at 300 kV. Precautions were taken to acquire images of areas that were previously unexposed to the electron beam to differentiate beam-induced and environment-induced phenomena. The CO oxidation activity of the NPs deposited on TiOx were studied by running flow reactor experiments with the samples and reactive gasses at various temperatures and measuring gas conversion via a quadrupole mass spectrometer.
Results
ISS of the as-synthesized NPs, produced from the Au0.5Ti0.5 alloy, showed that only a small portion of the outermost layer contained Au atoms. HRTEM imaging of the nanoparticles after air exposure demonstrated that the NPs were composed of a 2.1±2 nm metallic Au core phase surrounded by a lighter ~0.8 nm shell. By XPS measurement the shell layer was identified as primarily consisting of TiOx. Imaging of the NPs in the reactive environment showed that a filament growth mechanism was present in the interface between the Au NPs and silicon nitride support at temperatures ≥200 °C, mobilizing the Au NPs. The AuTiOx NPs maintained their core-shell shape and size up to at least a temperature of 400 °C and did not demonstrate any growth mechanisms. This finding suggests that the TiOx shell acts as a protective layer for the Au NPs in this instance. Comparative activity measurements of the AuTiOx and Au NPs deposited on a TiOx support showed an improved stability

of the NP activity for the AuTiOx NPs in comparison to the Au NPs. Furthermore, the AuTiOx NPs showed a characteristic in which their activity increased over time after the sample temperature was increased. In certain cases, the activity would increase by >2 fold over the span of hours while maintaining a certain temperature. This phenomenon was observed to be reversible when lowering the sample temperature. Nonetheless, the average NP site turnover frequency (TOF) was lower for the AuTiOx NPs than the Au NPs, likely due to a blocking of active sites on the core-shell structure.
Conclusion
Characterization of the AuTiOx alloy nanoparticles revealed an Au core and TiOx dominant shell containing small traces of Au atoms. Supported on silicon nitride, the Au NPs were observed to facilitate a filament growth under CO oxidation conditions while the phenomenon was not observed for the AuTiOx NPS, suggesting that the TiOx shell can act as a protective layer. Activity measurements of the NPs supported on TiOx, showed a time dependent deactivation was observable for the Au NPs and not for the AuTiOx NPs. The average TOF of the core-shell NPs was observed to be lower than the Au NPs, which could be explained by a blocking of NP active sites by the shell layer. Treatment methods to enhance the shell layer porosity could likely improve the activity of the core-shell nanoparticles while maintaining their stability characteristics. Development of such colloidal alloy NPs could lead to significant advances in producing highly stable catalysts for industrial use.

Poster Group 1

Background and Aims
Present ultra-high-resolution SEM and S(T)EM commonly use high brightness electron source such as Schottky source (SFE) or cold field emitter (CFE) with a relatively high reduced brightness of about 1x108 and 2x108 [A/Sr.m.V] respectively. A typical energy spread of these electron sources are 1eV and 0.4eV respectively. For most applications requiring narrower energy spread, these are too large. Two examples of these applications could be: 1]- Extremely low voltage imaging with electrons known as LVSEM with a typical landing energy (LE) of only a few tens of electron-volts where chromatic aberration limits the resolution, 2]- Energy resolved applications such as high-resolution electron energy-loss spectroscopy (HREELS) where an extremely lower energy spread of only a few meV is required. A lower energy spread could only be obtained when a monochromator is used.
In the current monochromators, the increased demand on performance has increased the complexity of the monochromator designs, decreasing their user friendliness: to reach a few meV energy resolution, multiple power supplies have to be tuned to reach an optimal performance. The complexity in terms of large number of power supplies with extremely accurate temporal stability can partly be attributed to the form factor of the design. For instance, the main feature of a monochromator is a large deflection angle, with an associated three dimensionally shaped macroscopic geometry with inherently large aberrations, while also being very sensitive to small mechanical misalignments . These geometric and parasitic aberrations require compensation using extra multipole correctors. Moreover, adding extra multipoles in the design, extends the geometry of the monochromator, and consequently requires a reduced probe current for suppressing the energy broadening due to the Boersch effect. The increasing complexity demands a new design capable of achieving similar output in terms of energy resolution and current while reducing the number of required voltage supplies and their combined stability.
Methods
We present a new fully electrostatic monochromator based on Micro-Electro-Mechanical-Systems (MEMS). This manufacturing approach allows fabrication of monochromator parts with an unprecedentedly accuracy. While conventional monochromator deflectors can be approximated using 2D methods with multipole approximation, this approach is inadequate when the aperture sizes are large compared to the curvature of an electron beam's path. A 3D approach is required in the case of free form MEMS-based electron optics. To do so, a BEM method, is used for design and optimization of a new, fully electrostatic design. The optimization is partially automated by tuning the voltages in the design based on fitted optical aberrations.
Results
The new monochromator consists of 8 power supplies (including ground), and has a 1-to-1 ratio between voltage supply and beam energy drift. The new 5 mm long monochromator images / disperses the input plane to a selection slit plane with a unit magnification and a dispersion of 6 µm/eV at a beam energy of 500 eV. At the slit plane, an energy resolution better than 20 meV with a probe current of 5nA can be selected. The dispersion is a result of a (large) deflection angle using Fring Field deflectors. These fringe fields are created by extremely low aspect ratio MEMS multipoles.

Accurate fabrication and lower aspect ratio arrangement of main deflection fields eliminates the need for additional multipoles to compensate for geometric and parasitic mechanical misalignments.
Conclusions
In conclusion, monochromators represent a field of technology where the integration of MEMS techniques has shown novel promise in reducing complexity while maintaining crucial parameters. In addition to energy filtering, the newly found configuration could be used for other related applications such as energy analysis. The next step in the project will thus be to manufacture the new design for integration and testing in an electron microscope.
Figure:
Cross-section of monochromator layout, with an exaggerated initial energy distribution (+/- 5 V). The electrodes in the design are a series of stacked electrodes, with differing shapes of apertures created in each layer. The colours of the elements depict the surface charge densities resulting from the application of optimal voltages in the geometry. The dispersed beam enters in the left of the image, and is deflected and imaged towards the output plane on the right. The field free energy selection slit has been left out to favour simulation and make show the dispersed spot in the image plane.

PS-01 (3), Lecture Theater 3, august 30, 2024, 14:00 - 16:00

Correlating single wall carbon nanotubes (SWCNT) structural properties with growth conditions during catalytic chemical vapor deposition (C-CVD) is the key to understand the fundamental mechanism involved during this process. However, characterization of individual SWCNTs has always been a challenge, especially under real growth conditions. Recently, homodyne polarization microscopy was able to perform in-situ observations of SWCNT growth inside a CVD reactor [1]. While this technique provides high-throughput growth kinetic measurements, it is still unable to determine the atomic configuration, i.e. chirality, of each individual tube. On the other hand, transmission electron microscopy (TEM) is the technique of choice to directly image SWCNT at the atomic scale and therefore unambiguously determine their chirality [2]. Combining both characterization on the same tubes would reveal significant information about the growth mechanism of CNT. However, TEM sample preparation often relies on random CNT dispersion onto a TEM grid preventing any individual tube identification inside the microscope. In addition, manually determine the chirality for each tube from high-resolution (HR) TEM images is a long process limiting the analysis to a small number of tubes. Here, we aim to develop a new sample preparation protocol to transfer SWCNTs from a substrate to a TEM grid while preserving their location and allowing high quality atomic scale imaging. Furthermore, our goal is also to speed up chirality determination using artificial intelligence (AI) based image analysis.

First, SWCNTs were grown on a quartz substrate inside a custom CVD reactor allowing in-situ optical microscopy imaging. After growth, Au markers were deposited by optical lithography and scanning electron microscopy of the sample was performed to locate tube positions relative to the markers. Before transferring SWCNTs onto a TEM grid, the latter was covered with a graphene monolayer using the PMMA-mediated graphene-transfer method [3]. This layer acts as a mechanical support, preventing tube breaking above grid holes, and facilitating charge evacuation during TEM imaging. Then both SWCNTs and Au markers were transferred onto the graphene coated TEM grid using a similar wet transfer method. Atomic scale images of SWCNT on graphene were then obtained using an aberration corrected TEM equipped with a field emission gun and a monochromator. Finally, fast chirality determination was performed using an open source deep learning code based on convolutional neural networks [4]. This AI code is intended to analyze only SWCNT images; hence, the graphene layer signal must be removed. We developed a new filtering method called Geometric Amplitude and Phase Interpolation (GAPI) based on Fourier transform (FT) filtering that allows us to subtract the graphene signal even when it is superimposed over the SWCNT signal in both real and reciprocal space.

SWCNTs were successfully transferred with the Au markers on the custom TEM grid coated with graphene. Nanotubes, previously observed by in-situ techniques were imaged at high resolution inside the TEM. Both AI and manual methods were used to determine the chirality of the tubes of interest. The strong agreement between the chiral indices measured by both methods highlighted the efficiency of the AI algorithm. In comparison to other FT-based methods, the GAPI filtering method significantly improved AI chirality determination. Our protocol offers the possibility to track down defects and eventual chirality changes induced during growth. However, residual polymer contamination from the transfer processes prevented the analysis of all tubes across their entire length. Nevertheless, we were able to follow single chirality tubes across 10s of µm, providing a direct correlation between their structure and previously measured growth kinetic.

For the first time, the same individual SWCNTs were characterized by both in-situ optical and ex-situ HRTEM observations. The combination of a new image filtering method with automated atomic structure determination using AI, enabled a fast and unambiguous determination of their chirality providing a direct correlation between growth kinetics and tube structures. While the TEM characterization is still limited by polymer contamination, tubes chirality could still be measured in different areas, tens of µm apart.

Poster Group 1

Background
Transporting currently used and potentially anticipated active substances to tissues through drug carrier systems, particularly nanocarrier systems or nanoparticles (NPs), is feasible. The unique properties of NPs facilitate increasing the concentration of active substances in the bloodstream, extending their half-life, and optimizing dosing frequency to enhance active substance solubility and stability. Moreover, NPs may enhance treatment efficiency in systemic applications by accelerating the passage of active substances through biological barriers such as the blood-brain barrier (BBB), thus potentially improving therapeutic outcomes. There is a growing body of research on NPs crossing the BBB, although most studies are conducted on experimental animals, particularly rodents. Therefore, understanding the interaction of nanoparticles with the human BBB is crucial for advancing biomedical applications.

Methods
The Brust-Schriffrin method was utilized to synthesize gold nanoparticles (AuNPs) for cell imaging purposes. These AuNPs, acting as markers, were subsequently encapsulated within human serum albumin (HSA) and bovine serum albumin (BSA) nanoparticle structures using the desolvation method. Another nanoparticle formulation employing AuNPs as markers is the nano lipid carrier (NLC), synthesized via hot homogenization. Furthermore, Zr-based metal-organic framework (MOF) structures were utilized as markers in cell imaging, with Zr nanoparticles encapsulated within Polylactide-co-glycolide (PLGA) nanoparticles. A concentration dose of 62.5 µg/ml of these NPs was administered to primary human microvascular endothelial cells (1oh BMECs) and human brain vascular pericytes (HBVPs) for 3 hours. Subsequently, the cells were subjected to light microscopic and transmission electron microscopy (TEM) analysis.

Results
NP formulations of HSA, BSA, and PLGA were observed within cells by light microscopic analysis using the silver enhancement method. In contrast, no NP uptake was observed for NLC formulations in both 1oh BMECs and HBVPs after a 3-hour incubation period. Furthermore, TEM analysis of 1oh BMEC revealed no significant ultrastructural alterations following NP applications. Moreover, NLCs were not detected under TEM, whereas the other NP formulations were observed within the cells, consistent with the findings from light microscopic analysis. Interestingly, HSA was found within some autophagic vacuoles, randomly associated with myelin figures, and within numerous vesicles, particularly at the peripheral region of the cytoplasm.

Conclusion

There are various types of NP formulations showing promise as potential solutions to enhance drug transport to the BBB. However, their interactions within the cells of the human BBB are poorly understood. Therefore, it is crucial to comprehend the mechanisms and behavior of NPs within the human BBB.

Poster Group 1

Background incl. Aims
The World Health Organization defines obesity as hyperplasia and hypertrophy of adipose tissue that poses a health risk. Obesity is increasing in Western countries and is one of the major epidemic problems. In particular, the high-fat diet (HFD) is one of the most important factors in the spread of obesity in these countries. It is also known that HFD causes cognitive dysfunction and impaired memory, and exercise can improve cognitive function in animals. It is known that neuroinflammation, which is associated with progressive neuronal loss, is exacerbated by cognitive decline and obesity. Orexin neurons are projected throughout the central nervous system, including the hippocampus. Orexin neurons are also involved in operant activities, and cognitive functions. In addition, the loss of orexin also impairs memory. Experimental studies have shown that mice lacking orexin neurons exhibit increased cognitive deficits, and the brain also becomes more susceptible to neuronal insults and increased levels of neuroinflammation. HFD induces impairment of long-term memory, and HFD exposure and orexin loss in mice lead to increased inflammatory markers. In this study, we focused on the possible neuronal degenerative effects of HFD on brain tissue and the protective effect of swimming training. The aim of this study is to investigate HFD-induced brain damage and the putative healing effect of exercise on orexin expression on cortical neuroinflammation and cognitive decline.
Methods
Male Sprague-Dawley rats were fed either standard chow (Control group, 6% fat) or a HFD (HFD group, 45% fat) for 18 weeks. Half of the animals fed with each diet were trained by swimming exercise (1 h/day, 5 days/week) for the last 6 weeks of the experimental period (Ex and HFD-Ex groups). At the end of the study, an object recognition test was applied to evaluate cognitive function, and brains were collected for routine light and transmission electron microscopy (TEM) and biochemical analysis. Histopathological evaluation was performed in hematoxylin-eosin (H&E)-stained paraffin sections and Orexin-2 (OX-2) and Glial fibrillary acidic protein (GFAP) immunohistochemistry were performed. Malondialdehyde (MDA) and glutathione (GSH) levels were measured in the brain homogenates. The histological and biochemical data were evaluated statistically and a p-value <0.05 was accepted as significant.
Results
Deteriorated object recognition test was observed in the HFD group compared to the rats in the control group, which was ameliorated with exercise. Morphological evaluation revealed increased neuronal degeneration compared to that of the control groups in the HFD group ($p<0.05$). The HFD+Ex group showed decreased neuronal degeneration relative to the HFD group ($p<0.05$). Altered GFAP immunohistochemistry and OX-2 immunofluorescence observed in the HFD group were similar to controls in the HFD+Ex groups. Increased MDA and decreased GSH levels of the HFD group compared to control and Ex groups ($p<0.001$) were observed. However, decreased MDA levels ($p<0.001$) and increased GSH levels ($p<0.01$) in the HFD-Ex group relative to the HFD group.
Conclusions

Our study revealed HFD-induced neuronal damage and increased oxidative stress in the brain tissue. Swimming exercise protects the high fat diet-induced brain damage including the alteration of GFAP and OX-2 immunoreactivity in the cortex of rats by modulating oxidant/antioxidant balance. It is also thought that the regulation and neuronal development of the rodent cerebral cortex is influenced by HFD and that Ox-2 expression may contribute to this cortical development.

“This study was supported by European Commission Horizon Europe Programme under the call HORIZON-WIDERA-2021-ACCESS-03 (grant number 101078981 – GEMSTONE).”

Towards Single-Pattern Absolute High angular Resolution EBSD without using Simulated Patterns as Reference

Dr. Tijmen Vermeij[1,2], Lloyd Dodsworth[1], Dr. Aimo Winkelmann[3], Dr. René De Kloe[4], Dr. Johan Hoefnagels[1]
[1]Mechanical Engineering, Eindhoven University of Technology, Eindhoven, Netherlands, [2]Laboratory for Mechanics of Materials and Nanostructures, Swiss Federal Laboratories for Materials Science and Technology (EMPA), Thun, Switzerland, [3]AGH University of Science and Technology, Krakow, Poland, [4]EDAX, Tilburg, Netherlands

IM-06 (3), Lecture Theater 1, august 30, 2024, 14:00 - 16:00

Background
Over the years, High angular Resolution EBSD (HR-EBSD) has evolved into a reliable tool for measuring misorientations and relative stresses (elastic strains) in crystalline materials with high sensitivity [1]. However, in the absence of stress-free intragranular reference points, absolute stress measurements are not yet routinely performed, while they could potentially provide new insights in the micromechanics of a range of (poly)crystalline materials.
The extension from relative to absolute cross-correlation based HR-EBSD, by using a simulated EBSD pattern as a reference, is under continuous development in the literature [2]. However, there are limitations by factors such as the inaccurate simulation of EBSD patterns and the uncertainty of the experimental EBSD geometry [3]. Consequently, an absolute HR-EBSD approach without using simulated reference patterns, or any experimental stress-free reference pattern, would be of huge interest to the community.
In the past years, several developments were proposed to extend HR-EBSD from a local cross-correlation based approach to a global full-field correlation [4]. Besides improved accuracy and robustness, such consistent correlation frameworks have shown the potential for non-simulation based absolute HR-EBSD, by exploiting crystal symmetry, simultaneous correlation between multiple (intergranular) patterns and co-correlating the pattern centre [5]. However, experimental validation is non-trivial on polycrystalline materials and excess-deficiency features (band asymmetry) in the patterns were expected to cause problems.

Methods
Therefore, we have continued developments on this framework to reduce the complexity towards an absolute non-simulation-based HR-EBSD correlation of only a single pattern. Specifically, we correlate one area within a pattern to another area of the same pattern by using crystal symmetry operators, as visualized for a single symmetry operator in the figure attached. Using all available symmetry operators, we correlate multiple areas within the same pattern in parallel, using absolute in-plane stress components, absolute orientation, and the pattern centre parameters as degrees of freedom.

Results
In this presentation, we will first show how the framework works and how it performs on idealized simulated patterns. Further testing on single experimental stress-free patterns, acquired with a direct electron EBSD camera, will show how excess-deficiency features can significantly degrade the experimental accuracy, as verified on dedicated dynamically simulated patterns. Therefore, the

method is extended with an integrated excess-deficiency correction approach which shows how non-simulation based absolute HR-EBSD is finally within reach.

Conclusion
In summary, we advance absolute HR-EBSD while avoiding the use of simulated patterns as a reference. Through single-pattern correlation in an advanced DIC framework, we show the potential for measuring absolute elastic strains at high resolution.

Background incl. aims
The formation bone tissue and the mineralization are positively influenced by the nanostructure or microstructure of calcium phosphate ceramics and by pore architecture of implants (1). Moreover, the release of Ca2+ was shown to induce cell growth, and PO43- released into medium induced osteogenic genes expression (2). The nano- or microstructure may significantly influence cell adhesion, proliferation and differentiation. The aim of this work was to study the effect of hydroxyapatite (HA) and beta tricalcium phosphate (β-TCP) of different structure on osteosarcoma cells adhesion, proliferation and osteogenic differentiation using microscopy techniques.
Methods
Porous ceramics from hydroxyapatite (HA), nanostructured HA (N-HA), calcium-depleted HA (CDHA), β-tricalcium phosphate (β-TCP), and nanostructured β-TCP (N-β-TCP) were prepared by 3D printing and sintering, and were characterized with SEM, XRD and tested in vitro with osteosarcoma SaOS-2 cells, seeded at a density of 368 x 103 cells/cm2 cultured in McCoy's 5A, 15% foetal bovine serum, 1 % of antibiotics (Penicilin/Streptomycin), and 40 µg/mL ascorbic acid. Cell proliferation was evaluated by dsDNA assay, and the metabolic activity was tested using MTS assay on days 7, 14, and 21. Focal adhesions were visualized using mouse monoclonal antibody Anti-Talin (T3287, Sigma Aldrich, 1:200), secondary Anti-mouse IgG Fab2-AlexaFluor488 (1:400, Molecular probes) and beta-actin was stained with Phalloidon-ATTO633 (1:1000, Sigma Aldrich) on day 1. Moreover, gene expressions of alkaline phosphatase (ALP) activity, Runx2, osteocalcin, collagen type I were tested. RNA was isolated from discs using RNeasy Mini Kit (74104, Qiagen, Hilden, Germany). The isolated mRNA was reverse transcribed to cDNA using qScript cDNA Synthesis Kit (QuantaBio, USA), following the manufacturer's protocol. Polymerase chain reaction was performed on Light Cycler 480 (Roche, Basel, Switzerlands), primers and probe were obtained from ThermoFisher Scientific. Data were evaluated using the 2−ΔCp method, for each gene relative to the housekeeping gene GAPDH.
Collagen type I, a midterm marker, was visualized using monoclonal antibody anti collagen I M-38c (1:50, DSHB, Iowa City, USA) and Anti-mouse IgG Fab2-AlexaFluor488 (1:400, Molecular probes) and propidium iodide (cell nuclei) on day 7 and 14. Osteocalcin, a late marker of osteogenic differentiation, was stained with Rabbit Anti-Osteocalcin (1:20, T4744, BMA Biomedicals) and Alexa Fluor 633 goat anti-Rabbit IgG (H+L) (1:200, Invitrogen) and Hoechst 34580 (2 µg/mL, H21486, Invitrogen) on day 21. All proteins were visualized using confocal microscopy and quantified using ImageJ. Statistical analysis was performed using GraphPad Prism 8.1.2. software, using One-way analysis of variance (ANOVA), according to normality test. The significance was set at $p < 0.05$.
Results
CDHA, N-HA and N-β-TCP had a nanostructure made of plate-like crystals. In contrast, HA and β-TCP had a microstructure of polyhedral grains. All nanostructured samples showed dot-like talin shape

with low density of focal adhesions. Oppositely, both microstructured HA and β-TCP ceramics showed well visible and fibrous-like talin structures.
β-TCP showed significantly higher proliferation of Saos-2 cells compared to all groups on day 7. CDHA showed lower proliferation than HA, and β-TCP on day 7, and 14, respectively.
Gene expression of collagen I, Runx2 were highest in HA and N-HA samples on day 1, and 7, Runx2 was lowest in β-TCP on day 14. ALP expression of HA and N-HA was higher than on CDHA on day 7 and higher than N-β-TCP on day 1. Osteocalcin showed significantly increased expression on β-TCP compared to HA, N-HA and N- β-TCP on day 14. CDHA showed higher osteocalcin expression on HA on day 7. Interestingly, both collagen I and osteocalcin synthesis were positive in high amounts in all scaffolds without significant differences.
Conclusions
Nanostructured calcium phosphate ceramics significantly influenced the localization of focal adhesions. HA scaffolds supports early and midterm marker expression, while β-TCP supported osteocalcin gene expression. Collagen I and osteocalcin synthesis were highly produced in all scaffolds but were not influenced by different ceramics structures or chemical composition.

4-dimensional scanning transmission electron microscopy (4DSTEM) based imaging techniques, in particular multislice electron ptychography, demonstrated unprecedented lateral spatial resolution while also providing depth-resolved imaging of the sample [1]. It is therefore, one of the most promising technique for 3D imaging of TEM samples at the atomic scale. Carbon nanotubes (CNT) are an ideal test subject for multislice ptychographic reconstructions using electron beams. While CNT atomic scale imaging can be achieved by high-resolution HR(S)TEM imaging, resolving their complex atomic structure is still a challenge, mainly because of the overlapping signal coming from both side of the tubes [2]. It becomes even more difficult when one wants to solve the structure of atomic defects inside CNTs. Here, we investigate the efficiency of 4DSTEM experiments combined with multiple iterative phase retrieval methods to resolved topological defects in CNTs. In particular, our goal is to resolve separately both sides of nanotubes using multislice ptychographic reconstructions of a single projection.

We used defective carbon nanotube structures, obtained by molecular dynamic calculations in a previous work [2], to simulate 4DSTEM datasets. Diffraction pattern simulations were computed using the open source abTEM package [3]. These simulated datasets serve two purposes: optimizing experimental conditions for high resolution imaging of nanotubes and evaluating the efficiency of phase retrieval algorithms. We performed phase images reconstruction using the open source py4DSTEM package [4], which features several iterative phase retrieval algorithms. We focused our work on the following methods: differential phase contrast, parallax, single and multislice ptychography [5]. 4DSTEM experiments were conducted on a double corrected TEM operating at 80kV and equipped with a Schottky field emission gun (X-FEG) and a direct electron detector. Experimental parameters were set as close to the optimum previously determined by simulations and phase images were reconstructed using the previously presented methods

In order to preserve tubes from contamination and irradiation damage, 4DSTEM experiments must be carried out in less than ideal conditions; i.e. low beam current (<20pA), short dwell time per pixel (<2ms), large real space step size (>1.5Å) and defocused STEM probe (tens of nm). In these conditions, the efficiency of the iterative ptychographic reconstructions strongly depends on the first guess given for the incident probe wave function. To optimize the determination of the initial probe parameters, i.e. defocus and residual aberrations, from experimental datasets, we computed differential phase contrast and parallax reconstructions [5], prior to the ptychographic reconstructions. We also acquired a vacuum probe reference in a separated dataset to constrain the incident wave function intensity. This method allowed the reconstructions to converge and strongly improved the resolution of CNTs images compared to high-resolution STEM images. However, phase images did not achieve the ultimate spatial resolution. Using simulated 4DSTEM datasets, we found

out that both lateral and depth (in the case of multislice ptychography) resolutions were strongly degraded when dealing with partial temporal coherence, i.e. energy spread, of electron beams. The energy resolution of the microscope used in this study is limited to a FWHM of 1.5 eV. We showed that with a greater energy resolution, which is available on microscopes equipped with a cold FEG gun for example, it is possible to improve lateral resolution and even perform CNT depth sectioning using multislice electron ptychography to capture a direct image of topological defects.

4DSTEM based high-resolution imaging techniques, are very promising to obtain direct imaging of topological defects in carbon nanotubes. By conducting two parallel studies, one based on simulation and one based on real 4DSTEM experiments, we were able to improve the resolution of CNT STEM images by performing iterative phase retrieval reconstructions. We demonstrated that 3D imaging of carbon nanotubes is even possible using multislice electron ptychography when the electron beam's energy spread is reduced. We argue that this limitation can be overcome by state-of-the-art-microscopes and improved reconstruction algorithms.

Multimodal imaging accelerates the analysis of composition in bone implant sites

Joshua Lea[1], Pedro Machado[1], Zhidao Xia[2], Dr Louise Hughes[1]

Poster Group 1

Multimodal imaging approaches are essential for the characterisation of biomaterials and tissue-biomaterials interactions. We focused on multi-modal imaging techniques to acquire combined structural, molecular, and chemical information.
Confocal Raman imaging uses the inelastic scattering of photons to provide molecular bonding information and chemical identification. Hyperspectral Raman mapping gives the discrete distribution of chemical compounds within a material. Backscattered Electron and X-ray (BEX) imaging is the combined acquisition of backscattered electron (BSE) and x-ray data in a scanning electron microscope (SEM). BEX provides fast and automated mapping across a large area, collecting ultrastructural and composition data simultaneously.
We used a multimodal approach that combines Raman, SEM and BEX for investigating the interface regions between hydroxyapatite implants and bone tissue, connecting materials and tissue analysis. Resin embedded bone samples were polished to expose the implant regions. For SEM imaging we used a Zeiss 460 (Carl Zeiss Microscopy GmbH, Germany) operated at 10kV, 800pA - 1nA probe current, at 8.5mm WD, in variable pressure mode (30 Pa). BEX imaging was collected in the SEM with Unity (BEX detector, Oxford Instruments, UK) combined with an Ultim 100 (Oxford Instruments, UK). Implant areas were collected automatically, using cartography mode.
Regions of interest (ROIs) were identified with low magnification (500x magnification), large field of view (2 x 1.5mm ROIs, 30min acquisition time) rapid mapping using BEX (Fig 1a, b). High resolution images (2500x magnification) show that the implants are heterogenous, with distinct higher contras foci, rich in phosphate (Fig 1d, e). The same ROIs were subsequently imaged with Raman mapping using a 785 nm laser at 50 mW focused using a 100x objective with a spatial resolution of less than 500 nm.
We observed differences in electron density between bone and implant, as well as variability within the implant itself (Fig 1a, d). The combination of BEX and Raman analysis of the ROIs shows that electron density variation is explained by differences in concentration of calcium and phosphate (Fig 1g) and molecular composition, apatite vs hydrogenphosphate (Fig1 f, h).
The fast mapping of large samples using BEX was vital for an efficient selection of multiple ROIs of implant-bone interface. In addition, the speed of data acquisition using BEX permits the imaging of beam sensitive samples with compatibility for Raman imaging (no coating and lower electron dose related damage). The compositional information from BEX and Raman provides valuable context for the interpretation of bone and implant ultrastructure.

Poster Group 2

Background incl. aims
Intermediate layers have been observed at the interfaces between Ga_2O_3 and Al_2O_3 [1] as well as Ga_2O_3 and AlN [2]. These layers exhibit the crystal structure of the substrate but with altered composition. For the first heterostructures, stabilization of the intermediated layer due to strain was proposed under the assumption of pure α-Ga_2O_3. Recently, it was shown that the composition is about 25% Ga [3] only. To better understand their physical origin, the composition of samples grown under different conditions were investigated using TEM and complemented by DFT computations.
Methods
For composition determination different methods were employed: energy dispersive x-ray spectroscopy (EDX) evaluated using ThermoFisher's Velox software, composition determination from quantitative HAADF-STEM [4] and strain state analysis from measurement of atomic distances [5]. Measurements were carried out in a probe-corrected ThermoFisher Spectra 300 and an imaging-corrected FEI Titan 80-300 on specimens prepared using a FEI Nova 200 FIB by the lift-out technique. DFT studies were performed using VASP [6]. Specimens were grown by molecular beam epitaxy (MBE), MOCATAXY [2] and suboxide MBE [2].
Results
Fig. 1 a) and b) show a HRSTEM image and a Ga concentration profile measured on a Ga_2O_3/Al_2O_3 interface formed by MBE in conditions, where actually no growth can be observed. The afore mentioned α-$(AlGa)_2O_3$ intermediate layer with a Ga concentration of about 25% can be seen as the layer with higher intensity. The composition of this sample formed at 300 °C for 3 minutes was rather similar to samples obtained at 700 °C for 180 minutes and at 700 °C for 3 minutes. This result shows that the composition significantly differs from the one (100% Ga) proposed in Schewski et al. [1]. To elucidate whether the layer stabilizes due to strain for the low concentration, DFT computations were carried out. For that, strained and unstrained α- and β-Ga_2O_3 unit cells were generated and Al atoms according to different concentrations were substituted. All possible atomic configurations in 1x1x1 cells were considered. Their mean values and respective standard deviations are displayed in Fig. 2 a) as function of Ga concentration. In general, the strained β-phase has significantly higher energy compared to all other cases due to the very large strain. In the limits (100% Ga and 0% Ga) unstrained β-Ga_2O_3 and α-Al_2O_3 are found to be energetically lowest as expected. This means that critical concentrations exist at which the energies of the 3 cases cross: Strained α-$(AlGa)_2O_3$ was found lower in energy up to Ga concentrations of 33% compared to β-$(AlGa)_2O_3$. β-$(AlGa)_2O_3$ becomes lower in energy than unstrained α-$(AlGa)_2O_3$ above about 62 % Ga. This shows that the occurrence of the layer can be explained just by its low concentration. In order to elucidate its origin further, Al_2O_3 surface slabs were generated in which two Al atoms were substituted by Ga atoms, respectively. Fig. 2 b) shows the energy difference between a cell, in which both Ga atoms were in the 2 topmost layers compared to cells where one Ga atom is in the topmost layer and the second

atom is placed deeper in the slab as a function of distance of the second atom to the top atom. Two cells could be identified for which the second atom being deeper in the crystal was energetically lower than both atoms close to the surface. These special positions were found within the topmost 3 atomic double layers and thus, it could be possible that Ga atoms chemisorbing can diffuse into the topmost 3 double layers of the substrate resulting in an effective concentration of 33% Ga. Fig. 1 c) and d) show HRSTEM images of MOCATAXY (with In as catalyst) and suboxide MBE grown Ga_2O_3/AlN samples. A bright layer with wurtzite type crystal structure can be observed similar to the Ga_2O_3/Al_2O_3 interfaces. In e) respective relative lattice distance profiles are shown for both samples. Simulated lattice distances as a function of Ga concentration are depicted in f). For the suboxide MBE the comparison results in a nearly pure GaN composition of the layer, whereas for the MOCATAXY sample the measured lattice distance is larger than all simulated ones indicating that In atoms have been incorporated into the layer. Note, that we neglected O incorporation in these considerations. Further studies in this direction are under way.

Conclusion

Our measurements and computations for the Ga_2O_3/Al_2O_3 interface show that the intermediate layer's composition is significantly smaller than assumed in previous publications and its occurrence can be explained by the low Ga concentration. For the Ga_2O_3/AlN interface a nearly pure GaN layer was found, possibly containing In in the case of In-mediated MOCATAXY.

Cryo-electron microscopy for the study of sensitive energy materials

Dr. Zdravko Kochovski[1], Dr. Yaolin Xu[1], Prof. Dr. Yan Lu[1]
[1]Department of Electrochemical Energy Storage, Helmholtz-Zentrum Berlin für Materialien und Energie, Berlin, Germany

Poster Group 1

Background incl. aims

As current batteries are nearing their theoretical limits, future generation high-energy-density battery chemistries demand a fundamental understanding of their operation and failure pathways at the atomic level. However, most energy materials and most notably lithium (Li) are sensitive and unstable under the electron beam in conventional TEM. This problem has been addressed in recent years by the application of Cryo-EM methods, borrowed from structural biology.
A major obstacle hindering the implementation of Li-metal batteries is the limited understanding of the Li nucleation and growth mechanisms. Furthermore, the solid-electrolyte interphase (SEI) is essential for the reversibility of the lithium Li-metal electrode, but the lack of in-depth understanding of its structure and unclear formation/evolution mechanisms have significantly hampered its rational design. We applied Cryo-EM and Cryo-ET to unravel the morphology and inner structure of Li deposits and to investigate the morphological evolution of Li deposition and the interface confined SEI.

Methods

We have used a JEM2100 Cryo-TEM equipped with a bottom mounted 4k TVIPS F416 camera and a Gatan 914 cryo-transfer holder. We have used a cryo-transfer procedure where the TEM grids containing the Li deposits are transferred to the TEM column without exposure to the ambient environment. Cryo-EM micrographs and tilt series have been acquired using SerialEM. Tilt series have been processed with IMOD and segmentation has been done in Amira.

Results

In one work, Cryo-EM revealed two distinct types of Li deposits, depending on the current density: Li-balls, which were found to be primarily amorphous and Li-whiskers, which were found to be highly crystalline. Additionally, their solid electrolyte interface (SEI) layers showed a difference in structure and composition, correlated to the underlying deposition mechanism. In another work, we used Cryo-EM to reveal the morphological evolution of the SEI layer during Li plating, showing a thick (~100 nm) and wrinkled SEI layers forming in the initial stage, which progressively stretched and thinned to up to 7nm after 24 min of Li deposition. Cryo-EM and Cryo-ET also revealed in detail the morphologies of the Li deposits.

Conclusion

Cryo-EM and Cryo-ET, which are methods well established in the field of structural biology, could be well adapted to the study of sensitive energy materials.

Automated Identification of Slip System and Twinning Activity Fields from Digital Image Correlation Data

Dr. Tijmen Vermeij[1,2], Dr. Ron Peerlings[1], Prof. Marc Geers[1], Dr. Johan Hoefnagels[1]
[1]Mechanical Engineering, Eindhoven University of Technology, Eindhoven, Netherlands, [2]Laboratory for Mechanics of Materials and Nanostructures, Swiss Federal Laboratories for Materials Science and Technology (EMPA), Thun, Switzerland

Poster Group 2

Background
Plastic deformation in metals predominantly occurs through crystallographic slip, which requires identification to advance the understanding of mechanical behaviour and micromechanical deformation mechanisms. Current identification methods include (i) the use of the Schmid Factor (SF), (ii) matching of observed experimental slip traces to theoretical slip traces as determined by, e.g., EBSD and, (iii) calculation and matching of the 'Relative Displacement Ratio' (RDR) along a pre-determined slip trace, derived from SEM-DIC data. However, these methods require the presence of clear and straight slip traces in the strain field. To identify plasticity which involves, e.g., cross-slip, curved slip, and/or diffuse slip, a method is required that performs a one-step identification, locally, on the SEM-DIC displacement/strain field, i.e., without requiring an initial identification of slip trace lines in the strain map.

Methods
This paper proposes a novel slip system identification framework, termed SSLIP (for Slip Systems based Local Identification of Plasticity), in which the measured displacement gradient fields (from Digital Image Correlation) are locally matched to the kinematics of one or multiple combined theoretical slip systems, based on the measured crystal orientations. To identify the amount of slip that conforms to the measured kinematics, an optimization problem is solved for every datapoint individually, resulting in a slip activity field for every considered slip system.

Results
The identification framework is demonstrated and validated on an HCP virtual experiment, for discrete and diffuse slip, incorporating 24 slip systems. Experimental case studies on FCC and BCC metals show how full-field identification of discrete slip, diffuse slip and cross-slip becomes feasible, even when considering 48 slip systems for BCC. Additionally, recent developments now also allow identification of slip and twinning systems on challenging HCP Zn coatings.

Conclusion
In summary, we will show how the SSLIP method can be very useful for the materials science community, especially since we provide the codes in open-source format on Github [1,2].

SEM Automated Quantitative Mineralogy Method-development with Mineralogic: 200-nm-resolution Quantitative Assessment and Mineral-specific element mapping

Phd Nynke Keulen[1], MSc Sebastian N. Malkki[1], PhD Rikke Weibel[1], PhD Adam Garde[1]
[1]GEUS: Geological Survey of Denmark and Greenland, Copenhagen,

Poster Group 2

The study of fine-grained materials at the sub-micrometer scale with energy-dispersive X-ray spectroscopy (EDX) analysis using a scanning electron microscope (SEM) is often challenging. The primary electron beam's interaction-volume typically exceeds the grain size to be analyzed, resulting in mixed signals from individual grains. Consequently, EDX is rarely applied to such fine-grained materials. However, by employing a low primary beam acceleration voltage, a large aperture, and a dedicated mineral classification within the Zeiss Mineralogic software platform, mixed signals can be deconvoluted down to a spatial resolution of 200 nm [1]. This enables EDX and automated quantitative mineralogy (AQM) investigations of sub-micrometer-sized grains. Here, we would like to demonstrate reliable quantitative mineralogy on three case studies with geological samples with fine-grained material: 1) Fine-crushed fault gouge exhibiting a heterogeneous mineralogy, 2) fine needles in glass particles of a meteorite impact crater, and 3) rims in glauconite clasts affected by burial diagenesis.

Background

Automated Quantitative Mineralogy (AQM) has been applied since the early 1980s, applying technologies like QEMSCAN and the more recently TIMA-X. These techniques involve controlling the electron beam to scan the sample surface at a user-defined spatial resolution, capturing unquantified energy-dispersive spectroscopy (EDX) spectra. These unprocessed spectra are then matched to a reference library of known EDX spectra to identify minerals. This approach is very fast, however it provides only a rough assessment of mineralogy when elemental concentrations exceed ca. 10 wt%.

Method

The introduction of ZEISS' Mineralogic software advance AQM capabilities by integrating matrix corrections, and peak deconvolution in EDX spectra for each analysis point rather than matching spectra. Minerals are classified based on stoichiometry values. Importantly, the software retains the chemistry information for each pixel, allowing reinterpretation of mineralogy after analysis. Samples were polished and coated with carbon and examined using a Zeiss SIGMA 300VP SEM equipped with two Bruker XFlash 6|30 EDX detectors (129-eV energy resolution) and the Zeiss Mineralogic AQM mineralogy software platform. A specific region of interest was imaged to create a high-resolution back-scattered electron contrast mosaic [2]. Additionally, a 200-nm step-size AQM analysis was performed using Mineralogic, resulting in a detailed mineral map.

X-rays are generated from an interaction volume, which size depends on the primary energy of the beam and the mean atomic number of the sample. The interaction volumes for geological samples (silicates) typically ranges from 2 to 5 µm when using a 20-kV primary electron beam. For minerals with finer grain sizes however, accurate chemical analysis and mineral classification based solely on EDX spectra is therefore challenging as the resulting spectrum will consist of a compositional "mixing" of multiple grains. To address this, the interaction volume was reduced by setting the

acceleration volume of the primary beam to 10 kV, while applying a 60-µm aperture providing a 1.8-nA beam current, to minimizing the interaction volume and therefore the amount of signal mixing, while keeping a high-enough signal to resolve all relevant elements in silicates. Despite this reduction, Monte Carlo simulations indicated that minerals with the lowest average atomic number (Z) still yielded an interaction volume diameter of approximately 1 µm, while high-Z phases reached down to 400 nm. The 200-nm EDX pixel size allowed for oversampling and captured a significant volume of mixed pixel signatures. But the integration of fully quantitative energy-dispersive X-ray spectroscopy (EDX) classifications within the Zeiss Mineralogic software allows for precise analysis at the pixel level [2]. By quantifying the weight percent contribution of elements on a per-pixel basis, the software discriminates minerals effectively, even when dealing a certain amount of contamination resulting from mixed signals. Even for minerals with a low atomic number (Z), where the interaction volume is relatively high, Monte Carlo simulations demonstrate that a significant portion of chemical information originates from the localized area where the electron beam strikes the sample. By leveraging this insight, the software accurately translates mixed signals into mineral classifications, ensuring correct identification and analysis of these particles [1].

To perform mineral-specific element mapping, the technique above is further adapted in the ZEISS Mineralogic software platform to be able to visualise the element distribution in selected minerals, while masking out the other minerals simultaneously [3].

Results
In the presentation will be shown that polymineralic fault gouge down to 200 nm in diameter can be differentiated, classified from the data for that pixel, and its grain size distribution can be assessed [1]. Micrometer and submicrometer scale features in grains collected from the Hiawatha impact crater reveal the history of the area during and after the impact. Acicular orthopyroxene microlites, with a 1-2 µm width, were crystallized from melts above the solidus under different degrees of undercooling. Emulsion microstructures with siliceous melt droplets in an iron-rich melt phase show internal zonation at µm-scale, interpreted as incomplete mixing between two shock melts with different compositions forming equant, micrometer-sized microlites. Felsic melt grains contains abundant, closely packed microspherulites of 1-3 µm mordenite, giving evidence for a hydration event [4]. Rimmed glauconitic clasts reveal different trends during burial of glauconitic sandstone: the composition of the glauconite grains changes with depth, they become on average more K-rich and Fe-poor, with exception those being chlorite-replaced. This is an alteration effect, depending on temperature, distance to embedding mudstones and/or fluid composition, and the illitization of glauconitic clasts, at increasing depth. Nearly all glauconitic clasts have rims richer in Al and poorer in Fe and K, related to late diagenetic alteration, either resulting from the reaction to smectite or due to interaction with brine or hydrocarbons [3,5].

Conclusions
The ability to quantify the EDX spectrum at each analyzed point into its primary chemical components, and the use of in-built matrix corrections and peak deconvolutions, provide a robust analytical framework to provide high-quality quantitative chemical and mineralogical data that open up for a range of new applications in AQM.

Depositing biological segmentation datasets FAIRly

Dr Elaine Ho[1], Dr Dimitris Ladakis[1], Dr Michele C. Darrow[1]
[1]Artificial Intelligence and Informatics, The Rosalind Franklin Institute, Harwell, United Kingdom

Poster Group 2

Background incl. aims
Segmentation of biological images identifies regions of an image which correspond to specific features of interest, which can be analysed quantitatively to answer biological questions. This task has long been a barrier to conducting large-scale biological imaging studies as it is time- and labour-intensive. Modern artificial intelligence segmentation tools can automate this process, but require high quality segmentation data for training, which is challenging to acquire. Biological segmentation data has been produced for many years, but this data is not often re-used to develop new tools as it is hard to find, access, and use. Recent disparate efforts [1-4] have been made to facilitate deposition and re-use of these valuable datasets, but more work is needed to increase re-usability. In this work, we review the current state of publicly available annotation and segmentation datasets and make specific recommendations to increase re-usability following FAIR (findable, accessible, interoperable, re-usable) principles [5] for the future.
Methods
A collection of publicly available segmentation and annotation datasets for 3-D volumetric electron microscopy and associated metadata was assembled from searches in the EMDB, EMPIAR, and Open Organelle databases, and a literature search with Pubmed from 2012-2023. Characteristics about these datasets were collected and trends over time were investigated, e.g., the purpose of the segmentations, data formats, biological feature type and size scale, imaging modality, and others.
Results
Whilst there were many examples of publicly available segmentation data that could be easily reused, these datasets were few and far between. We identified barriers to reusing published segmentation data according to FAIR principles. Many publications we reviewed were not findable or accessible as they were deposited at defunct URLs, were only available on request, or required researchers to search separately through citations or online to download the data. We found that data was deposited across at least 12 different formats, and 9 different online repositories, limiting the interoperability of these datasets as significant effort would be required to parse these formats into a single unified database for training segmentation tools. We found that there were considerable differences in the definitions of certain terms such as “segmentation”, “reconstruction”, and “ground truth”. A consensus is required across the breadth of the bioimaging community to ensure that these datasets can be re-used appropriately without misinterpretation.
Enhanced metadata capture and search capabilities would help developers find suitable datasets for their use case and determine how much (if any) manual curation would be required to bring segmentation data to the required standard for their study. This metadata could include the number and size of the feature being segmented relative to the image, the quality of the segmentation or the intended use of the dataset (qualitative visualisation, quantitative morphology, etc).
Conclusion
Re-use of biological segmentation data is important for enhancing development of segmentation software tools, particularly those using artificial intelligence techniques requiring large amounts of training data. Enhanced metadata capture, quality evaluation, community consensus in ontology and

standardisation in data formats is required for encouraging re-use of these precious segmentation datasets.

PS-04 (4), Plenary, august 27, 2024, 14:00 - 16:00

Background incl. aims
Improving upon the current generation of lithium-ion batteries requires a fundamental understanding of electrochemical and structural/chemical changes due to work-cycles of the electrodes/electrolyte heterostructure. Multiple mechanisms exist for cell degradation, whether this be through structural fatigue in the bulk of the electrodes or via formation of solid electrolyte interfaces (SEIs). With resolutions achievable below 1 Å in aberration corrected transmission electron microscopy (TEM), structural analysis of grains, grain boundaries, as well as interfaces between electrode (LiCoO2, LCO) and electrolyte (Li7La3Zr2O12, LLZO) as well as formed current induced SEIs is possible on atomic scale. Determining the structural characteristics of the boundaries and interfaces will allow us to build atomistic models for calculating the electronic properties for lithium diffusion. The observation of defects and interfacial composition down to atomic resolutions is fundamental to understanding the specific characteristics changing the efficiency of lithium-ion movement through the device. By combining ptychography and high resolution EELS we demonstrate that Li can be uniquely traced through the grown films, and more importantly at the grain boundaries that delimitate higher with lower regions of Li.

Methods
The thin films were grown by pulsed laser ablation (PLD) on several substrates including Al2O3, GGG and SrTiO3. STEM-EELS was done using Nion UltraSTEM100MC – Hermes Scanning Transmission Electron Microscope (STEM), operated at 60kV. The instrument is equipped with a cold field emission source, with energy spread of around 6meV.
The electron energy loss spectroscopy (EELS) spectrum images (SI) were acquired with a probe with an energy spread of 150 meV with a collection half-angle of 22 mrad. The HAADF-STEM imaging and 4D STEM imaging was done by aberration corrected JEOL Grand ARM at 300keV.

Results
Single layer films of LCO, annealed at various temperatures, have been imaged in HAADF-STEM with regions of rhombohedral, spinel and cubic phases identified. As temperature increases during the annealing process the films show a reduction in rhombohedral phase grains and an increase in number of cubic grains. This fits with the assumption that the spinel and cubic phases are the stabilisation of an increased reduction in lithium content, respectively. Grain boundaries between the three phases of the deposited films have been studied via EELS in order to map the Li content and potential channels between the nanograins. Further to this electron ptychography was performed showing the Li position in the grains and across boundaries, corroborating the spectroscopic data.

Heterostructures of LCO and LLZO grown on GGG substrates have also been studied via STEM, EDS and EELS datasets to understand the details of both electrode and electrolyte as well as features appearing at the interface. Interfacial decomposition appears most dependant on temperature, with the scale of intermixing greatly reduced when subjecting heterostructures to applied bias. LCO will grow crystalline on LLZO (LCO/LLZO) allowing a crystalline electrode/electrolyte interface to form, whereas the electrolyte remains amorphous when deposited on top of crystalline LCO (LLZO/LCO). However, LLZO/LCO structures promote the formation of $LaCoO_3$ interfacial layers and crystallites of cobalt-containing structures growing through into the LLZO layer. These contribute to a complex system formed during thermal decomposition and intermixing occurring at the solid-state interface.

Conclusion

The position of Li atoms, within three phases of differing Li content, in LCO have been imaged. This insight can help engineer LCO films with optimal Li transport properties, and provide insiights of the effect of annealing in crustalisation process of these thin films and heterostructures. LCO and LLZO interfaces have been grown and studied via STEM-HAADF, and STEM-EELS. The orientation of the substrate only allows for crystalline LCO/LLZO interfaces whilst LLZO/ LCO heterostructures have an intermixing $LaCoO_3$ layer and large crystallites that pierce into the LLZO film.

The combined approach of imaging and spectroscopy have been shown to be rather beneficial in determining the structure and Li content in the thin films and heterostructures of Li based oxides used as electrolyte and electrodes.

Spectrally resolved brightfield widefield microscopy by an ordinary digital camera

Prof. Dalibor Štys[1], Dr. Renata Stysova Rychtarikova[1], Dr. Kirill Lonhus[1]
[1]Visible Truth, Institute of Complex Systems FFPW, South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses, University of South Bohemia in České Budějovice, Nové Hrady, Czechia

Poster Group 1

Background
The signal at the digital sensor of the microscope camera contains much more information than is typically extracted by commonplace visualization software. Combined with spectra-based calibration (1) and quasi-spectral analysis (2), we obtained an information set with a visible range spectrum for each camera point. Instead of an image, we have a physical dataset completely independent of the measuring system by which the image was obtained. Multiple types of visualization and physical analysis may be applied.
Methods
We use the simplest possible set-up -- a telecentric objective, a reflected light source, and a black background -- with no optical path modifications. In this way, we reduce the number of aberrations to the minimum. The optical signal is detected by a full frame colour digital camera sensor. Interpolation in the high-dimensional spectral space compensates for geometrical limitations caused by the construction of the camera sensor.
Samples are unmodified as possible: cells and tissues are unstained in their native states; materials are only commonly surface treated.
Physico-chemically different regions in the sample are determined as regions of similar visible light spectra.
Results
We show results of quasi-spectral analysis on living leukocytes (Fig. 1 and 2), unlabeled necrotic lung tissue (Fig. 3), and a polished metal surface (Fig. 4). In each case, we observe regions of ~100 nm in diameter with homogeneous spectra.
Conclusion
There is much more information in the primary dataset of the digital microscope camera sensor than is typically utilized. By combining the knowledge of spectra of the incoming light, transparency spectra of the camera RGB sensor filters, and geometric considerations, we approach the physical and information limit of light microscopy. The results are comparable to standard results obtained by stained samples and contain more chemically specific information than scanning electron microscopy imaging. The experiment requires minimal sample preparation. Most practical tasks may be heavily simplified.
No artificial intelligence is required up to this point, only physical measurement, geometry, and advanced statistics.
The large sensor enables the obtaining of excellent statistics on observed sample properties.
Using maximum physical and information analysis on the primary dataset is essential before applying artificial intelligence. Otherwise, we follow the rule "garbage in, garbage out".

Panel 1. Overview of the image of unstained human leukocytes. The APS-H camera sensor captures the image of 3.08x1.92 mm2 with the pixel size of 230×230 nm2. The image typically contains over 2000 cells.

Panel 2. Detail of the image of unstained human leukocytes. The details of organelles allow us to identify the types of cells, even much more details may be found than in the stained image.

Panel 3. Histological section of necrotic lung tissue after massive fat embolism. Tissue was generally unlabeled, fat aggregates are oil red stained (pink objects) and cells and nuclei appear as bright objects inside the tissue.

Panel 4. Weld of two types of steel of different composition and internal structure.

Nanoparticle Self Diffraction in the TEM: A proposal

Prof. Stefan Nimmrichter[1], Prof. Dennis Rätzel[2,3], Prof. Peter Schattschneider[4,5], Prof. Philipp Haslinger[4,6]
[1]Naturwissenschaftlich-Technische Fakultät, Universität Siegen,, Siegen, Germany , [2]Institut für Physik, Humboldt-Universität zu Berlin, Berlin, Germany, [3]ZARM, University of Bremen, Bremen, Germany, [4]USTEM, TU Wien, Vienna, Austria, [5]Institute of Solid State Physics, TU Wien, Vienna, Austria, [6]Vienna Center for Quantum Science and Technology, Atominstitut, TU Wien, Vienna, Austria

Poster Group 2

Background and aims
Entanglement in the TEM has been proposed to study the superposition of mesoscopic quantum states and their decoherence via the reduced density matrix of the probe electron [1]. Here, we take this idea further and discuss the possibility to prepare a massive nanoparticle in a quantum superposition of distinct momentum states and observe its interference. Contrary to previous proposals for nanoparticle diffraction at optical standing-wave gratings [2], the spatial and temporal coherence requirements are substantially lower. TEM-assisted diffraction might be therefore a viable alternative route towards new mass records in matter-wave interferometry.
Methods
We propose to diffract a single electron on a (crystalline) nanoparticle of about 50 nm radius and lattice plane distance d. By virtue of momentum conservation, each Bragg reflection gn=2 π n/d imparts a momentum of nhg/2 π onto the center of mass (CM) of the nanoparticle (red dot in Fig. 1A). Detecting the electron in the image plane (Fig. 1B) then prepares the nanoparticle in a quantum superposition of wave packets with different momenta – a Schrödinger kitten state with a relative phase conditioned on the detected electron position. As the particle propagates freely in time (Fig. 1C), the wave packets disperse and interference fringes form. A position measurement, e.g., in an optical dipole trap (Fig. 1D), would reveal these fringes, demonstrating the quantum wave nature of the nanoparticle's CM. This can be viewed as resulting from the diffraction of the nanoparticle on its own crystal lattice.
Results
We predict fringe patterns caused by quantum interference, different from both a classical mixture of individually spreading states that would not show fringes, and from a semiclassical model of Moiré fringes, which presumes that the Wigner function of the nanoparticle be non-negative at all times. For didactical reasons, we demonstrate the principle in Fig. 2 showing the density matrix of a hypothetical particle's CM with an initial position spread of the pure state of d/20. ξ/d is the main diagonal, η/d shows the degree of coherence. The red curve is the density profile. A realistic scenario with a crystalline nanoparticle in the mass regime of 10^6 to 10^8 atomic mass units will be benchmarked against the semiclassical model.
Conclusion
In a dedicated TEM the observation of macroscopic quantum interference should be feasible.

Tungsten nanoparticles generated in an atmospheric pressure plasma jet

Dr. Martin Müller[1], Maren Dworschak[2], Prof. Jan Benedikt[2], Prof. Lorenz Kienle[1]
[1]Faculty of Engineering, Kiel University, Kiel, Germany, [2]Faculty of Mathematics and Natural Sciences, Kiel University, Kiel, Germany

Poster Group 2

Background
Atmospheric pressure plasma sources have proven to be a cost and space efficient technology for the preparation of various nanostructures. However, synthesis of high melting point metal nanoparticles remains an ongoing challenge. In this work, tungsten nanoparticles are synthesized by the HelixJet atmospheric pressure plasma source using a tungsten wire as a source material and an oxygen free argon plasma. This offers the opportunity to fabricate a wide range of nanoparticles in terms of particle size, morphology and chemical composition in a single preparation step.
Methods
Tungsten nanoparticles were synthesized in an atmospheric pressure plasma jet (APPJ) with helix electrodes (HelixJet) and a metal wire inserted into the plasma. The metal wire was heated by the interaction with the plasma. The vaporized material is carried in the gas stream and condensates to form nanoparticle nuclei. The synthesized nanoparticles were measured with a commercial scanning mobility particle sizer (SMPS) spectrometer. The morphology and the crystal structure of the resulting particles were analyzed by bright field transmission electron microscopy (TEM) and selected area electron diffraction (SAED). Energy dispersive X-ray spectroscopy (EDX) combined with scanning TEM was used to gain local information on the chemical composition of the particles.
Results
TEM along with SAED and EDX showed monocrystalline tungsten nanoparticles with an average size of 14 nm, consisting of beta-tungsten with a thin oxygen-rich layer on the surface. The composition of such particles was studied with EDX profiling and analyzed using a so called sub-shell approach revealing that the core of the particle is composed of pure tungsten while the approximately 1.5nm surface layer has a tungsten to oxygen ratio of around 1:9. When increasing the plasma power, the average size of the nanoparticles also increased. The weakest plasma power used led to nanoparticles of average size of 12 nm. As the working gas flow rate increased, the time spent by the nanoparticles in the plasma decreased and the resulting size decreased. For the highest flow rates, when the residence time dropped to 0.4 s, the resulting particles had a thick oxide layer on the surface, while for the lowest flow rates with residence times above 1.8 s, the resulting particles were composed mainly of alpha-tungsten. Nanoparticles agglomerate into clusters, which are then measured by SMPS. The resulting size spectrum was fitted and individual peaks were sequentially assigned to agglomerates with increasing number of particles. It turns out that the SMPS measures the mobility of agglomerates as if they were larger particles than their actual size given by the sum of individual volumes or masses of particles in the agglomerate, making them to appear significantly larger.
Conclusion
Synthesis of monocrystalline tungsten nanoparticles with an average size as low as 12 nm and with a fairly uniform distribution has been shown. The HelixJet APPJ gives the possibility to prepare nanoparticles of high melting point materials and due to its versatility allows to prepare particles with complex morphology (alloys, oxides, core shells).

Poster Group 1

Background and Aims
Cilia are highly conserved cell organells which emerge from the cell surface. They are frequently involved in signaling functions as well as in the coordinated motion of extracellular fluids and particles along epithelial surfaces. While monocilia are present in many cell types, the generation of multiple elongated cilia in multiciliated cells is restricted to specialized epithelia, e.g. the respiratory epithelium covering the trachea and the nasal conchae.
Until now there is still limited knowledge on the development of multiciliated cells, specifically regarding the details of their cell surface morphology during the ciliogenesis process. Using scanning electron microscopy (SEM) we have investigated the appearance and spatial extension of multiciliary cells in the trachea, in the concha nasalis media and adjacent regions of the embryonic chicken addressing developmental days E12 to E18. In addition, the esophageal epithelium bearing a more restricted lining of multiciliated cells was analyzed from E10 onwards.

Methods
Embryonic tissues were collected from fertilized chicken eggs (var. white leghorn) at the indicated days of incubation (E) and, after fixation, were processed for critical point drying for SEM using pieces with longitudinal cuts from trachea or oesophagus and coronal slices for evaluation of the nasal conchae. Additional processing for histology included resin embedding for transmission electron microscopy (TEM), or paraffin embedding for immunohistochemistry. Here, antibodies to acetylated tubulin have been used as a ciliary marker.

Results
At E12 to E14 short monocilia are detected with SEM on the surface of epithelial cells of the trachea and concha nasalis media. Following E14 the formation of much more elongated monocilia is observed and at E14,5 first multiciliated cells are found next to many cells with elongated monocila. At E15 an increased number of multiciliated cells is present showing multiple growing cilia with different length profiles whereas fewer cells with extended monocilia remain next to the clustered multiciliated cells until E16. At E17 monociliated cells are largely absent and most of the multiciliated cells have grown a large number of individual cilia to their final length of 5-6 µm. Here and in the following stages, the epithelial surface of the trachea and concha nasalis media is almost completely covered by cilia, whereas epithelial grooves that have emerged during development and have gradually increased in depth show a strongly reduced number of multiciliary cells, e.g. at E18 in the conchae nasalis media.
Interestingly, a distinct earlier onset of this ciliogenesis process was noted in the nasal septum adjacent to the former conchae, where cells with elongated monocilia and multiciliated cells are detected starting at E13. Accordingly the full coverage of the epithelium with cilia does occur earlier in the nasal septum i.e. at E16. Again, a much earlier onset of ciliogenesis is observed in the developing epithelium of the esophagus where at places we have detected nascent multiciliary cells

at E10 onwards which are located next to cells with short monocilia and some cells with extended monocilia. While much less multiciliated cells are formed during development in the esophageal epithelium compared to the respiratory epithelia examined above these findings suggest a similar sequence of ciliogenesis in multiciliated cells of the esophagus epithelium that involves transitory monocilia and a specific temporal development.

Conclusions
Our findings indicate that the appearance of cells with extended monocilia is a morphological marker for cells that are likely to further develop as multiciliated cells in an epithelium and will emerge with multiple cilia in the following. The observed developmental sequence of multicilated cells is completed in a relatively short period of time comprising approximately 3 days after onset in the chicken embryo.

Poster Group 1

A promising route for the synthesis of kesterite solar cell absorber layers consists in the annealing of thin layers in vapours resulting in alloys of kesterites, a route that has recently also be used for the synthesis of van der Waals materials. This straightforward annealing procedure includes several structural transformations of the absorber thin film layer such as phase transformations, diffusion processes and grain growth. The disentanglement of these different processes is difficult and TEM analysis is essential to understand the structural changes during the annealing of those materials. The best approach to follow the structural changes during the synthesis process of such kesterite materials is to carry out the related annealing steps in situ in the TEM. Since the layers have a certain thickness and the annealing must be carried out in a Se atmosphere, the high voltage TEM (HVTEM) is an appropriate method for this type of in situ annealing which we carry out in this work.

Methods
For the TEM in-situ synthesis of kesterite structures of Cu2ZnSnSe4, we used the JEOL-1000K RS HVTEM at Nagoya University. The starting materials are Cu2ZnSnS4 and AgCu2ZnSnS4, which are annealed in a Se atmosphere to obtain a Cu2ZnSnSSe phase with as high as possible Se content. The temperature is increased in steps of 50-100 °C up to 500 °C while the Se-enriched carrier gas streams along the sample surface. At each temperature ramp, the sample is analysed by electron diffraction, TEM and STEM imaging as well as by EELS spectroscopy. In addition, the TEM is equipped with a highly sensitive mass spectrometer, which enables us to analyse the gases coming from the sample during annealing.

Results
We started the synthesis either from the metallic stacks or from Cu2ZnSnS4 which are exposed to Se vapours. Though the analysis of the metallic stacks has promising results, the thickness increase of about a factor of 2 during the selenisation process made the sample so thick that it was difficult to analyse nanometric changes in the sample happening during the synthesis process. This situation changed by using thin Cu2ZnSnS4 and AgCu2ZnSnS4 films as a starting material since these films preserve their thickness during the synthesis.
During the in-situ annealing of AgCu2ZnSnS4, we observed the nucleation of the kesterite Cu2ZnSn(S)Se4 phase, which is precedented by the formation of Ag- and Se-containing nanoprecipitates. Those partially disappear during higher annealing temperatures, when the AgCu2ZnSnSe4 grains grow. By in-situ EELS analysis and post-annealing EDS measurements of the thin layers we could follow the chemical modifications of the crystallites forming a core-shell structure.
When the Cu2ZnSnS4 is synthesised, the replacement of S by Se causes an expansion of the lattice parameter. We applied a Hough transform to extract the lattice plane spacing from the diffraction patterns and conclude that in Cu2ZnSnS(4-x)Sex, Se is inserted at a concentration of 50±10 %. One goal of this annealing process is to increase the grain size to reduce the impact of grain boundaries

on carrier transport. Whereas the starting kesterite has a grain size in the 10 nm range, after the annealing process, a grain size of 50 nm is reached.

Conclusion
Using in situ HVTEM synthesis of Cu2ZnSn S(1-x)Sex kesterite structures, we could successfully demonstrate the grain growth and replacement of S by Se in the kesterite crystal. This replacement reaction happens at elevated temperatures of 400-500 °C.

Poster Group 2

Background incl. aims
Transition metal hydroxides ($TM(OH)_2$) have garnered significant attention in research due to their diverse applications in the energy and environmental sectors. These hydroxides exhibit promising capabilities in catalysis, supercapacitors, and battery materials [1-3]. For instance, cobalt hydroxides ($Co(OH)_2$) can decompose to form cobalt oxides (e.g., Co_3O_4), which are materials known for their applications as catalysts in the Fisher-Tropsch process, water splitting, and N2O decomposition [1,4].

Catalytic processes typically occur at elevated temperatures. Understanding the morphological changes and phase transitions of Co_3O_4 upon heating is crucial for controlling its properties in various applications, including those listed above. Furthermore, studies suggest that besides particle size and morphology, the distribution of exposed facets in Co_3O_4 plays a role in the catalyst's activity during N_2O decomposition [4].

In this work, a visualization of the morphological evolution of Co_3O_4 crystals synthesized by calcination of $Co(OH)_2$ at different temperatures is carried out through ex-situ (S)TEM imaging of samples. Furthermore, the facet distribution of a Co_3O_4 particle, revealing the concentration of exposed surfaces, is determined and visualized in 3D by combining STEM-HAADF electron tomography (ET) and high-resolution TEM.

Methods
In an in-situ XRD experiment, the precursor $Co(OH)_2$ underwent calcination to 1200°C in steps of 25°C in synthetic air (20%O_2), mapping the crystal-size evolution of Co_3O_4 and its phase transitions. For visualization of the sample morphologies by electron microscopy, several Co_3O_4 samples were prepared separately by calcining $Co(OH)_2$ at varying temperatures. The choice of temperatures was based on the in-situ XRD experiment.

Transmission electron microscopy was carried out using a probe-corrected Spectra 200 (S)TEM (Thermo Fischer Scientific), operated at 200 kV in scanning mode (STEM), or in parallel beam mode (TEM) for high-resolution imaging. Electron tomography tilt series were acquired in scanning mode using the high-angle annular dark field detector (STEM-HAADF) and a low convergence angle of 5.6 mrad for enhanced depth-of-field [5]. The tilt-series, recorded from +70 to -70 degrees in 2-degree intervals, were reconstructed into a tomogram with voxel size $(0.43\ nm)^3$ using fiducial marker tracking (10nm) and weighted back projection (WBP) in Inspect3D v.4.5. The crystallographic orientation of the reconstruction was determined from additional high-resolution TEM images.

Finally, the facet distribution of the 3D reconstructed Co_3O_4 particle was evaluated from a 3D printed model of the reconstructed volume, by identifying the facets.

Results

The decomposition of $Co(OH)_2$ in synthetic air to form Co_3O_4 initiated at 150°C. As the calcination process continued, the mean crystal size of Co_3O_4, as measured by XRD, gradually increased from about 10 nm to 500 nm, indicating sintering. The maximum sintering rate was observed around 850°C, right before an abrupt full phase transition into CoO, which occurred between 875°C and 900°C. Upon cooling, the CoO phase fully transformed back to a Co_3O_4 structure with an average crystallite size (XRD) of ~150 nm. (S)TEM images confirm the presence of both large and small Co_3O_4 nanocrystals in the residual sample.

STEM imaging reveals that the cobalt spinel samples, calcined at 350°C, 450°C, and 550°C, are present in a pseudo-morph structure, resembling the overall shape of the hydroxide precursor, across all three samples. This morphology can be characterized as monocrystalline mesoporous nanograin sheets. While the sheet morphology is consistent across all three samples, an increase in the size of both the grains and pores is observed with increasing calcination temperature.

STEM images of a sample calcined at a high sintering rate (850°C), revealed large particles which appear to be partly faceted. One particle was reconstructed in 3D, revealing clear facets with the (100) facet being predominantly present, followed by (111) and (110). 24% of the surface could not be identified due to rounding, suggesting that the facet formation was not fully completed or equilibrated. This observation was supported by a 50-hour XRD experiment which showed that the mean crystal size of Co_3O_4 initially converges after several hours at 850°C, revealing that the 1-hour heated sample was captured in a dynamic sintering process.

Conclusion

By utilizing electron microscopy – specifically tomography – we were able to observe the morphological changes of Co_3O_4 synthesized by calcination of $Co(OH)_2$ at various temperatures. The Co_3O_4 samples exhibited a sheet-like monocrystalline mesoporous nanograin structure at 350°C and underwent drastic morphological changes as the material sintered to form large particles at higher temperatures. The shape and facet distribution of a Co_3O_4 crystal (calcined at 850°C for 1 hour) were determined using electron tomography combined with high-resolution TEM imaging, revealing the (100) facet as predominantly present, followed by (111) and (110). This approach provides valuable insights into the complex transformation processes (e.g., sintering) occurring in catalytic processes.

FLIPs: Novel genetically encoded biosensors for polarization microscopy

Paul Miclea[1], Vendula Nagy Markova[1], Alexey Bondar[1,2,3], Alina Sakhi[4], Dr. Josef Lazar[1]
[1]First Faculty of Medicine, Charles University in Prague, Prague, Czechia, [2]Biological Center CAS, Budweis, Czechia, [3]University of South Bohemia, Budweis, Czechia, [4]Inst. of Organic Chemistry and Biochemistry CAS, Prague, Czechia

LS-02 (2), Lecture Theater 4, august 26, 2024, 14:00 - 15:00

Background
Genetically encoded fluorescent biosensors convert specific biomolecular events into optically detectable signals. Typically, such probes utilize a suitable fluorescence quenching process in order to modulate the absorption or emission spectrum the fluorophore, or the fluorophore's lifetime. However, an unrelated detection principle, directionality of optical properties of fluorescent molecules, should also allow development of genetically encoded biosensors. Remarkably, despite numerous potential advantages of such biosensors (ratiometric readout, resistance to bleaching artifacts, information about protein structure, possibility of multiplexing, orthogonality to other approaches), optical directionality has remained largely unexploited as a detection principle. Our goal was to make optical directionality of fluorescent molecules widely applicable to imaging of biomolecular processes of cell signaling.

Methods
Using techniques of molecular biology, we set out to develop a series of genetically encoded biosensors suitable for observations of molecular processes of cell signaling by polarization-resolved fluorescence microscopy.

Results
We have now identified a novel design of genetically encoded fluorescent biosensors, which we term FLIPs(1,2,3) (Fluorescence anisotropy and LInear dichroism Probes). FLIPs offer an extremely simple design, high sensitivity, multiplexing capability, ratiometric output and resilience to bleaching artifacts. Importantly, FLIPs allow their targets to remain non-modified. The probes are applicable to imaging cellular activity of G protein coupled receptors, G proteins, arrestins, receptor tyrosine kinases and other signaling proteins, using simple microscopy instrumentation. The sensitivity of the probes allows even imaging of endogenously expressed targets.

Conclusion
The simplicity, modularity and versatility of the FLIP design allows rapid creation of biosensors of desirable properties. By exploiting a simple, universal, yet long overlooked detection principle, FLIPs open a wide new area of development both in genetically encoded fluorescent biosensors and in optical instrumentation.

IM-10 (1), Lecture Theater 3, august 29, 2024, 10:30 - 12:30

Background
High resolution scanning and transmission electron microscopy (S/TEM) enable the observation and exploration even of complex materials and interfaces down to the atomic level. It is often desired to uncover the atomic scale building blocks of materials, which is pivotal in understanding their physical nature and to tailor material properties. Identifying local features of the nanostructure of a material and deciphering latent attributes of them is of vital importance to discover new material phenomena. However, the increasing rate at which atomic resolution data is generated in modern electron microscopes makes human-based analysis tedious and renders it nearly impossible in the near future. This requires the development of automatic data analysis approaches to automatically extract meaningful physical information from local image features.

Methods
We present unsupervised and supervised machine learning approaches to classify phases and interfaces in atomic resolution microscopy images. An unsupervised image segmentation approach based on local symmetry descriptors to detect crystallographic features without prior knowledge of the underlying crystal structure is introduced [1]. The segmentation algorithm relies on self-similarity measures based on local symmetry operators that map the image into a symmetry score vector space. The dimensionality of the local descriptor is reduced by principal component analysis and the pattern labels are assigned by K-means clustering. We then show a supervised image classification framework that automatically labels crystal symmetries and orientations as well as interface regions in atomic resolution STEM images [2]. The underlying convolutional neural network is trained on simulated images of pristine crystal structures, while using the fast Fourier transform of local window regions as the descriptor. Typical noise sources, lattice distortions and rotations are taken into account by augmenting the training data.

Results
We show that the unsupervised segmentation approach can identify the different crystalline regions across a grain boundary in atomic resolution STEM images. By including rotational symmetry, it is even possible to segment the interface itself in an automatic fashion. We then apply the segmentation to atomic scale compositional faults in tetrahedrally complex phases and demonstrate its robustness on noisy data. In a final example, we show that the approach is even capable to segment image regions in an in situ atomic resolution video sequence. The supervised image classification is demonstrated on atomic resolution STEM images of grain boundaries in fcc, bcc and

hcp systems of pure metals. By adopting a Bayesian neural network, the uncertainty estimates of the prediction are considered, which provides information even on structures not contained in the training data. To test the model, we first apply it to synthetic polycrystalline images and demonstrate that amorphous regions can be indirectly identified by high uncertainty estimates. We then show the applicability to experimental STEM images of grain boundaries, where the mutual information is used to identify the interface regions automatically. The higher-dimensional neural network representations are explored via unsupervised learning and we find that it does not only provide information on the different crystal symmetries, but also the interface types.

Conclusions
We developed unsupervised and supervised machine learning approaches to automatically segment and classify image regions in atomic resolution images. It is demonstrated that the supervised segmentation is robust against noise in images and can be applied to image video sequences for in situ experimentation. The supervised learning provides quantitative classification of atomic resolution images of crystalline phases and is even capable to identify structural features not contained in the training data.

Synthesis and Characterization of Ultrathin Unconventional Mixed 2H-HCP/FCC Phase Au Nanowire

Dr. Abhijit Roy[1,2], Dr. Raul Arenal[1,2,3]
[1]Laboratorio de Microscopías Avanzadas (LMA), Universidad de Zaragoza, ZARAGOZA, SPAIN, [2]Instituto de Nanociencia y Materiales de Aragón (INMA), CSIC-Universidad de Zaragoza, ZARAGOZA, SPAIN, [3]ARAID Foundation Zaragoza , Zaragoza, Spain

Poster Group 2

Background incl. aims
Crystal structure engineering enables the cultivation of noble metal nanostructures featuring unique crystal phases, showcasing innovative optical, catalytic, and electronic characteristics. Variations in atomic stacking sequences within these nanostructures are termed polymorphs, often showcasing distinct properties and functionalities despite being of the same material. The crystal structure of nanocrystals is frequently influenced by synthesis conditions such as reaction temperature, surfactants, precursor properties and gas environment. Polytypism, evidenced by the coexistence of several phases within a single nanostructure, defines this phenomenon. Compared to the typical stacking arrangement of "ABC" along the [111] fcc direction in fcc gold, the 4H/2H gold structure exhibits a stacking sequence of "ABCB/AB" along the [001] 4H/2H direction. 1,2
Ultrathin gold nanowires (NWs) with a diameter of approximately 2 nanometers hold significant interest for both nanoscience research and nanotechnology applications. Due to their high surface area and quantum-confined dimensions, these nanowires exhibit fascinating properties such as quantum conductance and ballistic conduction.3 The synthesis of high-quality, single-crystalline ultrathin gold NWs is essential for accurate physical property measurements and further application exploration. Recent reports have surfaced, highlighting successful advancements in the synthesis of these ultrathin gold NWs. However, reports on the synthesis and characterization of ultrathin 2H/4H Au nanowire is still very limited and a detailed structural and optical study of this nanostructure is nedded to be examined closely.1,2,4,5

Methods
In a typical synthesis process, 4.08 mg gold chloride hydrate (HauCl4, H2O) were dissolved into a mixture of 220 µL of oleylamine, 3.54 mL hexane and 250 µL of 1,2-dichloropropane, in a 20 mL glass vial. The solution was shaken for complete dissolution of HauCl4. Next, 80 mL de-ionized water is added into a 500 mL beaker, which was heated to 58°C. The glass vial is kept on the beaker for 16h and after that the solution is centrifuged at 5000 rpm for 2 minutes to filter the residue. The residue was further washed using hexane 3 times. For TEM characterization the Au nanowire solution in hexane was drop-casted on a C coated Cu grid. The HRTEM, selected area diffraction (SAD) were done in an image corrected FEI TECNAI F-30 operated at 300 kV. HRSTEM, energy dispersive X-ray spectroscopy (EDS) were carried out in a probe-corrected FEI TITAN TEM equipped with high-brightness gun and an Oxford Instruments Ultim X-MaxN 100TLE detector for EDS measurements.

Results
We have observed uniform formation of ultrathin Au nanowire. The diameter of the nanowire is between 1.9 nm – 2.3 nm and the length varies between 50nm to 300 nm. The EDS meaurement on them clearly shows the naowires are indeed Au. HRTEM measurement shows formation of 2H-HCP phase mostly on the top of the nanowire and a mixed 2H/HCP and FCC phase in the middle portion as

observed form the IFFT image also. A detailed study on the structural evolution of this nanostructure upon electron beam irradiation will be prersented in this work.

Conclusion

We have done successful synthesis of ultrathin Au nanowire consisting of mixed 2H-HCP/FCC phase. Interestingly the nanowire contains bead like structure as observed from the HRSTEM and HRTEM images and they are observed to be very much sensitive to the electron beam.

Poster Group 2

Background incl. aims

Although inherently dealing with the past, archaeology has profited immensely from the use of modern advanced analysis techniques like electron microscopy [1,2]. Especially TEM can provide inaccessible insights, for example when only miniscule amounts of material are available or faint traces are studied [3,4]. Furthermore, the combination of in situ techniques (like heat treatment) with replicas can lead to vital insights into the exact methods and paramters used for the fabrication of historic artifacts.

In Sweden, two copper axes were found buried in the soil. Both axes were from the late neolithic and comparable to the axe found alongside “Ötzi”. First measurements with X-ray fluorescence spectroscopy (XRF) indicated a silver-rich surface layer next to the obvious strong corrosion. These axes are historic artefacts and therefore a non-destructive sample preparation is necessary. A FIB cut TEM analysis of the surface layers could be carried out adhering to the strict rules of artifact preservation.

The very first settlers in Europe used cow dong as a reinforcement in pottery around 7000 B.C. Mechanical testing measured a higher mechanical strength at certain firing conditions for the reinforced pottery. Apart from the astonishing finding that composite (nano) materials were utilized at this time the exact nature of the strengthening mechanism is not known: is it mechanical (carbon fibres from the grass) or chemical (cow dung ash reacts with clay) in nature? Detailed analysis using TEM can help to better understand the mechanism as well as identify the fabrication procedure of ceramic artifacts.

Methods
The axes were first investigated via XRF and XRD to validate the field measurements. Additionally, the axes were loaded into a FIB-SEM and lamellae were taken out and analyzed via SEM-EDX. The FIB lamellae were subsequently analyzed utilizing a FEI Tecnai F30 G2 and a Jeol JEM-200F NEOARM.
In order to better understand the formation mechanism of silver enrichment and the corrosion layer a replica artifact was produced and artificially aged using suspension in humic acid for multiple weeks.

For the analysis of the reinforced pottery visible grass fibres were extracted with tweezers, ground in a mortar while suspended in butanol and deposited on the TEM substrate via drop coating . The same process was used for the archaeological sample, the unfired replica and several fired replicas. In addition a small amount of material was transferred onto an in situ heating chip (DENS solutions

Wildfire) and heat treated up to 1100 °C in order to demonstrate the feasibility of in situ TEM observation of ceramic sintering and give insight into the mechanisms of the reinforced pottery during firing.

Results

XRD Rietveld analysis of the axe material showed a chemical composition in good agreement with XRF analysis . Since both techniques utilise X-rays the penetration depth is similar resulting in the same relative surface sensitivity. Analysis of the FIB-cut reveals the difference between the unoxidized bulk and the oxide layer, where in the CuO layer, precipitations of Ag are identified (see graphic). Additionally, the brittleness of the surface layer can be linked to the high amount of fractures visible in the CuO layer. The bulk material is uniform in contrast and has an Ag content of 0.8 at%.

In situ heating of a non-reinforced ceramic showed that for temperatures below 1000 °C the material showed a decrease in crystallinity as evidenced be loss of contrast in BF TEM and weaker diffraction rings in SAED. Above 1000 °C the material, which initially consisted of numerous crystallites, fused into larger crystals. Sophistaced backround subtraction in rotational averages of the SAED patterns allowed their evaluation even for faint diffraction patterns.

TEM analysis of the plant fiber reinforced ceramics did not reveal the presence of carbon nanofibers in the pristine as well as heated (in situ and ex situ) state. Carbon rich areas in the specimens could be found, yet not unambiguously linked to originate from the plant fibers. During heating no distinct differences to the non-reinforced ceramic were observed.

Conclusion

The investigation of the axes showed that the Ag-rich surface is a result of the corrosion process of the falutype copper, where the oxidization of the Cu reduces the AgO back to pure Ag, which then forms the grains visible in the EDS map. Consequently, the silver spots were not introduced deliberately, and thus, an initially ritualistic origin of the axes is disproven.

The feasibility of in situ TEM observation of ceramic sintering could be successfully shown. Due to the absence of carbon nanofibers for all sintering conditions mechanical reinforcement of the ceramic on the nanoscale can likely be ruled out. Due to the difficulty of unanbigously identifying specimen areas that originated from plant fibers the identification of the strengthening mechanism is the subject of ongoing investigation.

Biological systems are complex, encompassing intertwined spatial, molecular and functional features. However, methodological constraints always limit the completeness of information that can be extracted. Here, we report the development of INSIHGT, a minimally perturbative and cost-efficient three-dimensional (3D) spatial biology method utilizing solvent perturbative chemistry. This allows quantitative, highly multiplexed and multi-modal readout of tissue biomolecules in up to centimeter-scale biological systems. Diverse antigens, mRNA transcripts, neurotransmitters, and post-translational and epigenetic modifications, are well-preserved and visualized, allowing multi-round molecular probing for high-dimensional spatial biology and compatibility with downstream traditional histology. With INSIHGT, we mapped previously undescribed podocyte-to-parietal epithelial cell microfilaments and demonstrated their geodesic clustering in mouse glomeruli, catalogued sparsely located neurofilament-intensive inclusion bodies in the human cerebellum, and identified NPY-proximal cell types defined by spatial morpho-proteomics in mouse hypothalamus. We anticipate INSIHGT can form the foundations for 3D spatial multi-omics technology development and holistic systems biology studies.

Poster Group 1

Background incl. aims
Nestin, an interesting intermediate filament protein, is expressed in several tissues in the stem cells or within a certain period of development and reoccurs in the newly formed cells in adulthood. It is a proven marker of skeletal muscle regeneration and angiogenesis. Nestin is shortly expressed during the development of the heart and in some cell types in the adult myocardium, particularly in pathological conditions such as myocardial infarction or fibrosis. In this work we described expression and distribution pattern of nestin and its copolymerizing tissue-specific proteins desmin and vimentin in the intact and hypertrophic, adult and aged rat myocardium with the aim to contribute to understanding the reappearance of nestin in the diseased heart.
Methods
Nestin was detected by enzyme indirect two-step immunohistochemical method in the left ventricle myocardium of normotensive Wistar Kyoto (WKY) rats and in the hypertrophic left ventricle myocardium of spontaneously hypertensive (SHR) rats, both at the age of 1 and 1.5 year. Nestin expression in all samples of the myocardium was quantified by image analysis and statistically evaluated. For double immunofluorescent detections a novel method was introduced to enhance intensity of nestin signal based on application of Dako EnVision+ System-HRP Labelled Polymer.
Results
In the intact myocardium of normotensive rats nestin was expressed only in the endothelial cells of some blood vessels in 1.5-year-old animals, whereas in the 1-year-old WKY rats no nestin immunoreactivity was noticed. In the hypertrophic myocardium of SHR rats of both ages nestin was rarely detected in desmin+ vimentin- cardiomyocytes and in some vimentin+ interstitial cells that were usually accumulated forming the clusters and differing in intensity of desmin immunoreactivity. In addition, nestin was sparsely expressed in myocardial capillaries and in the endothelium of larger blood vessels in one-year-old SHR rats.
Quantitative image analysis of nestin expression in the myocardial samples confirmed significant increase in 1.5-year-old WKY rats and in SHR rats of both ages compared to the intact 1-year-old WKY rats.
Conclusion
This work firstly describes re-occurrence of intermediate filament nestin in some cardiomyocytes and in certain interstitial cells in the hypertrophic myocardium of adult and aged spontaneously hypertensive rats. Nestin re-appearance in the endothelial cells of the blood vessels documents important role of angiogenesis during aging in the intact and early hypertrophic myocardium. Nestin re-expression during cytoskeletal remodelling in the different cell types accompanies complex changes in the chronically pressure over-loaded heart and is related not only to myocardial hypertrophy and aging, but also likely to cardiac regeneration.

Poster Group 2

The local structure and morphology of a material is usually modified when submitted to an electro-catalytic process depending on the cycling and potential used. One way to learn more about the effects happening on the material is by using identical location, that is, examining a specific region of interest of the material before and after the electrochemical process takes place. In this work, we show different examples using identical location analytical scanning transmission electron microscopy (IL-STEM) to track specific changes of the material by observing before and after states. In this way, it is possible to study degradation mechanisms directly in the region of interest. Since some of the changes are occurring at the atomic level, understanding them can shed some light on the structural-properties relationship, including the metal support interaction. Most of the analyses shown in this work correspond to Pt-based nanoparticles typically employed in fuel cells and electrolysers that have been submitted to a particular electrochemical cycling protocol. The structural and morphological information gathered from the initial and after states suggests the occurrence of dissolution from specific atomic columns and atomic sites as well as redeposition for different columns and sites. These observations can lead to the conclusion that certain facets may be affected more than others, or in other cases, as it will be shown, to reveal how the support interacts with the catalysts. In this regard, the analysis of regions that suffered modifications can give us certain clues on how degradation started or evolved. Hence, the incorporation of advanced electron microscopy analytical techniques coupled with electro-chemistry experiments can provide crucial insights for a better catalyst design, including stability and durability.

Visualisation of lepidopteran silk gland morphology using X-ray micro-computed tomography scanning technique

Mgr. Šárka Podlahová[1,2], Mgr., Ph.D. Gabriela Krejčová[1], Mgr., Ph.D. Hana Sehadová[1,2]
[1]University of South Bohemia in České Budějovice, Faculty of Science, České Budějovice, Czech Republic, [2]Biology Centre of the Czech Academy of Sciences, Institute of Entomology, Ceske Budejovice, Czech Republic

Poster Group 1

Background incl. aims
Lepidopteran caterpillars are one of the most significant insect silk producers. Depending on diverse life strategies of the two sister families of Bombycoidea, Saturniidae and Sphingidae, the caterpillars have evolved various ways of using silk. Most of the sphingiid larvae use silk exclusively in their first instars to produce rescue silk fibres that prevent the tiny caterpillars from falling off the host plant. In contrast, their closest relatives, the Saturniidae, save all of their silk for the end of larval development to construct complex silk cocoons that serve as a protective outer shell for the individual during its pupal stage. In general, silk is secreted by specialised ectodermal cells that form a silk gland. The silk glands of individual lepidopteran families differ significantly in their overall morphology. This research aims to analyse the in situ localisation of silk glands of several representatives of the Saturniidae and Sphingidae using micro-computed tomography (microCT). The data obtained allow the generation of detailed 3D projections of a caterpillar body, including its internal organs. Here we compare the advantages of the Surface module for segmentation and surface rendering in three different versions of the Imaris software (Imaris 9.3, Imaris 10.0 and Imaris 10.1).
Methods
Last instar caterpillars of the Saturniidae and Sphingidae representatives were submerged in Bouin-Hollande's fixative and contrasted in Lugol's solution. X-ray microCT SkyScan, model 1272 (Bruker microCT, Belgium) was used to visualise iodine-contrasted specimens. High-resolution 3D output tomography data were reconstructed in SkyScan’s volumetric NRecon software version 2.2.0.6 (Bruker microCT, Belgium). 3D models were created in Imaris software versions 9.3, 10.0 and 10.1 (Bitplane AG, Oxford Instruments, UK) using the Surface module: Surpass - Contour Surface, and Machine learning segmentation based on Artificial Intelligence.
Results
Non-invasive microCT is the ideal technology to project internal structures and organs in situ without destroying the specimens. Using Imaris analysis software, we found that Imaris 9.3 is excellent at creating semi-transparent surfaces with adjustable transparency, while the latest Imaris 10.1 does not allow this. On the other hand, Imaris 10.1 uses Machine learning segmentation based on Artificial Intelligence, which makes surface creation much faster and easier.
Conclusions
The procedure for preparing caterpillars for microCT has been optimised. Detection of silk glands in members of the Saturniidae and Sphingidae families based on microCT scanning reveals their exact location in the larval body. This approach allows detailed comparison of the silk gland morphology in relation to the location of other internal organs. Imaris 9.3 and Imaris 10.1 are a suitable combination for complex 3D renderings of biological objects.

TEM structural analysis of photocatalytically active mesoporous single crystalline LaTiO2N particles

Dr. Mont. Jakub Zalesak[1], MSc. Jakob Praxmair[1], MSc. Julian Hörndl[1], Univ.-Prof. Simone Pokrant[1]
[1]Chemistry and Physics of Materials, University of Salzburg, Salzburg, Austria

Poster Group 2

Background incl. aims
Single crystalline mesoporous oxynitride particles have been studied as prospective catalysts in solar hydrogen-generating devices [1]. Both, photocatalytic and photoelectrochemical applications benefit from the high active surface area of catalytic particles in combination with good charge-transport properties [2]. A suitable combination of desired properties is achieved in the case of large mesoporous LaTiO2N single crystalline particles (up to 1 µm). The absence of grain boundaries reduces charge carrier recombination while at the same time their porosity results in increased surface area [3][4]. LaTiO2N mesoporous particles are obtained by transforming La2Ti2O7 particles in a thermal ammonolysis process. In this contribution, we focus on a structural description of pore formation and pore arrangement concerning the LaTiO2N orthorhombic lattice.

Methods
The photocatalytically active mesoporous single-crystalline LaTiO2N particles were synthesised via a thermal ammonolysis process $La2Ti2O7 + 2\ NH3 \rightleftharpoons 2\ LaTiO2N + 3\ H2O$, T > 900 °C.
A dual beam microscope Thermo Fisher Scientific Helios 5 FX was used for SEM imaging (immersion mode, in-lens detector, 3 kV, 100 pA) and orientation-specific preparation of electron transparent samples. Chunks of mesoporous particles were lifted out and transferred onto a compustage holder. The thinning was performed at ion accelerating voltage ranging from 30 to 2 kV and beam current ranging from 2 nA to 25 pA. During the thinning process, the sample was aligned using α and β tilts of the compustage holder in combination with a pixilated 4D STEM detector.
TEM/STEM analyses were performed using a JEOL F200 cold FEG microscope operated at an accelerating voltage of 200 kV. For the STEM-EELS analyses, CEOS CEFID energy filter equipped with a Tvips XF 416 CMOS camera was used. Tomograms were obtained by performing tilt series with a step width of 2° from −54° to 78° in STEM HAADF mode. For tomography, a 200 mesh copper grid coated with a continuous carbon thin film (Plano GmbH) was used. The 3D reconstruction was carried out with ImageJ and the 3D representation with the Amira software (Thermo Fisher Scientific).

Results
The topotactic thermal ammonolysis process conserves the overall size of the particles while at the same time creating a network of both closed and opened pores. Closed volume porosity was estimated to 12% based on a STEM tomography reconstruction. The orientation and arrangement of the pores were compared to the orientation of the crystal. TEM images in combination with SAD patterns show long axes of the pores (ranging from 20-60 nm) oriented along the [001] and [010] directions of the orthorhombic LaTiO2N Imma structure (ICSD-168551). The EELS data was recorded over closed pores and the surrounding matrix. The nitrogen K-eddge (402 eV) shows a higher content of nitrogen in the closed pores. This suggests the presence of entrapped nitrogen gas in the mesoporous structure.

Conclusions

Micrometer-sized mesoporous LaTiO2N particles were prepared by an ammonolysis process from La2Ti2O7 particles. The structural arrangement of the pores was analysed using TEM and STEM tomography techniques. The pores have their long axes oriented along the [001] and [010] lattice directions. The closed pores have a volume fraction of 12% and contain encapsulated nitrogen gas.

Correlating microscopy methods: the case of precipitation in lean, bioabsorbable Mg alloys

Dr. Robin Schäublin[1,2], Ms. Tatiana Akhmetshina[1], Dr. Peng Zeng[2], Dr. Stephan Gerstl[1,2], Prof. Jörg Löffler[1]
[1]Department of Materials, ETH Zürich, Zürich, Switzerland, [2]ScopeM, ETH Zürich, Zürich, Switzerland

Poster Group 2

Background incl. aims
Many of the properties of metallic systems are driven by nanoscale precipitation. We present our workflow in the correlative microstructural study of "ZX" lean Mg alloys, which contain zinc and calcium, as a test case. Such alloys are promising candidates for bioabsorbable implants due to their excellent biocompatibility and degradation rate matching tissue regeneration. Because the nanoscale intermetallic precipitates within the alloys drive the mechanical properties and degradation behavior, it is critical to understand their type and role to tailor the alloys for specific applications.
Methods
We are deploying a correlative approach, utilizing mainly atom probe tomography (APT) and transmission electron microscopy (TEM), to cover a wide range of spatial length scales and obtain quantitative information. Despite its power, the correlative approach presents technical hurdles: sample preparation requires meticulous methods, including focused ion beam. Ideally, the same region of interest should be analyzed across all instruments, which can be challenging considering the vastly different size scales involved. Minimizing damage or corrosion during transfer between instruments, which usually occurs in air, is also crucial. Finally, to fully leverage the harvested data, one must apply data-treatment techniques, including AI and simulations to aid data interpretation.
Results
Starting from the solid solution, we were able to elucidate the precipitation sequence via APT at the smallest scales, and, as precipitates matured and grew in size, with STEM imaging and EDS chemical mapping supported by simulations. We revealed that the debated equilibrium phase of the ternary precipitates is based on the Ca2Mg5Zn5 crystal [1]. However, its composition derived from EDS and APT presented a broader range, which we also noted in the correlative nanoscale analysis of Fe–Cr alloys [2, 3]. This showed us that the correlative evaluation of APT- and EDS-derived results is beneficial when assessing a composition. We conclude with an outlook on further correlative approaches, including X-ray nanotomography.
Conclusion
This study showed us that correlating APT and TEM is beneficial for the study of precipitation of metallic systems, starting from the solid solution, and when assessing the composition of nanoscale precipitate. We conclude our presentation with an outlook on further correlative approaches, including X-ray nanotomography, which allows to further bridge the gap between spatial scales.

Background incl. aims
Magnetism and spintronics play increasingly significant roles in modern technologies such as data storage and logic devices, sensors, quantum computing, and transportation and electricity generation. The three-dimensional nanoscale spin texture within magnetic materials plays a large role in the behavior of these technologies, and also provides a rich area of fundamental study. Electron, x-ray, and scanning probe microscopies can be used to image 2-D projections of spin textures, yet each technique has strengths and limitations. Lorentz TEM, for example, projects images of the average magnetic field inside a specimen while exposing it to an external field or temperature, but it is insensitive to the field component along the beam path. We aim to combine these techniques with new ones to obtain the 3-D structure of magnetic spin textures.

Methods
Here we discuss the use of specialized electron microscopies, STEM holography and scanning electron microscopy with polarization analysis (SEMPA), to understand the 3D structure of nanomagnetic spin textures such as skyrmions. STEM holography [1,2] is an interferometric 4D-STEM technique where electrons in the beam are coherently divided into a superposition of two or more separate probes and then scanned over the specimen. If one probe passes through vacuum while the other transmits through the specimen, the resulting phase shift can be measured by recording the interference pattern formed in the far-field at the detector. That is, the bright field discs of the two probes overlap at the detector, forming interference fringes (Fig. 1). Unlike defocus- and deflection-based magnetic imaging techniques such as Lorentz TEM or DPC which are sensitive to phase gradients within the specimen, STEM holography is directly sensitive to the phase relative to the reference beam. With this, STEM holography can be used to directly measure the component of the magnetic vector potential parallel to the beam.
SEM with polarization analysis (SEMPA) [3] is a surface-sensitive technique that can image all three vector components of the surface magnetization. Special detectors can measure the average spin polarization of secondary electrons. Each detector returns information about two components of the magnetization vector; one returns in-plane (Mx and My) and the other returns one in-plane (Mx) and the out-of-plane component (Mz). Therefore, two consecutive scans provides complete, quantitative imaging of the in-plane and out-of-plane magnetic nanostructure as well as normal SE contrast.

Results
STEM holography and Lorentz TEM were used to provide images of the skyrmion magnetic field projected through the thickness of the specimen, and SEMPA was provided images of the magnetization at the surface. We find that whereas crystalline specimens can host magnetic skyrmions with whorl-like magnetic fields that extend uniformly through the thickness of the material, here we observe a more intricate magnetic structure. TEM indicates that in the bulk of the material, the magnetic flux wraps around the core like a vortex, yet SEMPA indicates that near the surface the magnetic flux points radially [4], such that the 3D structure is akin to that of a vortex ring.

Conclusion

We used SEMPA, STEM holography, and Lorentz TEM on the same Fe/Gd multilayer materials to understand the 3D structure of magnetic skyrmions, observing knotted vortex ring-like structures. This illustrates that multimodal magnetic electron microscopy can be used to provide 3D information about magnetic skyrmions that cannot be observed with a single technique alone.

IMG Electron Microscopy Core Facility

Dr Vlada Filimonenko[1,2], Dominik Pinkas[1], Helena Raabová[1], Markéta Dalecká[1]
[1]Core Facility for Electron Microscopy, Institute of Molecular Genetics, Czech Academy of Sciences, , Prague, Czech Republic, [2]Laboratory of Biology of the Cell Nucleus, Institute of Molecular Genetics, Czech Academy of Sciences, Prague, Czech Republic

Poster Group 1

Background and objectives
Imaging techniques are essential for modern biomedical research. State-of-the-art microscopy technologies are becoming increasingly sophisticated and require not only expensive equipment, but also highly qualified personnel to operate the instruments, collect high-quality data and analyse the results. This is why imaging core facilities are becoming increasingly important, helping scientists to use advanced imaging techniques in a time and cost efficient manner. The Electron Microscopy Core Facility at the Institute of Molecular Genetics in Prague provides open access to a wide range of imaging, analysis and sample preparation methods in biological electron microscopy.
Methods and results
Our team's expertise is supported by state-of-the-art equipment for sample preparation and ultrastructural imaging. A high-end transmission electron microscope (TEM) operates at up to 200kV and offers high resolution TEM, imaging in STEM mode, 3D analysis by TEM or STEM tomography, cryo-electron microscopy and STEM-EDS elemental analysis. A standard 120kV TEM with the user-friendly Limitless Panorama application is used for routine observation. Recently we have incorporated a cryoFIB-SEM microscope and set up cryo workflows for cryoTEM tomography or diffraction analysis on FIB-milled frozen-hydrated lamella. For precise targeting of the region of interest within the sample, light fluorescent imaging in a specialized cryoCLEM microscope can be used.
Standard and advanced techniques are also used in sample preparation. Starting from routine chemical fixation and resin embedding or negative staining of weakly stained specimens, we can progress to better preservation of natural specimen appearance by cryofixation using plunge freezing or high pressure freezing, followed by freeze substitution, cryosectioning or freeze fracture replica labelling. Detection of specific moleculles within the cells or tissues can be achieved using pre- or post-embedding immunolabeling techniques using gold nanoparticles of different sizes.
The facility can accommodate a wide range of biological samples for processing and imaging, including human and animal cell cultures, plant and animal tissues, worms, microorganisms, lipid micelles, isolated DNA, and purified proteins. Furthermore, the facility offers tailored development and optimization of sample preparation, based on a longstanding expertise and fruitful collaborations with companies manufacturing equipment for electron microscopy.
Conclusions
The Electron Microscopy Core Facility is part of the IMG Czech-BioImaging node and Prague Euro-BioImaging node. It offers open access to its technologies and expertise, and is prepared to welcome users from all fields.

Poster Group 1

The potential of having high energy and power density in all-solid-state batteries (ASSBs) makes them attractive candidates for energy storage systems of the future [1]. They also have several advantages over traditional liquid electrolyte-based systems, including safety and a wide operating temperature range [2]. Furthermore, the higher abundance of sodium relative to lithium makes solid state sodium ion batteries a more cost-effective alternative [3]. One challenge is the limited ionic transport capabilities of current solid electrolytes (SE), but also the development of a suitable cathode, which is as crucial as having a promising SE for practical applications [4]. An optimized composite cathode (CC) should provide a percolating network of ions and electrons with short transport pathways and a large active interphase area between SE and cathode active material (CAM) [4,5]. Therefore, the composite cathode must be carefully built by optimizing the phase fractions between CAM, SE, and CA (conductive additive), particle characteristics, and phase distribution to ensure percolation and adequate ionic and electronic transport.
In this work, our motivation is to gain a deeper understanding of the relationship between the microstructure and the ionic/electronic conductivity of the composite cathode. Within this aim, as a CAM, NaCrO2 was mixed with the conductive matrix (CM), which consists of Na3PS4 as a SE and vapor growth carbon fiber (VGCF) as a CA. The effective ionic and electronic conductivity of the composite cathodes were measured using electrochemical impedance spectroscopy (EIS) with two different configurations (ion blocking and electron blocking). The cross-sectional microstructures of CCs were investigated via scanning electron microscopy (SEM) and FIB-tomography. Our findings revealed that reducing the Na3PS4 (SE) and VGCF (CA) content simultaneously results in a balanced ionic and electronic conductivity (70 wt. % CAM contained CC) at 10 MPa stack pressure. Additionally, both ionic and electronic conductivity values increase with increasing stack pressure. 2D microstructural information from SEM images showed slightly reduced density but a better CAM distribution by reducing CAM content. To obtain 3D information from the microstructures XRM & FIB tomography analyses will be performed and presented in this study.

Poster Group 2

Background
Portland cement is one of the most important material of any country infrastructure development. Due to the massive global production and consumption of Portland cement, the cement industry is responsible for almost 10% of the world's carbon dioxide emissions associated with anthropogenic activities [1] and consumes about 3% of the world's energy [2]. Recent studies have demonstrated that fly-ash (FA) can be used as a mineral admixture in the cement industry to reduce the consumption of the most common calcareous raw materials [3].
Herein, we report on the benefits of the ESEM (Environmental Scanning Electron Microscopy) technique to expand the in situ knowledge of the geo-polymerization mechanism of the FA-cement mixture in the wet state. Moreover, X-ray diffraction (XRD) results about the phase composition and crystallinity of the initial ash, as well as in-situ evaluation for hydration of cement pastes, are reported.

Methods
Ash and slag from the Turceni thermal power plant deposit were used as supplementary cementitious materials (SCMs) to replace ordinary Portland cement.
The microstructure of the cement pastes and the in-situ reaction products formed during the first minutes to hours were studied using the Versa 3D Scanning Electron Microscope, which allows the adjustment of pressure, temperature, and humidity. Imaging was performed at a temperature of 2 0C and relative humidity of 90%, with a beam voltage of 30 kV, at a working distance of 9 mm. Morphology changes during hydration of cement pastes were in-situ ESEM monitored under a relative humidity of 90% and at a temperature of 2 0C. According to the pressure-humidity-temperature diagram of the liquid-vapor phase diagram for water, the expected pressure in the working chamber was estimated to be ~640 Pa. It is worth mentioning that the is situ ESEM dynamic experiments were performed on uncoated fresh wet cement mixture pastes. Each sample was monitored for a period of 3 to 6 h (depending on the specificity of the observed morphological changes) and the images were acquired every 10 min at magnifications of ×5,000 and ×10,000. Scanning electron microscopy (SEM) analysis of the ash powder and cement pastes after several days of curing was performed using an FEI Inspect F50 microscope coupled with an energy dispersive spectrometer (EDS) (ThermoFisher, Eindhoven, The Netherlands).
The phase composition and crystallinity of the initial ash, as well as in-situ evaluation for hydration of cement pastes, were studied by X-ray diffraction (XRD) using PANalytical Empyrean equipment. The equipment was used in transmission geometry and was equipped with a hybrid monochromator and

a 1/20 divergent slit on the incident beam side and a programmable anti-scattering slit mounted on the PIXCel3D detector on the diffracted beam side. The sample was investigated in the range of 4–480 2θ angle. Measurements were performed every 15 min for 24 h. Reduction of X-ray diffraction data and full pattern fitting by the Rietveld method were performed using HighScorePlus 3.0.e software (PANalytical, Almelo, The Netherlands).

Results

The morphologies for the reference sample C0 (100% cement) and the sample C45 (55% cement and 45% ash) are shown in Figure 1. The legends show the time of acquisition, with the first image taken immediately after the “dead” time limit, called t0. In the micrographs in Figure 1a) of hydrated cement paste (sample C0) it can be seen the evolution of the first hydration products cement, with the formation of acicular structures of ettringite and CSH/CASH (calcium/aluminium silicate hydrates) [4, 5]. Smaller particles are more reactive compared to larger ones. The hydration products tended to crystallize into cracks and pore spaces. A significant amount of cement hydration reactions appeared to have occurred during the “dead” period. The soft and fragile bride’s veil morphology of CSH appeared to have emerged from all surfaces. As revealed by Figure 1b), the addition of high ash content (sample C45) induced a delay in the hydration reactions, with the formation of prismatic sheet structures over time. The hydration products appeared even more crystalline. The usual amorphous CSH veil structure appeared at later stages (420 min) of hydration. As the paste hydrates over time, the hydrogel resulting from the partial hydration of mineralogical compounds such as dicalcium silicate, tricalcium silicate, and tricalcium aluminate, covered the spaces between the particles of the specimen. At this highest loading content of ash into cement pastes (sample C45), the formed crystals appeared to have better-defined edges. Ca(OH)2 platelet structures could be captured after the “dead” time. The gel-like hydrosilicates covered the ash particles very well, and the needle structures responsible for the subsequent mechanical strengths of the binder material can be visualized in the advanced moments of hydration (t0 + 20’, t0 + 420’).

The XRD patterns obtained for the C0 and C45 sample, at the initial time point and after different time intervals from 15 min to 24 h, are depicted in Figure 2. According to the recorded spectrum, the intensity of the peaks decreases with time, as a consequence of a decreasing in the degree of crystallinity (anhydrous phase content). As seen in Figure 2, the cement substitution with FA in a proportion of 45% did not drastically alter the phase evolution during hydration.

Conclusions

The herein reported in-situ ESEM and in-situ XRD has revealed new insides about the geo-polymerization mechanism of the FA-cement mixture in the wet state. The addition of ash in different proportions affects the hydration kinetics in the sense that some hydration reactions of the mineralogical binders are delayed with increasing ash content whereas Ca-initiated ones are accelerated.

Sustainability through the reuse of accessible economic and social resources is a way to achieve environmental balance while ensuring long-term development. The obtained results have confirmed the ash from Turceni thermal power plant features as SCM material to replace ordinary Portland cement.

Poster Group 1

Conformationally fluid peptide-lipid complexes have been identified as potent tumoricidal agents in cellular models and clinical trials (1, 2). Here, we identify the mechanistic details of how the peptide-lipid complex, alpha1-oleate, achieves this outcome by rapidly engaging with the largest membranous organelle in the cell, the endoplasmic reticulum (ER). We identify a previously unknown mechanism of tumor cell death, involving ER and nuclear remodeling and the creation of a joint ER and nuclear compartment for the scavenging of cellular contents. Induced by the membrane-active alpha1-oleate complex. This response also affected molecular mechanisms of cancer and cell adhesion gene networks. Cell death was not affected by inhibitors of apoptosis, necrosis or autophagy but was sensitive to ion channel inhibitors. In addition, the novel cellular changes triggered by alpha1-oleate, included massive detachment of dying cells loaded with alpha1-oleate was also observed.

The results identify a new, ER-driven mechanism for capturing constituents of dying cells for final processing and shedding from treated tumors, to avoid tissue toxicity.

Effects of Myricetin on Mesenchymal Stem Cells Exposed to Oxidative Stress

Prof. Dr. Sibel Köktürk[1], Dr. Mehmet Berker[1], Aysel Bayramova[1], Sibel Doğan[1], Dr. Emel Usta[1], Feride Özdemir[1]
[1]Department of Histology and Embryology, Istanbul University, Istanbul Medical Faculty, İstanbul, İstanbul

Poster Group 1

Background: The mesenchymal stem cells (MSCs) have been widely used both in cell therapies. Myricetin is a flavonoid which suppresses oxidative stress and inflammation, reduces bioactivation of carcinogens, and affects cell signaling.
Aims: The aim was to evaluate the effects of myricetin in the hydrogen peroxide (H2O2) oxidative stress model in MSCs by immunocytochemical staining and electron microscopy.
Methods: The groups were determined by control, H2O2, myricetin and myricetin + H2O2 groups. The MSCs were treated with concentrations of 500 µM H2O2 and 5 µM myricetin for 24 hours. The MSCs ultrastructure and caspase-3, TIMP17 and TNF-α expressions were analyzed using transmission electron microscope and immunocytochemistry.
Results: The effects of myricetin against H2O2 oxidative stress damage in the MSCs, an increase in cell count, decrease in caspase-3 and TNF-α immunocytochemistry staining, increase in Tim17 immunocytochemistry staining and decrease in degenerative cell morphology in electron microscopic were observed.
Conclusion: Flavonoid myricetin may be a promising target for an alternative treatment option for increased cell viability, anti-apoptotic and anti-inflammatory effects in the MSCs.

Background incl. aims
Water-based aluminum batteries are a promising alternative to commonly used lithium batteries due to properties such as low production costs, safety in handling, and high theoretical capacity [1]. However, the formation of an oxide layer prevents achieving the desired electrochemical properties. By annealing Al-Cu multilayer heterogeneous nanostructures, the formation of a dendritic Al2Cu structure enveloped by pure aluminum can be achieved by a eutectic transformation [2]. Techniques such as FIB (focused ion beam) [3] for sample preparation and in-situ TEM analyses enable detailed monitoring of phase transformations and structural dynamics of materials at high temperatures. Research in this area is key to the development of new materials with potential applications in energy, especially in the context of improving performance and efficiency of water-based aluminum batteries.
The main objective of this work is to analyze the structural and phase changes of multilayer nanostructures at elevated temperatures through in-situ annealing in TEM. Another goal is to compare the processes occurring in lamellae annealed in-situ with lamellae created from ex-situ annealed material. The results contribute to a deeper understanding of properties of Al-Cu multilayer heterogeneous nanostructures and their potential for applications. Moreover, they validate the experimental in situ methods employed in studying the microstructural processes.
Methods
Al-Cu multilayer heterogeneous nanostructures, consisting of alternating thin layers of Al and Cu nanoparticles, were prepared using magnetron sputtering. The transmission electron microscopy (TEM) and scanning TEM (STEM) with high-angle annular dark field (HAADF) imaging on a Jeol 2200FS was used for the characterization of samples. This was complemented by energy dispersive spectroscopy (EDS), scanning electron microscopy (SEM) analyses and automated orientation and phase mapping (ASTAR). Cross-sectional lamellae were prepared using a focused ion beam (FIB) on a Zeiss Auriga SEM. In situ annealing was conducted within the TEM using a GATAN heating holder.
Results
Films of the Al-Cu heterogeneous nanostructures, with thicknesses of 200 nm and 1 µm, were produced. The thin films were annealed in situ to investigate structural changes. Cross-sectional lamellae made from the 1 µm thick films revealed a gradient structure, showing an increasing amount of Al towards the bottom of the specimen. The impact of film thickness on the resultant structures was examined through comparative analysis of in situ annealed lamellae of two different thicknesses and lamellae prepared from ex situ annealed film. Surface modifications, grain size, and the distribution of Al2Cu within Al were mapped using SEM, EDS, and HAADF detectors together with ASTAR imaging techniques.
Conclusion
This study demonstrates the capabilities of in-situ annealing for exploring the structural and phase transformations in Al-Cu multilayer heterogeneous nanostructures. Through characterization techniques, including TEM, STEM, EDS, and ASTAR, a gradient structure with varying aluminum concentration was observed, particularly in multilayer films. The comparisons between in-situ and

ex-situ annealed lamellae, highlight the thermal behavior and potential of these nanostructures for advanced material applications, such as in next-generation battery technologies.

The effects of resveratrol on liver damage and ferroptosis in fructose-streptozotocin induced diabetic model

Assoc. Prof Fatma Kaya Dagistanli[1], MSc Mahsa Hoseini[1], MSc Merve Aykac[2], Prof. Dr. Turgut Ulutin[1]

Poster Group 1

Background
The liver is the main detoxification organ in the body and regulates normal glucose homeostasis. There is a relationship between diabetes and liver disease. Pathological changes such as hepatic steatosis, accumulation of fatty acids, and fibrosis have been demonstrated in the livers of diabetic patients. Due to the connection between Type 2 Diabetes Mellitus (T2DM) and progressive liver disease, further research is needed to understand the pathogenesis of diabetic liver disease (1). Studies on liver damage in diabetes have focused on inflammatory and insulin signaling pathways, as well as oxidative stress. Recent studies have found that ferroptosis plays a significant role in acute or chronic liver damage (2).
Ferroptosis is a form of non-apoptotic cell death characterized by excessive lipid peroxidation, iron dependence, and is associated with various pathological conditions in the liver. Increased interest has been shown in the role of ferroptosis in liver diseases because excessive iron overload and oxidative stress are major triggers for liver damage and disease progression in many liver diseases. Therefore, targeting ferroptosis could provide a promising new therapeutic strategy for the treatment of liver disease in affected patients (2,3).
A fructose-rich diet impairs aerobic capacity and leads to diabetes and fatty liver disease. It triggers various metabolic disorders, including hypertriglyceridemia, hyperglycemia, insulin resistance, and glucose intolerance. Fructose reduces antioxidant activity and harms the livers of animals (4).
Resveratrol (RSV) is a compound belonging to the stilbenes group, found in grape skins and leaves. It exhibits properties of phytoalexins, which are produced by plants in response to fungal or bacterial infections, and it prevents cellular damage caused by free radicals. In addition to its antioxidant and anti-inflammatory effects, resveratrol has protective effects against cancer, aging, obesity, diabetes, cardiovascular, and nervous system diseases. Resveratrol has various beneficial effects, such as normalizing the activities of antioxidant enzymes like catalase, superoxide dismutase, and glutathione S-transferase, as well as lowering blood sugar levels. Low doses of resveratrol can reduce blood sugar levels and improve insulin sensitivity in diabetic patients (4,5).
The aim of this study is to demonstrate the role of ferroptosis in the formation of liver damage in a diabetic model created with a high fructose diet and streptozotocin (STZ) and to investigate the potential effects of resveratrol treatment on this process.
Methods
In the study, 8-week-old Sprague-Dawley rats were divided into four groups: 1) Diabetic group (D), fed with a 10% fructose solution for two weeks, injected with STZ (40mg/kg) at the end of the second week, and then fed with a 10% fructose solution for three more weeks. 2) Diabetic + resveratrol group (D+RSV), treated with 1mg/kg/day resveratrol for four weeks. 3) Non-diabetic rats treated with resveratrol (C+RSV) (1mg/kg/day) for four weeks. 4) Control group (C). At the end of the experiment (9th week), all rats were sacrificed, and liver tissues were collected. Throughout the experiment, calorie intake, body weight, and blood sugar levels were measured. The liver tissue sections were

immunostained with GPX-4, COX-2, and H2AX antibodies. All values were analyzed using statistical methods.

Results

In the fasting blood glucose measurements of the rats that were administered STZ (40 mg/kg, i.p.) after 10% fructose for 2 weeks ($p < 0.001$), a highly significant difference was detected between the diabetic groups and the control groups. At the end of the experiment, there was a significant difference between the diabetic group and the control groups ($p < 0.001$). Additionally, a significant difference in blood glucose levels was detected between the control and D+RSV groups ($p < 0.05$). The calorie intake in the second and fifth weeks was significantly different in the D and D+RSV groups compared to the control groups ($p < 0.001$). However, at the end of the study, there were no differences between all groups.

H&E, Van Gieson, and Prussian blue staining of liver tissue sections revealed vacuolization of hepatocytes, an increase in collagen fibers in the portal areas and around the central vein, which is an indicator of fibrosis, and iron accumulation in the tissue in the diabetic group. In the D+RSV group, it was found that the damage caused by diabetes was recovered and iron accumulation in liver tissue was inhibited. Decreased GPX-4 protein expression and increased COX-2 expression were detected by immunohistochemistry staining in the diabetic group. Additionally, GPX-4 immune positive cell numbers were significantly higher in the D+RSV group. H2AX is used by many researchers as a tool to measure induced DNA damage. In the D group, an increase in the number of cells marked with phosphorylated H2AX antibody was observed, while there was a decrease in the D+RSV groups.

Conclusion

We suggest that the high-fructose diet and low-dose STZ administration increased blood glucose levels, caused liver fibrosis, and led to iron accumulation. Additionally, resveratrol treatment decreased blood glucose levels in diabetic rats, positively affected oxidative stress by increasing GPX-4 expression, the main purifier of lipid peroxides in cells, and prevented iron accumulation in hepatocytes, thereby protecting liver tissue from ferroptosis.

Poster Group 2

The advent of Additive Manufacturing (AM) processes in recent years has given us access to parts with complex geometries that are difficult to machine using conventional manufacturing methods. However, Additive Manufacturing leads to microstructures and metallurgical states that differ from those obtained by conventional processes. In this context, it has become necessary to develop new alloy grades dedicated to Additive Manufacturing in order to take full advantage of the specific features of these processes. In the aeronautics sector, there is a strong interest in the study of lightweight titanium- and aluminum-based alloy grades [1,2].

In this work, we are interested in a model Al-Fe alloy, which is not possible to produce using conventional processes due to the precipitation of the embrittling Al13Fe4 phase. The use of the L-PBF (Laser Powder Bed Fusion) additive manufacturing process avoids this pitfall, thanks to a very rapid cooling rate that favors precipitation of the metastable Al6Fe phase. It should also be noted that in the Al-Fe system, due to the very low solubility of Fe in cfc aluminum, it is not possible to carry out post-elaboration homogenization annealing. The aim is therefore to optimize the processing parameters in order to obtain an alloy with the desired mechanical properties at the end of the process. This type of alloy is particularly interesting in the context of repairing parts by AM, since annealing the part is often either not possible or not desirable in order to preserve the mechanical properties of the other parts of the part.
The L-PBF process is an additive manufacturing process involving the successive fusion of layers of powdered material using a laser. This process is characterized by very short interactions between the raw material (powder) and the laser, resulting in very rapid cooling rates (of the order of 106 K/s). The result is a complex microstructure organized on several size scales, which we have characterized in the Al4wt%Fe alloy and which is presented in the figure : At the hundred-micron scale, we observe the melt baths generated by laser melting; Inside the baths, we observe a structure of often columnar grains; Inside the grains, we observe a cellular structure, whose walls are enriched in Fe; Finally, inside the cells, we sometimes observe precipitates, as well as dislocations formed during solidification due to the presence of strong thermal gradients.
We are particularly interested in the hardening mechanisms operating in this microstructure. In addition to a Hall-Pech effect and hardening caused by iron-rich precipitates and cells and by dislocations, hardening due to the presence of iron solute is likely to be significant. Indeed, it is well known that the very rapid cooling rate during the L-PBF process leads to solute trapping in the matrix [3]. Furthermore, it has been shown that the presence of a low concentration of Fe in an aluminum matrix has a significant contribution to yield strength, far greater than that of usual solutes such as copper [4]. For our alloys, it is therefore necessary to measure the Fe composition inside the cells in order to quantify its impact on alloy hardening.

Another point of clarification is the composition of the cell edges, which are also enriched in Fe: this is expected to deviate from the composition of the metastable Al6Fe phase reported in less rapid solidification processes.
A final point that is not stabilized for our samples, as for similar alloys in the literature [5], is the presence of oxygen. Oxygen is present due to the inevitable oxidation of the powders, and may also originate from the gas present in the preparation chamber. However, its presence and location in Al-Fe alloys produced by L-PBF needs to be investigated. Indeed, the lattice parameters of L-PBF Al-Fe alloys, measured by X-ray diffraction, deviate from the values expected for these alloys, and the explanation put forward in the literature is the presence of oxygen, which would deform the aluminum lattice.
To achieve these goals, detailed characterisation by transmission and scanning electron microscopy (Figure), X-ray diffraction and atomic probe tomography has been carried out on samples produced using different parameters. The impact of manufacturing parameters on microstructure is highlighted, particularly the fact that the size of the solidification cells largely controls the mechanical behaviour. The results also reveals the correlation between the Fe distribution in the microstructure and the material's local hardness. Using transmission electron microscopy enables analysis of the interactions between nanometric precipitates and dislocations resulting from the thermal process, providing a better understanding of the hardening mechanisms. Atomic probe tomography allows to estimate the remaining Fe in the Al matrix in the as-built alloy and local enrichment in iron that lead to precipitation or segregation in the solidification cells.
The results allow the contribution of the different microstructural elements to hardening to be assessed using a phenomenological model. This model, developed based on mechanical tests conducted on various metallurgical states, can be used to propose chemical optimization paths. The purpose is to define an alloy which, in the as-built state, will benefit from a mechanical behaviour combining work and precipitation hardening.

IM-10 (3), Lecture Theater 5, august 30, 2024, 14:00 - 16:00

Digitization and an increase in complexity and price of electron microscopy hardware and characterization techniques, as well as the maturation of machine learning tools to extract patterns from large amounts of very diverse (annotated) data, promise to accelerate materials development by synergistically combining research data from many sources. While some labs have started uploading their (raw) research data to data repositories, this is only a first but insufficient step to realize the above-mentioned potential, as such repositories are typically either specific to a very particular technique or agnostic to much of the domain-specific content of the uploaded data [1,2]. In both cases the research data cannot be easily compared and integrated with experimental data from other sources or numerical predictions, and certainly not without significant human effort,. Therefore, working towards an interoperable knowledge representation for experiments and computer simulations [3-6] is the main motivation for implementing FAIR research data management. This highlights the need for tools for information extraction and semantic mapping. Fundamental to these tools' effectiveness is the creation of thorough and transparent documentation. This needs to be made more complete, shared openly, and should benefit from activities where representatives of the communities agree on defining and using standardized knowledge representations.
We will report on recent progress by the FAIRmat NFDI consortium [7] in extending NOMAD, the world's largest data base for ab-initio computational materials data, to also host experimental research data on the synthesis and characterization of materials in a machine-accessible manner, i.e. annotated with well-defined and interoperable metadata that establish links between related (experimental and computational) quantities [8-10]. We will report on our work on developing a comprehensive data schema for electron microscopy and related techniques, and the corresponding software tools for data converting, visualizing, and online-processing. We have integrated these tools as customizations into NOMAD Oasis to offer a locally-installable version of the NOMAD research data management system to complement its note keeping, file format parsing, cloud-based domain-specific data analyses, and information retrieval capabilities.

A silicon micro-heater chip for in-situ transmission electron microscopy

Mr. Chen Wei[1]
[1]CNRS/Université Paris-Saclay, Palaiseau, France

Poster Group 1

For years, the monolithic integration of III-V compound semiconductors on silicon substrates has thrived, capitalizing on the superior photoelectric properties of III-V materials and the abundant availability of silicon. Among various integration methods, direct epitaxial growth is coveted for its optimal cost-to-performance. However, the heteroepitaxy process inevitably introduces defects due to lattice mismatch, crystal polarity, and different thermal properties. In the case of GaAs, which are extensively applied in solar cells, dislocations are prone to form due to the 4% misfit. Additionally, antiphase boundaries are anticipated concerning the polarized GaAs thin films grown on non-polarized Si surfaces.
While research has sought to understand growth mechanisms, reliance on ex-situ techniques limits real-time insights. Incorporating a silicon-based MEMS(micro electro-mechanical system) chip, we achieved epitaxial growth of GaAs crystal islands on silicon substrates within a source-equipped transmission electron microscope. The custom-made chip, compensated with FEM simulation and Raman spectroscopy, are further calibrated and optimized for different application purposes.
Through our direct visualization of the dynamic processes, encompassing the formation of crystal islands and facets, coalescence of islands, transitions from layer growth to island formation, and vice versa, have been thoroughly examined.

Background incl. aims
Gas-atomization is a powder production technique involving rapid solidification of molten metal by high-pressure gas jets. Molten metal is poured through a nozzle into a chamber filled with inert gas where it is rapidly cooled and fragmented into fine, spherical particles by gas jets. The resulting particles are generally spherical with a high degree of uniformity in composition. There is a wide range of applications, from additive manufacturing and as feedstock to thermal spray coatings. In this study, a nickel silicide powder alloyed with vanadium has been investigated, with composition as stated in [1]. Nickel silicides are well-known for their resistance to high temperatures, corrosion, and oxidation, particularly in demanding environments such as in offshore applications. The powders are known to has high brittleness, but the incorporation of transition metals such as vanadium has been shown to improve the ductility. By using electron microscopy, both the surface and the internal structure can be investigated to gain a deeper understanding of the properties of the powder.
Methods
First, the particles surface and polished cross-sections were studied by scanning electron microscopy (SEM). A thin cross-section of a particle was prepared using a focused ion beam (FIB) and then investigated using transmission electron microscopy (TEM) imaging and energy-dispersive X-ray spectrometry (EDS) mapping. Scanning precession electron diffraction (SPED) maps were acquired to obtain high-resolution information on crystal phases and orientation relationships. The data was processed and investigated using the open-source Python libraries Hyperspy [2] and pyxem [3].
Results
SEM imaging reveals spherical particles with diameters from a few hundred microns down to a couple hundred nanometres. The particles are mainly uniform in shape but show signs of irregularities such as helmets and satellites. The surfaces are not smooth, but show signs of parallel stripes, revealing a lamellar dual-phase structure. The same stripes are visible in SEM images of the cross-sections. When looking at TEM bright field images, lamellae with a thickness of around 100 nm can be seen. EDS maps confirm that the lamellae are two distinct phases, alternating between vanadium-rich and silicon-rich, while the nickel is evenly distributed. Vanadium is very soluble in nickel at low quantities, and SPED was used to identify the vanadium-rich areas as the nickel fcc phase, in which vanadium has a high solubility. Equally, the diffraction patterns from the silicon-rich areas suggest a nickel silicide phase. While the crystal structure of nickel is very uniform along the stripes, the nickel silicide phase exhibits signs of misorientations and planar defects.
Conclusion
Gas-atomized nickel silicide powders alloyed with vanadium were studied using electron microscopy. SEM images reveal defects such as helmets and satellites, and structures both on the surface and on the cross-section. TEM methods such as EDS and SPED were used to study this further, and we were able to identify stripes with thicknesses of around 100 nm of alternating nickel solution with vanadium, and nickel silicide. Nickel is shown to have a slightly increased lattice parameter with increasing amount of vanadium [4], which might make it a better lattice match with the nickel silicide

phas and could possibly explain the improved ductility of the material when alloyed with vanadium. Further work includes obtaining a deeper understanding of the variations in the nickel silicide phase along the stripes and what effect this has on the properties, as well as the orientation relationships between the two phases.

Poster Group 2

Heterogeneous nuclear ribonucleoproteins (hnRNPs) constitute a prominent family of RNA-binding proteins abundant within the nucleus. They play pivotal roles in various aspects of nucleic acid metabolism, encompassing mRNA stabilization, alternative splicing, transcriptional and translational regulation, RNA export, and degradation [1]. Early investigations in the 1970s revealed that upon lysing nuclei without RNase inhibitors, a significant portion of pre-mRNA formed a distinct protein-RNA complex, sedimenting at 40S [2]. Notably, the core constituents of this complex were identified as hnRNP C1/C2, hnRNP A1/B2, and hnRNP A2/B1. This observation brought up the intriguing proposition that the 40S hnRNP particle might serve as an analogue to the DNA nucleosome [3]. Our objective is to describe the biogenesis of the 40S particle, provide a structural description of the 40S particle using cryo-electron microscopy (cryo-EM) and visualize it in its native context. We have generated TRex-293 cell lines expressing FLAG-tagged hnRNPC1/C2 proteins, isolated the 40S particles and analyzed them by negative staining EM. Furthermore, to investigate the ribonucleosome within intact cells, we have immunostained the key ribonucleosome components and generated thin lamellae using cryo-focused ion beam scanning electron microscopy (cryo-FIB/SEM). Using cryo-electron tomography we have acquired data from FIB-milled lamellae.

Poster Group 1

The field of cryogenic electron microscopy (cryo-EM) has seen remarkable advancements, enabling researchers to visualize biomolecular structures with ångström-level resolution. While conventional transmission electron microscopy (CTEM) combined with single-particle analysis (SPA) has played a crucial role in these developments, it faces challenges with very small proteins and large biomolecules. Specifically, small proteins often exhibit insufficient contrast, and large biomolecules can produce opaque images due to multiple scattering.
Electron ptychography, a technique derived from 4D scanning transmission electron microscopy (4D-STEM), presents promising solutions to these issues. It enhances contrast through phase retrieval, aiding in imaging small proteins, and manages multiple scattering effects, which is vital for examining thicker specimens. Electron ptychography has already proven to be a powerful method for room temperature material science samples, achieving unprecedented resolutions[1]. However, the application of STEM-related techniques to biological specimens is relatively rare[2,3], and ptychographic imaging at low-dose conditions (less than 50 e/Å²) remains largely unexplored.
In our study, we applied this technique to frozen hydrated single protein samples and achieved sub-nanometer resolution with a relatively small number of particles, yielding micrographs of enhanced quality (signal-to-noise ratio, SNR). The scattering potential of single protein particles was iteratively reconstructed using the open-source software, py4DSTEM[4]. We present structures of apoferritin at 5.8 Å using 11,552 particles, a phi92 sheath structure at 8.4 Å using 1,600 particles, and a tobacco mosaic virus at 6.4 Å using 2,120 particles.
The application of ptychography to biological specimens, particularly when integrated within the SPA framework for smaller frozen hydrated protein particles or combined with tomography tilt series for thicker samples (e.g., bacteria, tissue), holds great promise.

Poster Group 2

Introduction
Bacterial abortive infection responses to bacteriophage infection play critical roles in bacteria population survival by limiting viral propagation, through activation of programmed cell death or metabolic arrest of the infected bacteria. Cyclic oligonucleotides produced by the bacteria in response to phage infection are responsible for activating certain abortive infection effector proteins. One such example is TIR-SAVED, which has been shown to degrade NAD+ when activated by cyclic tri-adenylate. Previous analysis by cryo-electron microscopy (cryo-EM) demonstrated that TIR-SAVED oligomerises into extended helical filaments in vitro when activated by cyclic oligonucleotide binding [1].
Here, we develop a high-throughput approach based on the Waffle method [2] to imaging filaments in situ in high numbers of high-pressure frozen bacteria using xenon plasma ion sources for lamella preparation. We use cryo-electron tomography (cryo-ET) and subtomogram averaging (STA) to characterise the structure and higher-order organisation of these filaments in a cellular context, as well as the morphological changes to the bacterial cells upon activation of the TIR-SAVED system. This research will provide insights into ancestral mechanisms of antiviral defence, and further our understanding of the innate immune systems of prokaryotes.

Materials and Methods
E. coli C43 (DE3) transformed with plasmids as for the plasmid immunity assay specified by Hogrel et al. [1] were incubated overnight at 37 °C in LB before the addition of D-lactose and L-arabinose to induce activation of the TIR-SAVED system.
Bacteria were vitrified by high pressure freezing and lamellae milled using xenon and argon plasma with an Arctis dual-beam FIB/SEM microscope following an adapted version of the Waffle Method [2].
Dose-symmetric tilt series were collected with a Titan Krios equipped with a Falcon 4i camera and Selectris energy filter. Warp was used for gain correction, CTF estimation, motion correction and tilt series stack generation. AreTomo was used for tomogram reconstruction. Particle picking for subtomogram averaging used a combination of IMOD, EMAN2, STOPGAP and custom scripts, and RELION was used for subtomogram averaging.

Results
Full induction of the TIR-SAVED system resulted in cell death of the bacteria. When partially induced to capture an intermediate state before total cell death, electron-dense regions were observed at the poles of cells. These regions of uncharacterised composition displayed increased sensitivity to radiation damage caused by electron beam exposure during tilt-series acquisition. Bacteria cells

containing a TIR-SAVED mutation (E84Q) that inhibits its NAD+-degrading activity did not typically contain these inclusions.
Filaments were observed in reconstructed tomograms of bacteria containing TIR-SAVED-E84Q in both single filaments and as tight bundles of filaments. Subtomogram averaging of the bundles has revealed the in-situ structure of a TIR-SAVED-E84Q helical filament at a resolution of 12 Å. This analysis shows large variations in helical parameters such as pitch along the length of each filament, indicating significant flexibility in the oligomeric structure. Mapping these averaged structures back into the cellular volumes reveals that the bundled filaments are arranged into hexameric assemblies.

Conclusion
Here, we present the first in-situ investigation of bacterial abortive infection systems by cryo-electron tomography. Our study gives insights into the structure and higher-order organisation of TIR-SAVED in cells, in addition to the morphological effects of the activation of TIR-SAVED on the whole bacteria.

Time ecology method

Marion Bitsch[1]
[1]Turku School of Economics, University of Turku, Turku, Finland

Poster Group 1

"[One] cannot solve a problem with the same level of thinking that created it" said Professor Albert Einstein. A new modeling [1] developed as 3 layers 4:3 dimensions frames may contribute to understanding how macromolecular complexes ultrastructure can influence cell physiology, and the reverse. As those 3 frames, 4D:OLI:LOI, connect to the concept of time and the dynamic perception of the flows in time ecology [2].
Are labeled [3] microorganisms oscillatory responses healthy or would those entrain inflammatory loop cascades? Is it fundamental, to gain an understanding of live cells, those forming living systems, to account for time and sound?
Background incl. aims.
The LOI (Location-Ownership-Internalization) dynamic conceptual positioning, enveloped in OLI (in existence since 1977), a static envelop, and the 4 structuring environmental dimensions, the chemotaxis motives of the environmentally active actor, as the: market, resources, efficiency (in existence since 1974) and strategic asset: associated with the notion of the time internalization, are various theoretical tools to conceptualize about time, timing, and transitions inside living systems. Internalization is a synonym for assimilation, for instance to quantify the assimilation of radioactive labeled or stable-isotope-labeled substrate (in single cell) to study the cell ecophysiology [3]. Combining LOI:OLI:4D frames together form a wider system view, as if several foreign languages would be simultaneously used to characterize one unique situation. This approach could be more specifically used to distinguish between macroscopic and microscopic entropy, to develop inferential statistics (see Results).
One purpose would be to conceptualize the formation of sound matter, based on a theoretical understanding of past literatures [4] to close a gap between cognitive psychology and the perception of sound as music.
Methods.
Imaging of microorganisms can be performed using the expansion microscopy to visualize intra- and extra-cellular components as well as the cellular ultrastructural context (the environment). Based on the tridimensional thinking described and the understanding of HOH molecules configurations dynamics [1] an understanding of time ownership could be formed from a multidimensional spectral sensing of 3 dimensions: hearing (sound goes faster than neural transmission speed. [2]), color vision and olfaction (most odorants do not contain nitrogen). The research could also focus on linear thinking, or one single ribbon, with the focus on the role of neuropeptides (one CKK, -4 or -8S), and NO; neuropeptides as signaling molecules, e.g. bombesin like peptides, can modify nerve impulse. CCK may have a universally conserved role in cognition depending on how significant lipids are in individuals' diet. I could defend the relevance of odd-chain fatty acids for the stability of thinking (gluconeogenesis) about complex stressful situations.
Time to be owned must be internalized. An envelope is thus necessary as a rigid frame to enable the dynamics to become dense enough to be observed.
The logic for dynamics to emerge is: first a location (minimal viable cavitation) will be required for resources to be gathered, which may become internalized or future resources would first be owned, before to become further internalized.

Results.
Accounting for time in research would imply to reveal time soft matter, beyond time measurement, dynamics. Or unpacking signals from noise using gentle ultraweak-photon emission intensities as non-invasive [3] spectroscopic tool for diagnosis of internal states.
Going back to the Viennese physicist Ludvig Boltzmann's aim to discover one objective interpretation of the law of increase of entropy in terms of microscopic mechanical properties of the system, the LOI [1] model of time internalization could be applied to understanding thermodynamics: hypotheses could be formulated regarding variables causing structural or transactional flows failure. The flow is driven by the hopping from electrons: a quantum-mechanical tunneling. Hopping is a long-range transfer across redox chains (oxidized radicals) using multi-step tunnelling. The process is required in several natural enzymes, it involves vibrational mode from hydrogen tunneling, producing volatile organic compounds.
Conclusions.
"Thermodynamic quantities should be assigned, not to single systems, but to ensembles of systems having a given probability to occupy this or that point in […] space." [5]. The LOI [1] dynamics based on the dipole moment of HOH mirror important biological models. Those would be forming, or contributing to form, the 'awareness' or 'consciousness' factor of human cognition, or a 'Zeitgeist'. The "chance factors" forms the major influence from the surrounding. It is important to account for the constant novelty provided by one surrounding. These can be observed through taking a standard view (proposed here). A system view is a simultaneously joint exploration of dynamics and the intersections: the fluids inside their enveloping structures. A system view can be systematically developed around 3 dimensions, as the dynamic framework: LOI, which is also embedded inside a static 3 dimensional frame: OLI.

Poster Group 2

Background incl. aims
Demands for increased information density in nanoscale devices used for applications in artificial intelligence and the internet of things (IoT) are resulting in the need for improved data storage and processing technologies. As current memory technologies are approaching their fundamental limits, so the development of architectures for novel memory devices, such as in-memory computing and neuro-inspired computing devices, is becoming more important. Memristive or resistive random-access memor (ReRAM) devices promise to provide non-volatile, fast, low-power and cost-effective technologies, and are leading candidates to replace flash memory in a broad range of applications, including high-density memory, low-power IoT devices, neuromorphic computing, sensors and security applications [1-5]. Phase change memory (PCM) devices based on chalcogenides and valence change memory (VCM) devices based on oxides are promising candidate materials for non-volatile ReRAM devices because they offer possibilities to encode information reversibly and rapidly.
The switching mechanisms of such devices are typically based on local changes in resistivity between a high resistance state (HRS) and a low resistance state (LRS). Local high spatial resolution imaging and spectroscopy, in combination with real-time electrical measurements, are required to understand fundamental aspects of resistive switching in both PCM and VCM devices, and in turn to achieve improvements in scalability, reliability and speed. Transmission electron microscopy (TEM) is a powerful technique that can be used to provide information about local variations in crystal structure, composition, phase, and electronic structure of materials. Therefore, studies of the details of where, when and how resistive switching processes take place in different material systems using TEM are of great interest to unravel resistive switching mechanisms.

Methods
In order to realize real-time electrical biasing in the TEM, either home-made chips with electrical contacts were fabricated using micro-electromechanical systems (MEMS) technologies, or a Nanofactory probing specimen holder was used to provide a moveable electrical contact to a TEM specimen. Reproducible switching of different materials systems was recorded using different TEM techniques, such as off-axis electron holography, four-dimensional scanning TEM (4D-STEM), energy-dispersive X-ray spectroscopy, and electron energy-loss spectroscopy (EELS). Efficient and reliable methods to extract meaningful features from complex and large datasets were developed using machine learning technologies, for example for differentiating between crystalline and amorphous phases, and between different valence states in oxides.

Results
For PCMs, scanning nanobeam electron diffraction in 4D-STEM was used to study $Ge_2Sb_2Te_5$ (GST) thin films to investigate local variations in their crystalline structure. Data processing methods were developed to differentiate between crystalline and amorphous phases, in order to identify local

distributions of crystalline phases in amorphous GST thin films. For VCMs, resistive switching mechanisms in TiO_2-based ReRAM devices were investigated in real time using correlative transmission X-ray microscopy in the synchrotron and EELS in the TEM. The formation of conductive filaments in oxides was confirmed by extracting features from noisy spectra using non-negative matrix factorization.

Conclusions
Advanced TEM techniques combined with real-time electrical biasing and machine learning allow resistive switching mechanisms to be studied in different material systems. Local changes in chemical composition, microstructure and electronic properties in PCM and VCM devices during resistive switching can be investigated successfully. These approaches are expected to lay the foundation for the development of advanced next-generation memory devices.

Poster Group 2

Background incl. aims
The accumulation of pathological tau protein aggregates is a hallmark of numerous neurodegenerative diseases, including Alzheimer's disease. The accumulation of misfolded tau in neurons is toxic, it disrupts cellular physiology, leading to neuronal death and the propagation of tau misfolding throughout the brain. Effects of tau pathology include disrupted axonal transport, mitochondrial and lysosomal dysfunction, and synapse degeneration. Despite advancements in understanding tau pathology, the relationships between initial tau misfolding, fibril formation, pathology propagation across connected neurons, and subsequent cytotoxicity on the level of individual neurons remain unclear. We aim to visualize the pathological changes in molecular architecture directly in the vitrified brain tissue of the murine model for tauopathy.

Methods
To visualize the native ultrastructure we use vitrified fresh brain without staining or fixation. We combine cryo-plasma-focused ion beam milling (FIB) and bio-contrast scanning electron microscopy (SEM) imaging with cryo-electron tomography (cryo-ET) on lamella. The cryo-plasma-FIB/SEM setup of the Helios Hydra V microscope allows imaging of non-stained vitrified hydrated biological samples with high biological contrast in nanometer resolution permitting volume imaging covering a much wider area than typical lamella used in cryo-ET.

Results
In this poster, we present our in situ visualization workflow and showcase preliminary bio-contrast cryo-plasma-FIB/SEM images and tomographs of murine brain tissue affected by tauopathy.

Conclusions
We showed that the novel bio-contrast cryo-plasma-FIB/SEM imaging workflow can be used for ultrastructural characterization of pathological tissues without chemical fixation and that the combination with lamella lift-out and in situ cryo-ET provides an excellent tool for uncovering the details of cellular mechanisms of neurodegeneration.

Novel scan coil design for high spatiotemporal-resolution imaging in the scanning transmission electron microscope

Mr Adam Phipps[1,2], Dr. Lewys Jones[1,2], Dr. Jonathan Peters[1,2]
[1]Advanced Microscopy Laboratory, CRANN, Dublin, Ireland, [2]School of Physics, Trinity College Dublin, Dublin, Ireland

Poster Group 1

The Scanning Transmission Electron Microscope (STEM) is a highly versatile tool that is used to study a wide range of materials, from semiconductors to biological cells. It operates by scanning a beam across a specimen and then recording the beam that has been transmitted through the specimen at these points. STEM is a powerful technique for probing specimens down to the atomic scale, but the slow imaging speeds can result in excessive beam exposure, and therefore damage, and the inability to capture dynamic in-situ events. Increasing the scanning speed is therefore an attractive proposition for better control of the dose-rate on the sample as well as improved temporal resolution

Currently, the main limitations to the scanning time in a STEM are imposed by the response time of the scanning coils, determined largely by their inductance. For this reason conventional imaging requires a flyback wait time between scan lines to reduce inductive hysteresis. Flyback time may be eliminated using novel scan paths, though at fast scan speeds the inductive effects are still problematic. Similarly, techniques such as compressed sensing can increase frame-rates but retains issues regarding the hysteresis of the scanning coils. Previous work by Ishikawa et al. shows scan coils with an inductance ~240 times less than the conventional scan coils, though with a limited scan area.

In this work we present a scan coil system to greatly improve the response time of the scanning system. Alongside the existing, main scan coils, we add additional deflectors with lower inductance to work simultaneously with the main scan coils. By using the second coils to counteract the effects of hysteresis in the main scanning coils, imaging at lower dwell and flyback times without image distortion or compromising scan area. The additional coils themselves are not perfect and further sets of coils could be used to compensate remaining hysteresis. Equally, the use of electrostatics due to the rapid response time and lack of hysteresis could be deployed in tandem. With our design, we hope to make fast scanning in STEM practicable and enable high-resolution imaging to improve dose-control and in-situ measurements.

In-situ cryo-biasing heating TEM sample holder with full-range temperature control from -170°C up to >1000°C

Dr. Calvin Parkin[1], Norman Salmon, Dr. Daan Hein Alsem
[1]Hummingbird Scientific, Lacey, USA

Poster Group 1

Background

Traditionally in-situ TEM biasing, heating and cooling have been split capabilities, requiring different TEM holders. In-situ cryogenic cooling and biasing of specimens during scanning/transmission electron microscopy (S/TEM) has previously enabled the in-situ characterization of various quantum interfaces and chemical phase interactions in battery materials and other strongly correlated systems [1]. Quantum material responses must be studied under cryogenic conditions because many of the relevant properties in these materials only manifest below certain temperatures, while battery material interfaces are sensitive to electron beam damage when not cooled.

Combined in-situ sample heating with biasing has only become available in recent years with the use of the chip-based experimental platform, which has enabled capture of high-temperature microstructural and microchemical evolution alongside measurement of high-temperature electrical response in materials systems. Now, with the inclusion of on-chip biasing and thin film heater chip designs, we have developed a novel in-situ cryo-biasing heating TEM holder which enables simultaneous electrical stimulus and imaging of a sample across the full temperature range from cryogenic temperatures to over 1000 °C, while matching room temperature (RT) microscope spec for resolution and drift. The basic functionalities of heating, cooling, biasing, and imaging are demonstrated alongside discussion of different applications.

Methods

The TEM sample holder has an attached LN2 dewar that cools the sample down from RT to the lowest operating temperature (< -170°C) and can be controlled via software with closed-loop feedback at any temperature up to RT. Below RT where on-chip temperature measurements become increasingly inaccurate, precise temperature control is maintained using a conventional resistance heater and miniature thermocouple at the sample in the TEM holder tip. Nine electrical contacts to the user's sample or device allow on-chip biasing. Biasing experiments can now also be extended above RT to >1000°C using thin film sample heating with reliable on-chip temperature sensing. Since the heated area is small, the response time to temperature changes is fast and sample drift is minimized across the entire temperature range, resulting in image stability that matches the RT performance. Here, we present an example of a battery process after cooling a single nanowire system from RT down to liquid nitrogen temperature ~ -170°C [2].

Results

In Fig 1a, electrical biasing was performed on a nanowire sample bridging the electrodes on a biasing chip using this holder at RT down to near-liquid nitrogen temperature to protect damage in these beam-sensitive materials [2]. With constant current applied at cold temperatures, the voltage drops across the nanowire as a reaction proceeds with the plating of a dendrite layer on the surface, as shown in Fig 1d. In Fig 1b, atomic lattices are shown as a demonstration of resolution. Temperature control of the cooled and heated ranges is also shown in Fig 1c and 1e, respectively. The figures exhibit the core functionalities of the tool: stable and reliable sample biasing, heating, and cooling under atomic resolution TEM.

Conclusions

The In-situ cryo-biasing heating TEM sample holder presented here enables, for the first time, simultaneous electrical stimulus and high-resolution imaging of a sample across the full temperature range, from cryogenic up to high temperatures. This instrument will accelerate the development of the next generation of electronic, quantum, and energy storage materials devices. Combination of the two temperature regimes expands the range of temperatures available for dynamic temperature experiments, wherein multiple processing, imaging, or synthesis steps must be performed at various temperatures. High-resolution in-situ observation of operating (solid-state) battery interfaces in their full operational range of -40°C to 80°C is traditionally difficult to achieve due to air sensitivity, electron beam damage at RT, and lack of temperature control in TEM biasing platforms [3-5]. With this new tool, batteries may now be electrochemically cycled in situ at their entire operating range and then lowered to cryogenic temperature for imaging to combat electron beam effects, without the need for sample transfer between tools. With increasing demand for batteries that function at high temperatures, quantum material responses, synthesis, and processing, and material phase information from cryogenic to high temperature, the cryo-biasing TEM holder will provide the expanded versatility required of temperature-controlled in-situ electrical biasing systems.

Spatiotemporal observation of ultrafast magnetization dynamics with 4D Lorentz Transmission Electron Microscope

Phd Yuzhu Fan[1], Researcher Gaolong Cao[1], Professor Jonas Weissenrieder[1]
[1]School of Engineering Sciences, KTH Royal Institute of Technology, Stockholm, Sweden

Poster Group 2

Background incl. aims
Since the discovery of the sub-picosecond-timescale ultrafast demagnetization induced by femtosecond laser pulse by Beaurepaire et al. in 1996, utilizing ultrafast light to manipulate the magnetization has opened up a new field compared with the conventional ways to control the spins by magnetic fields, charge, or spin currents. Known as 'femtomagnetism', ultrafast optical control of magnetization at femtosecond or sub-picosecond timescales is the currently fastest route known to demagnetize or switch a magnetic material, which conforms to the ever-increasing demand for energy-efficient high-speed magnetic storage devices or random-access memories. To promote further understanding of light-spin interaction and potential technological applications, however, exploiting experimental tools to characterize and understand the light-spin dynamics at the sub-picosecond and nanometer scale plays a decisive role.
Methods
We combine Lorentz Transmission Electron Microscope with transient optical gratings to control laser-induced gradients of the in-plane magnetization. The light absorption distribution is characterized by Photo-induced Near-Field Electron Microscopy (PINEM) technique.
Results
We have spatiotemporally analyzed patterned ultrafast demagnetization dynamics in Ni80Fe20 near the sample discontinuity excited by a transient optical grating. Our findings demonstrate that the propagating surface plasmon polariton (SPP) modulates the ultrafast demagnetization process in space, time, and amplitude. Furthermore, we demonstrate the sub-picosecond all-optical switching dynamics in GdFeCo at a local scale by utilizing the Lorentz contrast from the Bloch domain wall induced by local switching in constructive interference areas. Last but not least, we observe the laser-induced coherent precession in GdFeCo with both FMR mode and exchange mode.
Conclusion
Our findings demonstrate 4D Lorentz Transmission Electron Microscope as an effective tool for investigating laser-induced magnetization dynamics with sub-picosecond and nanometer spatiotemporal resolution.

Quantum Measurements using Interferometric STEM-EELS

Professor Benjamin McMorran[1], Dr. Cameron Johnson[1,2], Dr. Amy Turner[1]
[1]Department of Physics, University of Oregon, Eugene, USA, [2]Molecular Foundry, Lawrence Berkeley National Laboratory, Berkeley, USA

IM-03 (3), Plenary, august 29, 2024, 10:30 - 12:30

Background incl. aims
Nanoscale amplitude beamsplitters for electrons enable flexible electron interferometry in STEM instruments. Nanofabricated materials phase gratings provide a way to coherently diffract electron wavefunctions into different paths, and can easily be placed in probe-forming apertures of unmodified TEM instruments. These tools provide a way to manipulate both the phase, amplitude, and momentum of electrons [1]. This lends itself to the implementation of new interferometric methods in electron microscopy [2-4], with the ultimate goal of performing quantum measurements in the TEM.

Methods
We used a pair of nanoscale phase gratings as diffractive amplitude beamsplitters to provide a Mach-Zehnder electron interferometer inside an unmodified TEM [2]. One phase grating beamsplitter coherently divides the electrons into separated probes before the specimen, and the second beamsplitter recombines the paths after the specimen, creating a set of discrete interfering outputs. This enables several new imaging and measurement modalities. For example, phase contrast imaging can be provided if one of the probes transmits through a specimen region while the other passes through vacuum, acquiring a relative phase shift that can be recorded by monitoring a discrete electron beam output.
The setup also enables quantum-inspired measurements, such as interfering electron paths that have lost energy to the specimen. If the interferometer is tuned to provide destructive interference at the detector, blocking one of the probe paths with an object eliminates the destructive interference, allowing a non-zero probability current to be incident on the detector. This is a quantum interrogation method sometimes called “interaction-free” measurement, because a detection event in a dark detector indicates the presence of an absorbing sample; the electrons that did not scatter from the sample indicate its presence.

Results
We demonstrated using the 2-grating electron interferometer for STEM phase imaging of nanostructures [2], even using only inelastically scattered electrons [3]. We used this to determine that fast electrons passing on either side of a metallic nanoparticle that excite a plasmon acquire a relative π phase difference, corresponding to the symmetry of an optical dipole excitation. We also used the setup to demonstrate a quantum “interaction-free” measurement of the presence of an opaque object [4]. In this case, single electron events recorded at the detector indicate the presence of an object without scattering from or transmitting through it.

Conclusion
We used nanoscale phase gratings to implement electron interferometry in STEM without modifying the instrument other than an aperture change. Potential advantages of the techniques this enables relative to other methods will be discussed.

Poster Group 1

The effectiveness of ferroelectric materials is fundamentally dependent on their ability to switch polarization, a process driven by complex dynamics that include the movement of ferroelectric domain walls (DWs), domain growth, and the nucleation of new domains. Traditionally, the behaviour of ferroelectric domains and DWs has been examined using indirect methods, such as nonlinear ferroelectric / piezoelectric measurements or in situ x-ray diffraction techniques. While these methods have significantly enhanced our understanding of the relationship between domain structures and functional properties, they only offer an averaged, collective response that may mask the details of individual events. In contrast, in situ transmission electron microscopy (TEM) provides a direct observation method for ferroelectric switching and domain dynamics. This approach reveals phenomena that are often concealed in macroscopic studies, offering a clearer, more detailed view of the microscale processes that govern the macroscopic properties of ferroelectric materials.
One key aspect of ferroelectric research involves determining the direction and magnitude of polar ordering, typically achieved through precise measurements of atomic displacements from their equilibrium positions in centrosymmetric structures. The adoption of advanced atomic-scale Scanning Transmission Electron Microscopy (STEM) technologies, especially those equipped with 4D STEM pixelated detectors, combined with the insights from STEM image simulations and first-principles calculations, has not only enabled the direct determination of polar directions but has also expanded the research to include analysing various defect types such as oxygen vacancies, strain fields, and charge density distributions around defects. Moreover, the use of in-situ biasing/heating holders for structural examinations under applied external stimuli has enriched our understanding of the dynamic nature of ferroelectrics.
This presentation will focus on a series of structural studies exploring the dynamic properties of potassium sodium niobate. The STEM analyses were conducted using Jeol ARM 200CF and Thermo Fisher Scientific Spectra 300 Cs-corrected microscopes, both equipped with advanced Merlin and EMPAD pixelated detectors, respectively. Our studies of potassium sodium niobate materials focus on directly observing domain growth, coalescence, and interactions among different types of domain walls within the microscope's environment under applied voltage. Through these investigations, we aim to elucidate how the type, quantity, and dynamics of structural defects influence local material properties, offering opportunities for tailored manipulation and optimization.
In the study, we explore the voltage-driven dynamics of mobile, needle-like domains and DWs within a $(K,Na)NbO_3$ single crystal (KNNsc) utilizing in situ Transmission Electron Microscopy (TEM) in a miniaturized capacitor setup [1]. Our findings suggest that the immobile DWs act as random bound pinning centres, capable of pinning larger regions while the edges of the sample facilitate the nucleation of new domains. The process of domain growth and coalescence is not consistently continuous; specific voltages can disrupt it, leading to fine domain splitting and the creation of nanoscale domains. Discontinuities in the functional response also occur when two orthogonal,

needle-like domains intersect, resulting in soft-pinning events. These insights deepen our understanding of ferroelectric domain behaviour and may extend to other perovskite-based ferroelectric materials that exhibit similar domain morphologies or coexistence of dynamic and stationary DWs.

The use of EELS for the characterization of diamond interfaces: the ohmic contact

PhD Jackeline Valendolf[1]
[1]University of Cadiz, Cadiz, Spain

Poster Group 2

The use of EELS for the characterization of diamond interfaces: the ohmic contact
J. Valendolf1, J.C. Piñero2, F. Lloret3, D. Araujo 1
1Department of Materials Science and Metallurgical Engineering and Inorganic Chemistry. University of Cadiz, Puerto Real, Spain
2 Department of Didactics, section of Mathematics. University of Cadiz, Puerto Real, Spain
3 Department of Applied Physics. University of Cadiz, Puerto Real, Spain
Background
Electron energy-loss spectrometry (EELS) is a technique that provides information about the energy distribution of electrons that have come through the specimen. Moreover, EELS in scanning transmission electron microscopy (STEM-EELS) has information about atomic bonding configurations, local electronic information, oxidation, and spin states through the core-loss spectrum at the interface, indicating configurational changes to a metal oxide's crystal field with a resolution of nanometers. In this regard, STEM-EELS can be used to measure the energy bandgap (Eg) of a material. The energy bandgap refers to the difference between the highest energy-filled electron state (valence band) and the lowest energy-empty electron state (conduction band), which can determine the electrical properties of the material. It represents the minimum energy required to move an electron from the valence band to the conduction band, allowing it to conduct electricity. Among many materials existing, diamond is an example of a wide-bandgap one, since it is about 5.5 eV. This large bandgap makes it an interesting material for applications in electronics, such as high-power and high-frequency devices, as well as for optoelectronic applications, including ultraviolet (UV) light-emitting diodes (LEDs) and detectors. However, measuring the Eg by STEM-EELS is not a simple process because of the appearance of different effects on the energy loss spectrum that can lead to an ambiguous measurement. For that, low acceleration voltages of 60 keV are employed to avoid the Cherenkov effect. This event is produced by relativistic electrons and different plasmon peaks, which are collective excitations of charge carriers of the diamond. Another artifact to consider in an EELS spectrum is the zero-loss peak (ZPL). The ZPL depends on the local thickness of the specimen and needs to have a robust subtraction to interpret the low-loss region and to determine the local band gap.
For that, the aim of this research is the determination of bandgap for WC and Au-based ohmic contacts on diamond using the STEM-EELS technique.
Methods
For this study, two samples were employed:

- Sample #1: Chemical vapor deposition (CVD)-growth boron-doped ([B] ~ 10^{19} atoms·cm-3) diamond layer was contacted to a W layer (40 nm thick) deposited by electron beam-induced deposition (EBID). The sample was subject to a thermal treatment with the temperature ranging from 450 to 900 K for 30 min each. This process is expected to induce tungsten carbide (WC) formation at the interface.
- Sample #2: CVD-growth boron-doped ([B] ~ 10^{20} atoms·cm-3) diamond layer was contacted to an Au layer (50 nm thick) deposited by sputtering. In this case, the thermal treatment was not

employed because the ohmic behavior was obtained with Au as-deposited, and there is not a carbide formation with Au and diamond.
Regarding the electron microscopy analysis, a FEI-TITAN 3 THEMIS electron microscope at 300 kV was used for chemical and structural analysis. The structural analysis was performed using the High-Angle Annular Dark-Field STEM (HAADF-STEM) image, High-Resolution STEM (HRSTEM), and Energy-Dispersive X-ray Spectroscopy (EDS) techniques. Electron Energy Loss Spectroscopy (EELS) data of the metal-diamond interface were acquired at 60 keV, using a monochromator.
Results
The EELS spectrum recorded on the < 80 nm lamella of WC and Au samples is generally composed of a variety of phenomena such as the zero loss peak (ZLP) (0-2 eV), Cherenkov effect (4-6 eV), or plasmonic peaks, which can mask the assessment of the electronic transitions and bandgap determination. At 60 keV, the bandgap nature of WC and Au is deduced to be indirect by fitting the energy loss spectrum to a (Eloss-Egap)3/2 function. The measured bandgap of WC and Au is 3.21 and 3.10 eV, respectively. These values are higher than the bandgap of tungsten oxide and gold nanoparticles, which are attributed to the bonding with carbon, in the case of tungsten-diamond, and the good adhesion between gold-diamond. Moreover, the ZLP contribution was deconvoluted using a logarithmic tail fit to the range 2 eV to 5 eV of the spectrum, leaving a plateau in the 5 to 8 eV region, as no contribution was expected at these energies. No Cherenkov-effect-related contribution was observed in the spectrum due to the low beam energy used (60 keV).
Conclusion
It was reported a method to measure the bandgap energy at the nanometer scale using the STEM-EELS technique. For that, W and Au contacts on the diamond were annealed at 800 K to obtain an ohmic behavior and thermal stabilization. An indirect bandgap of 3.10 eV is deduced for WC which is in good correspondence with literature. The bandgap of the Au-C contact is reported to be constant among the layers on a nanometric level with a value of 3.21 eV.

Large-angle Lorentz 4D-STEM for Simultaneous Magnetic and Atomic Structure Mapping

Dr Sangjun Kang[1], Prof. Xiaoke Mu[1,3], Dr Di Wang[1], Prof Christian Kübel[1]
[1]Tu Darmstadt, Darmstadt, Germany, [2]Karlsruhe Institute of Technology , Karlsruhe , Germany, [3]Lanzhou University, Lanzhou , China

Poster Group 1

Achieving a correlative measurement of both magnetic and atomic structures at the nanoscale is imperative to understand the fundamental magnetism of matters and for fostering the development of new magnetic nanomaterials. Conventional microscopy methods fall short in providing the two information simultaneously. Here, we develop a new approach, large-angle Lorentz 4-dimensional scanning transmission electron microscopy (LA-Ltz-4D-STEM), to simultaneously map the magnetic field and atomic structure at the nanoscale (figure 1).
To achieve field-free conditions for studying magnetic materials, both the upper and lower pole pieces of the objective lens must be turned off. This limits the probe diameter and thus the spatial resolution of the scanned image. At the same time, as the diffraction lens is located far away from the sample (more than 10 cm for uncorrected systems), the liner tube of TEM acts as a physical aperture and blocks diffracted beams at high angles, thus hindering the recording of atomic-level structural information (e.g., the recording angle is limited to < 2.2 mrad, corresponding to observable lattice spacings larger than ~ 0.9 nm in a TEM). Only the direct beam and surroundings can be used for the imaging of magnetic domains. In order to overcome this issue and to get access to highly scattered electrons containing lattice information < 1 Å, we employ the Lorentz lens, designed for regular field-free TEM, in the field-free STEM mode. The Lorentz lens allows the lens to capture highly scattered electrons before they are obstructed by the liner tube, all while ensuring that the magnetic field acting on the sample remains unaffected. As a result, the highest accessible diffraction angle in the new setup is increased to about 25 mrad without introducing significant distortions. Thereby, the attainable maximum structural information was enhanced from approximately about 9 Å (in the conventional field-free mode) to < 0.8 Å (in the new mode). Arrays of diffraction patterns containing both unscattered and highly scattered beams can be captured using 4D-STEM with the new lens setup, which we refer to as LA-Ltz-4D-STEM.
The LA-Ltz-4D-STEM data offer rich structural and magnetic information through reciprocal space. For instance, in the case of crystalline materials, the diffraction spots convey details of the crystal symmetry, lattice parameters, and orientation (refer to Figure 1b, top). For amorphous matter characterized by a set of diffuse rings due to the lack of long-range order (Figure 1b, bottom), the diffraction rings provide information on the short/medium-range atomic arrangement e.g., the inter-atomic distance and atomic coordination. The in-plane component of the magnetic fields inside of the sample deflects the electron beam through the Lorentz force. Therefore, the center position of the diffraction pattern at each probe position reflects the direction and strength of the local in-plane magnetic field that the electron probe has passed through.
This method enables precise measurement of the characteristic atomic and magnetic structures across an extensive field of view, [1] a critical aspect for investigating real-world ferromagnetic materials. The pixel-by-pixel correlation of the different information offers comprehensive visualization and statistical evaluation of the nanoscale magnetic phenomena. We applied the new method to directly visualize the magnetoelastic coupling as well as the competition between magnetoelastic and magnetostatic energy in an amorphous ferromagnet. [2] This approach opens

new avenues for in-depth studying the structure-property correlation of nanoscale magnetic materials.

Ceramic capacitors are passive electronic components designed to store and release electrical energy through an electric field [1]. Polycrystalline barium titanate (BaTiO3) and strontium titanate (SrTiO3) have been widely employed in ceramic capacitors due to their reliable dielectric properties, compact size, and cost-effectiveness [2]. However, this material experiences degradation, such as increased leakage current, as a result of diminishing resistance under elevated temperatures and voltage stress. According to the ionic de-mixing model, the primary cause of this degradation is the migration of oxygen vacancies, which move toward grain boundaries and eventually reach the cathode [3].
The migration of oxygen vacancies can be effectively altered by doping with elements such as Fe and Mn. This doping modifies the Fermi level and the space charge region (SCR) at grain boundaries. The SCR is the result of an accumulation or depletion of oxygen vacancies and cations around grain boundaries, limiting their migration and preventing degradation. However, this general description lacks validation of the details such as the influence of grain boundary character on the SCR due to limited microscopic observations of grain boundaries and SCR in ceramic capacitors, making it challenging to further develop the theory.

In this study, we employ 4-dimensional scanning transmission electron microscopy (4D-STEM) [4] in combination with electron precession to map electric fields at grain boundaries in Fe-doped BaTiO3 and SrTiO3. Unlike conventional differential phase contrast (DPC) analysis, electric field mapping by 4D-STEM reduces diffraction and channeling artifacts thus enabling accurate measurement of electric field and charge density at the grain boundary. Combining it with an in-situ biasing TEM setup, we can visualize SCRs under different biasing conditions at various temperatures. Through our presentation, we aim to showcase our methodological developments and observations of SCRs in BaTiO3 and SrTiO3. These findings promise to significantly advance the fundamental scientific understanding of ceramic capacitor performance and illuminate the degradation mechanisms under high voltage stress.

Direct observation of quadrupolar strain fields forming a shear band in metallic glasses

Dr Sangjun Kang[1], Dr Di Wang[2], Prof Xiaoke Mu[3], Prof Christian Kübel[1]
[1]Tu Darmstadt, Darmstadt, Germany, [2]Karlsruhe Institute of Technology , Karlsruhe , Germany, [3]Lanzhou University, Lanzhou , China

Poster Group 2

The promising application of metallic glasses is limited by their catastrophic failure at low strain due to shear banding [1]. For decades, scanning/transmission electron microscopy (S/TEM) techniques have been employed to analyze shear bands in metallic glasses and understand their formation [2]. However, due to a lack of direct information in reciprocal space, conventional S/TEM cannot characterize structural variation, e.g. local atomic strain, of amorphous materials, which are key to describe the deformation of glasses. With this work [3-4], we solved the longstanding difficulty of experimentally imaging atomic packing structure and local strain of amorphous materials using 4-dimensional scanning transmission electron microscopy (4D-STEM). Figure 1a schematically shows the 4D-STEM setup. A quasi-parallel electron probe is focused to ~5 nm diameter on an electron transparent sample. 4D-STEM records 2D images of local diffraction patterns over a 2D grid of each probe position by stepwise scanning of the probe over the area of interest. As shown in Figure 1b, the local strain is quantified by the elliptical deviation present in each diffraction pattern. We obtain the principal strains from the long and short axes of the ellipse indicated by qmax and qmin. The strain tensor is obtained by algebraic transformation of the principal strains to the loading coordinates. Moreover, a PDF analysis is performed as a structural descriptor based on the 4D-STEM dataset to analyze the local atomic structure of metallic glasses. Thereby, the 4D-STEM approach provides a correlative visualization of the nanoscale strain field and the atomic structure information. We used a Fe85.2Si0.5B9.5P4Cu0.8 (at.%) metallic glass ribbon as an example in this study, which receives attention owing to its soft ferromagnetism. The metallic glass was deformed by scratch testing at ambient conditions using a diamond tip. We observe residual strain fields concentrated at inclusions (Figure 1c). It provides for the first time an experimental visualization of the Eshelby-like inclusions surrounded by quadrupolar strain fields aligned on a shear band in deformed metallic glasses. The results provide direct experimental evidence for a concrete scenario for the initiation of a shear band: the dilatated Eshelby inclusions are the result of local plastic atomic displacements in the glassy matrix, which concentrate a stress field with quadrupolar symmetry. The quadrupolar stress field perturbs the surrounding material in a vortex-like manner and percolates neighboring inclusions. This eventually leads to the formation of a shear band. This provides a new understanding of the formation of shear bands in metallic glass. Our new method is also expected to initiate broad research possibilities for solving questions in amorphous matters.

CARS microscopy for studies in skin physiology and pharmacology

Professor Jonathan Brewer[1], PhD Irina Iachina[1], MA Lomholt[1], Kim Nielsen[2], Morten Ebbesen[1]
[1]University of Southern Denmark , Odense, Denmark, [2]Leo Pharma, Ballerup, Denmark

LS-02 (1), Lecture Theater 4, august 26, 2024, 10:30 - 12:30

The application of Coherent anti-Stokes Raman Scattering (CARS) microscopy in biomedical research represents an extension in our ability to study complex biological systems with unique resolution and specificity. This presentation highlights the use of CARS microscopy to explore various aspects of skin physiology and pharmacology, demonstrating the technique's versatility and its potential to extend our understanding of biological tissues and treatment efficacy.
Firstly, utilizing CARS microscopy enabled the direct observation of time-dependent, spatially resolved diffusion of water (D2O) within human skin tissue, unveiling significant variations in diffusion coefficients across different strata of the Stratum Corneum (SC). This heterogeneity challenges the prevailing notion of the SC as a monolithic barrier, instead positing it as a complex, layered defense mechanism. This study show CARS microscopy's ability to quantitatively measure diffusion coefficients at varying tissue depths and locations.
Further, the examination of dissolvable microneedles for transdermal drug delivery underlines CARS microscopy's unique ability to visualize penetration of the microneedles and follow their morphology within the skin. By providing detailed images of microneedle degradation and drug dispersion, CARS microscopy offers valuable insights into the mechanisms of drug release and absorption, supporting the development of more effective transdermal therapeutics.
Additionally, employing CARS microscopy in conjunction with a perspiring skin simulator to assess sunscreen substantivity offers a novel approach to studying the interaction between topical formulations and physiological processes like sweating. This application highlights the technique's potential to dynamically follow the redistribution of specific active ingredients in the sunscreen during perspiration. Thus, evaluate product performance under realistic conditions, informing the design of more resilient and effective sunscreens.
Overall, these studies exemplify the power of CARS microscopy to provide detailed, molecule-specific insights into complex molecular interactions in tissue.

Exploring Melanoma Dynamics: Insights from a 3D Cell Culture Model with Vemurafenib Treatment

Rikke Tholstrup[1], Nicoine Dorothea Daugaard[1], Daniela De Zio[2], Jonathan Brewer[1]
[1]University of Southern Denmark, Odense, Denmark, [2]Danish Cancer Institute, Copenhagen, Denmark
Poster Group 1

Background and aim
Malignant melanoma represents a difficult challenge in oncology due to its high mortality rates and frequent development of treatment resistance mechanisms. Phenotype switching, a recognized phenomenon in melanoma cells wherein they transition from a highly proliferative/low invasive state to a low proliferative/highly invasive state, is implicated in the development of treatment resistance. To enhance our comprehension of this dynamic process, elucidating the underlying mechanisms is imperative to identify optimal therapeutic targets for novel treatments.
Despite the necessity for effective treatments, the use of animal models in drug development is hindered by time constraints, high costs, and ethical considerations, underscoring the urgency for improved in vitro models. Utilizing 3D human tissue models presents a promising avenue to address these challenges, offering cost-effective and expedited experimentation while closely mimicking human physiology. Therefore, improving 3D in vitro human tissue models is pivotal in drug development and biomedical research in general.
For these models to be suitable for preclinical studies, it is important to thoroughly characterize and recognize their restrictions and applicability. Our study aims to establish a simple yet robust 3D melanoma model and employ multiple assays to investigate the dynamics of melanoma spheroids, facilitating their utility as a platform for drug screening, notably utilizing the MAPK inhibitor, vemurafenib, a key agent in melanoma therapy.

Methods
A viability assay and migration assay were performed on spheroids in suspension and spheroids in a collagen matrix, respectively, after 96-hour treatment with the MAPK inhibitor, vemurafenib. The viability assay was performed using a sensitive colorimetric assay, CCK-8. For the migration assay, images were obtained every 24 hours for a total of 96 hours, and the spheroid core and migrating cells were identified.
Volume measurements were performed in GFP-expressing human melanoma spheroids, after performing live-cell imaging of full thickness human melanoma skin models treated with vemurafenib for 72 hours, using confocal microscopy.

Results
Treatment with vemurafenib led to a significant reduction in spheroid viability and attenuated migration compared to untreated controls. Live cell imaging revealed a marked decrease in spheroid volume following 72-hour vemurafenib treatment

Conclusion
Our findings demonstrate the efficacy of vemurafenib treatment in 3D melanoma spheroids across multiple assays, highlighting the utility of this model in assessing diverse melanoma therapies.

Background incl. aims
Volume electron microscopy (vEM) is recognized as a powerful imaging tool capable of providing detailed insights into the 3D structure of cells, tissues, and model organisms at the nanometer scale. However, the manual segmentation process required for analyzing vEM datasets is time-consuming and limits the application and throughput of this technique. In response, this study aims to address these limitations by implementing deep learning approaches for automated segmentation based on a Panoptic-DeepLab (PDL) architecture. Specifically, the researchers aim to develop an automated segmentation workflow using Empanada-Napari plugins for reconstructing airway cells and efferent ductules of the male reproductive system in 3D. Furthermore, the study seeks to demonstrate the adaptability of these tools for generating tissue and organelle-specific segmentation models trained on relatively few 2D images, with the goal of improving efficiency and accuracy.
Methods
The researchers employed a deep learning-based approach utilizing the PDL architecture for automated segmentation of vEM datasets. Empanada-Napari plugins were developed to facilitate the 3D reconstruction of airway cells and efferent ductules, originally designed for segmenting mitochondria. The segmentation models were trained on a limited number of 2D images, highlighting a strategy for achieving robust results with minimal training data. Additionally, custom Python scripts were developed to extract cells of interest from the automatically segmented volumes, enabling single-cell quantitative analysis. Adapted image analysis methods were utilized to quantify spatial relationships between distinct organelles within the cell volume, including identifying points of contact on both semantic and instance segmented objects.
Results
The study demonstrates the effectiveness of the automated segmentation workflow in accurately segmenting airway cells and efferent ductules from vEM datasets. The segmentation models, trained on a relatively small number of 2D images, yield exceptional results when compared to human-validated data. The developed tools enable precise quantitative analyses of cellular metrics such as volume, surface area, and number of organelles, enhancing understanding of cellular processes and functions. Furthermore, the adapted image analysis methods successfully quantify spatial relationships between organelles, providing insights into organelle topology within cells.
Conclusion
The automated segmentation workflow and accompanying tools presented in this study represent a significant advancement in the analysis of vEM data. By alleviating the laborious process of manual segmentation, these tools enhance the efficiency and throughput of vEM imaging, thereby enabling comprehensive studies of cellular structures and functions. The adaptability of the segmentation models to different tissues and organelles underscores their versatility and potential for widespread application in biological research. Overall, the study provides a robust framework for accurate and

effective quantitative analysis of vEM data, offering unprecedented insights into mammalian cellular biology.

Poster Group 1

The tick is a ubiquitous parasite whose life is highly dependent on the haemoglobin of its host. Tick ability to synthesize its own haem group has been lost in the course of its evolution. The haem group is an inevitable part of the tick's reproduction, as the haem group is deposited on the eggs. Previous studies have shown that the adult females can survive even without the haem group, but the requirement of the nymphs is still unknown.
We observed the morphology of the tick nymph gut through SBF-SEM (Serial Block Face Scanning Electron Microscopy), followed by a 3D reconstruction of its inner structures, including the granules, which were identified by a parallel immunolabelling study of host albumin and haemoglobin. The total volume of 0.003 mm3 was reconstructed using MIB/deepMIB[1, 2] and then visualised using AMIRA (Thermo Fisher Scientific).
The results of our work presented here show the distribution of haemoglobin and albumin in the midgut cells and, in addition, the distribution of lipid droplets, which occupy the majority of the cells at this feeding time.
All these components are important for the metamorphosis of the nymph and for the further life of the adult males and females.

In-situ liquid-cell dynamic TEM observations of liquid crystal nanocomposite phase transitions

Ms Olga Kaczmarczyk[1], Katarzyna Matczyszyn[1], Andrzej Żak[1]
[1]Institute of Advanced Materials, Faculty of Chemistry, Wroclaw University of Science and Technology, Wroclaw, Poland

Poster Group 1

Background incl. aims
Liquid crystals (LCs) possess distinctive, anisotropic optical properties, and because of their fluidity combined with a partially ordered structure, they are easily influenced by external stimuli, making them extensively utilised in technology. The primary techniques used for their examination include polarised light microscopy (PLM), differential scanning calorimetry (DSC), small angle X-ray scattering (SAXS), and nonlinear optical imaging methods. Transmission electron microscopy (TEM) is known for its exceptional resolution and analytical capabilities. Although liquid crystals have been recognised for more than a century, only one study has reported TEM imaging of liquid crystals in their native state in the air [1]. This is partly due to the high vacuum environment of microscopes. To observe dynamic processes in a liquid environment, samples must be isolated from the vacuum, as imaging under high pressure leads to electron scattering and vacuum pump issues, hindering conventional TEM methods [2]. Another challenge, particularly for hydrated samples such as liquid crystals, is the impact of the electron beam, which requires precise control over the electron dose for reliable results.
Methods
In our study, we investigated the liquid crystal 4’-Octyl-4-biphenylcarbonitrile (8CB) and its nanocomposite that contains gold nanoparticles using polarizing microscopy and in-situ liquid-cell TEM.
Results
Our findings demonstrated the possibility of studying not only the arrangement of nanomaterials within the matrix but also the phase transitions kinetics of liquid crystal using the liquid-cell TEM approach. Polarising microscopy revealed changes in the optical properties of the nanocomposites upon the addition of Au nanomaterials, along with a uniform distribution of defects in the smectic A mesophase. We will discuss these results along with sample preparation for liquid-cell electron microscopy, the interaction between the electron beam and the sample, and dynamic observations of phase transitions.
Conclusion
Observations of LCs phase transitions and nanoparticle dynamics within the LCs matrix using TEM are possible with specified electron dose restrictions. Electron beam damage at low doses was negligible, and the phase transition was fully reversible. The dynamic behaviour of nanoparticle aggregates inLCs is linked to the electron dose value.

Adding Dimensions to Intravital Imaging to Better Eavesdrop on Biology

Professor Scott Fraser[1,2]
[1]Vice President of Science Grant Programs, Chan-Zuckeberg Initiative, , , [2]Elizabeth Garrett Chair of Convergent Bioscience University of Southern California, ,

LS-02 (2), Lecture Theater 4, august 26, 2024, 14:00 - 15:00

Imaging of living specimens can animate the wealth of high-throughput molecular data to better understand complex events ranging from embryonic development to disease processes. We are advancing this approach despite the unavoidable tradeoffs - between spatial & temporal resolution, field of view, limited photon budget - by constructing faster and more efficient light sheet and laser-scanning microscopes that maintain subcellular resolution.
Our two-photon light-sheet microscope combines the deep penetration of two-photon microscopy and the speed of light sheet microscopy to generate images with more than 10x improved imaging speed & sensitivity. Better engineering of the detection objective's point-spread-function improves this another 3-fold. Two-photon excitation light is far less scattered, permitting subcellular resolution to be maintained better than conventional light sheet microscopes, resulting in 4D (3D over time) cell and molecular imaging with sufficient speed and resolution to unambiguous trace cell lineages, movements and signals in intact systems.
To increase the 5th Dimension (# of simultaneous labels), we are refining new multispectral image analysis tools that exceed the performance of our previous work on Linear Unmixing by orders of magnitude in speed, error propagation and accuracy. Novel denoising strategies using machine learning permit imaging at far lower light levels, yielding rapid and unambiguous analyses without perturbing even fragile multiplex-labeled specimens.
Parallel refinements in label-free approaches extend imaging to patient-derived tissues and even human subjects. The low concentrations of these intrinsic labels required us to refine fluorescence lifetime imaging (FLIM), and combine it with multispectral and advanced denoising tools, to perform intravital imaging in such challenging settings.
Combined, these imaging and analysis tools offer the multi-dimensional imaging required to follow key events in intact systems as they take place, and allow us to use noise and variance as experimental tools rather than experimental limitations.

Dynamics of molecules at the nanoscale: from RESOLFT to STARSS

Ilaria Testa

LS-03 (2), Lecture Theater 4, august 27, 2024, 10:30 - 12:30

Molecular interactions and complex formation are the base of cellular processes and therefore human activities. However, it is very hard with state-of-the-art techniques to precisely, efficiently and specifically follow their formation directly in physiological relevant system such as living cells. The goal of this project is to develop a novel apparatus for measuring the formation of large molecular complexes with unprecedented level of precision and in living cells, providing new capabilities in the functional aspects of imaging.
Measuring rotational diffusion properties of biological macromolecules is an extremely useful tool in cell biology because of its high sensibility to molecular weight changes, giving direct insight into several biological processes such as molecular binding, enzymatic activity, and protein complex formation. Here, we present a novel methodology based on the time-resolved fluorescence anisotropy experiment (TR-FA), and named Super Time-resolved Fluorescence Anisotropy with Switchable States (STARSS), which aims to measure complex formation in living cells by providing rotational accuracy far beyond the current fluorescence lifetime temporal limit. STARSS translates powerful and fundamental ideas from the field of super-resolution microscopy, which deals with increasing the precision of the determination of the spatial coordinates of fluorescent probes, into rotational accuracy. We used STARSS to measure the maturation state of viral-like particles as well as chromatin packing and the oligomerization of protein in cells.

Mechanics of blastocyst morphogenesis

Jean-Léon Maître

LS-02 (1), Lecture Theater 4, august 26, 2024, 10:30 - 12:30

During pre-implantation development, the mammalian embryo forms the blastocyst. The architecture of the blastocyst is essential to the specification of the first mammalian lineages and to the implantation of the embryo. Consisting of an epithelium enveloping a fluid-filled lumen and the inner cell mass, the blastocyst is sculpted by a succession of morphogenetic events. These deformations result from the changes in the forces and mechanical properties of the tissue composing the embryo. Combining microscopy (spinning disk, light sheet and lattice light sheet confocal microscopy), image analysis, biophysical tools (such as optical tweezers) and genetics, we study the mechanical and cellular changes leading to the formation of the blastocyst.

Scanning patterns evaluations towards FIB-SEM/SIMS low-dose high-speed acquisition

Dr Andrés Miranda Martínez[1], Dr. Tom Wirtz[1], Dr. Santhana Eswara[1]
[1]Luxembourg Institute of Science and Technology (LIST), , Luxembourg

Poster Group 1

Two fundamental artifacts that affect resolution in Focused Ion Beam - Scanning Electron Microscopy (FIB-SEM) and Secondary Ion Mass Spectrometry (SIMS) are beam damage and shot noise. Beam damage is a well-known factor that causes structural modifications and impacts the image quality of sensitive samples. On the other hand, shot noise limits the signal-to-noise ratio (SNR) of the image, increasing distortion. These limitations affect the mentioned techniques and reduce their capabilities to analyse beam sensitive materials properly [1].
For image acquisition, the scanning process involves focusing the ion (or electron) beam to scan the sample row by row. At the end of each line, the beam is returned to the start of the next line, a movement known as “flyback”. This conventional raster is the most used due to its simple application and ease of reconstruction. However, for fast scan, it suffers from deformations due to flyback, thus requiring a delay time to avoid distortion. Also, an extra dose is injected into the sample during the flyback, which may further alter sensitive samples [2].
Reducing the dose rate can be achieved by accelerating the scan. This can be done by decreasing the dwell time, but this reduction will lead to a low SNR. Other solution is to implement a continuous scanning method to eliminate the need for flyback. A moderate number of studies have focused on the development of alternative scanning patterns to reduce beam damage or increase image acquisition speed in FIB-SEM/SIMS. Patterns like bi-directional, spiral, Hilbert, and Z-order are pointed out for this application. These different patterns move the ion or electron beam continuously along the raster, aiming to improve acquisition time and reduce beam damage [1].
The bidirectional (serpentine) scan pattern, also simple to implement, improves scanning by avoiding flyback but encounters distinct distortions for leftwards and rightwards trajectories, necessitating post-processing for image improvement. The spiral scan pattern also avoids flyback delay and benefits from smooth movements that reduces distortions, yet it produces non-uniform image quality and requires post-processing. The Hilbert pattern is a space-filling curve that changes the scanning direction by no more than two steps, resulting in small changes in both axes during the scan. This method avoids flyback delay, follows an isotropic path, and reduces acquisition time but experiences distortions when using small dwell times. Similarly, the Z-order scan pattern provides an isotropic path and reduces acquisition time, with the drawback of potential distortions due to short flyback times in small dwell times [2, 3].
Lastly, the sparse scan pattern reduces acquisition time by scanning only a portion of the total pixels and minimizes distortions caused by the finite response time while maintaining an isotropic path. However, it is sensitive to drift and necessitates a reconstruction procedure. Its implementation requires a higher level of complexity [4].
Each pattern offers unique benefits and challenges, influencing their suitability for different microscopy applications.
As an aid to implementing the scanning methods previously discussed, the application of deep learning algorithms contributes to the smart low-dose high-speed acquisition and reconstruction. However, their implementation involves increasing the complexity of the system and requires more computational resources [4].

Our objective is the implementation of new scanning methods that allow for low-dose high-speed acquisition in a high-vacuum FIB-SEM platform (Scios) from Thermo Fisher Scientific equipped with a SEM column, a Ga liquid metal ion source (LMIS)-based FIB column (Ga-FIB), and a magnetic sector SIMS system [5].
To achieve this goal, we have successfully implemented and tested the different patterns mentioned before to control the raster of ion and electron beams to form secondary electrons images in the Scios instrument.
To control the deflection system and collect data from the Everhart Thornley Detector (ETD), we employed a custom-built acquisition system that uses a USB-6351 acquisition card from National Instruments. The system is divided into two parts: i) scan control and ii) data acquisition. The scan control was managed using the two analog outputs of the acquisition card, with each signal controlling one coordinate position of the beam (X, Y). The data acquisition involved receiving secondary electron signals from the ETD via the digital input. A LabVIEW program was developed to manage the system.
To test the functionalities of the system, we used a non-sensitive solid sample (FeTi). The system can set the image size in pixels, dwell time, and scan pattern. Other parameters, such as accelerating voltage, field of view (FOV), or beam current, must be defined using the microscope's internal system.
The novel raster schemes being explored for low-dose high-speed ion or electron beam imaging are expected to accelerate materials research by enabling high-resolution imaging of transient processes and/or radiation sensitive samples.

The authors acknowledge funding from Opincharge and Battery 2030+ projects, and Tim Dahmen of DFKI (Deutsches Forschungszentrum für Künstliche Intelligenz) for his support.

Pushing the limits of Coupled Extreme Environments during In-situ TEM

Professor Khalid Hattar

PS-12, Lecture Theater 2, august 29, 2024, 10:30 - 12:30

Background
In-situ TEM and STEM have pushed our understanding of the nanoscale and atomistic mechanisms active in materials exposed to thermal, mechanical, electrical, magnetic forces. Understanding at this length scale has been instrumental in the validation and refinement of many models developed to understand and predict materials degradation. In many ways, the ability of in-situ electron microscopy to explore a range of coupled extreme environments has become a path to an integrated materials science characterization toolbox. [1]

Methods
In the subfield of TEM with in-situ irradiation, it has been commonplace to combine in-situ ion irradiation with heating or cooling, mechanical loading, or both simultaneously. These advancements have been greatly advanced in the last decade or two with advancements in miniaturization that permit the inclusion of multiple probes into the same often small pole-piece gap, automation to permit the user to run multiple aspects of the experiment without assistance, and advanced manufacturing that permit costly development of parts for a specific microscope. One such example of a facility was the In-situ Ion Irradiation TEM (I3TEM) that was developed at Sandia National Laboratories to explore such coupled extreme environments. [2] This facility was unique in that it coupled two lasers into the I3TEM to permit both dynamic TEM (DTEM) imaging with 6 ns resolution and laser-based heating above 2000 °C for some samples. [3] Such examples raise the question of what the physical limit for is coupled in-situ TEM experiments and what are the limits set by historical presidents or engineering costs.

Results
Within the last year, the Tennessee Ion Beam Materials Laboratory (TIBML) has taken on the challenge of pushing the limit in coupled in-situ experiments in various extreme environments. This facility will be based on a JEOL 2100+ STEM with PyJEM compatibility. This microscope was chosen due to a combination of robust nature and ease of use. The high tilt pole-piece and LaB6 options were chosen to permit greatest access to the sample and excellent imaging of dislocation loop structures in two-beam and related imaging conditions, respectively. The JEOL 2100+ has already been modified by JEOL/IDES for the inclusion of a C0 lens for increased brightness, a laser port aimed at the electron gun for potential DTEM experiments in the future, a laser port for sample heating, and a port for ion optics coming in perpendicular to the electron optics. In addition, the microscope has been outfitted with a Gas Injection System (GIS) from Waviks, the ability to do Automated Crystallographic Orientation Mapping (ACOM) from Nanomegas, and real-time defect analysis via edge computing from Theia Scientific. The process for the development of this instrument, the current status of the microscope, and the planned vision for coupling it with 20 W 1064 nm laser, 20 W 532 nm laser, 20 kV ion source, and 3 MV tandem accelerator will be presented.

Conclusion

Similar to advancements in electron microscopy resolution resulting from advancements in aberration correction, advancements in miniaturization, automation, and advanced manufacturing have greatly increased the potential for various coupled in-situ TEM experiments. This work will discuss the physical limits of coupled in-situ experiments and compare them to the current engineering limits. It will also highlight the current status of the Tennessee in-situ ion irradiation STEM that is being developed to explore these extreme coupled environments.

Breaking Resolution Limits with Ptychography using Topological Materials

Professor Kayla Nguyen[1]
[1]University of Oregon, Eugene, , United States

IM-03 (1), Plenary, august 28, 2024, 10:30 - 12:30

Electrons play a pivotal role in stabilizing matter, but they are also tools that can reveal the underlying physics of complex systems from high energy physics to condensed matter. One advantage of electrons is that they can also be used imaging probes, where properties of matter such as ferroelectricity, magnetism or topology can be observed atom-by-atom. While previous works have used vortex beam to uncover changes in orbital angular momentum [1,2], we use a generation of new direct electron detectors [3] and develop a mathematical algorithmic approach to uncover the torque transfer of an electron beam as it imparts upon a topological ferroelectric vortex [4]. Furthermore, using these new detector systems, we can also push imaging resolution on a conventional, non-aberration corrected STEM to sub-angstrom 0.5 resolution with electron ptychography [5,6].

Firstly, I will discuss a new type of electron probe which can image orbital angular momentum and torque transfer of topological structures in ferroelectrics. Using these new electron probes, we show that the presence of an electric toroidal moment transfers a measurable torque and orbital angular momentum to a localized electron beam in the ballistic limit. In Figure 1, we showed that the torque transfer could be measured where the point of reference is at the center of the vortex [4]. Depending on the rotation of the polarization vortices in our structure, we obtain a signal for the change in orbital angular momentum in either a counter-clockwise or clockwise direction (Figure 1).

Secondly, I will show how electron ptychography, an iterative computation imaging technique, can improve resolution beyond the numerical aperture of the electromagnetic lenses to the sub-angstrom limit in a conventional electron microscope for a two-dimensional moiré system (Figure 2, right image). Using this technique, we essentially use a 'computation lens' approach to imaging, opening opportunities to explore new physics in emergent materials beyond physical lenses and providing high-resolution imaging access to institutions that lack the funds to house such expensive equipment [6].

Finally, the interplay between technological and computational progress will be discussed in my talk, including the challenges that still arise for electron microscopy. Moreover, our research efforts described in these works were pursued using non-aberration-corrected electron microscopes. We believe that combining new detector technologies with computation, we can make electron microscopy more accessible while still developing new efforts for investigating new physics in emergent topological materials.

Background including aims
Scanning transmission electron microscopy (STEM) has become an essential tool for materials science research, where it has been applied to atomic-scale imaging, diffraction, spectroscopy, and 3D tomography of many materials. High speed direct electron detectors have now become ubiquitous, allowing researchers to record full 2D diffraction patterns for each electron probe position in a 2D grid, producing very large 4D-STEM datasets [1]. Extracting material properties and structures from 4D-STEM datasets requires efficient and robust software methods. In this talk, I will highlight various 4D-STEM analysis workflows using our open source py4DSTEM toolkit [2].

Methods
The py4DSTEM toolkit is an open-source python library hosted on GitHub, along with many tutorials and example datasets. It contains various analysis modules including those aimed at calibration, classification, diffraction pattern simulation and matching, Bragg diffraction analysis, amorphous diffraction analysis, phase contrast imaging, and others. To analyze nanobeam diffraction patterns generated by crystalline samples, we use template matching for disk detection, correlation for orientation mapping, and lattice fitting to measure strain [2,3]. Phase contrast imaging modes are implemented using iterative gradient descent with regularization [4].

Results
We have performed high resolution 4D-STEM strain mapping on metallurgical samples and energy materials, both ex situ and in situ. We have also demonstrated improved precision and accuracy for nanobeam strain measurements by using patterned apertures [5]. We have also used 4D-STEM to characterize the morphology of highly beam-sensitive soft matter samples, including block copolymers with both crystalline and amorphous constituent phases. We have also used dictionary lookup methods to determine the crystalline phases of complex samples, and machine learning methods for blind estimation of crystal systems, space groups and lattice constants. Finally, we have also used STEM phase contrast imaging methods to measure the atomic structure of materials in 2D and 3D. I will show how each of these results were generated using the py4DSTEM code. I will also demonstrate how modern machine learning methods can be used to analyze the most challenging 4D-STEM experiments: those where multiple scattering and dynamical effects from thick samples produce highly nonlinear diffraction contrast.

Conclusion
While 4D-STEM is a powerful tool to characterize the material structure and properties, modern high speed electron detectors produce a truly prodigious amount of data. These experiments therefore require highly robust and efficient software analysis tools to analyze the results. We have

implemented many algorithmic methods in the open source py4DSTEM code, and we welcome additional contributions from the microscopy community.

Poster Group 1

Background incl. aims
The enteric nervous system (ENS) regulates the function of the gastrointestinal tract. Numerous congenital neurointestinal disorders underlie its defective function, mostly affecting the migration and differentiation of neural stem cells of neural crest origin. Treatments for these diseases are limited; surgery treats the symptoms only, and no regenerative cell therapy is available yet. Direct cell reprogramming (transdifferentiation) is a novel technique where patient-derived somatic cells are reprogrammed into neuronal lineage without going through an intermediate proliferative pluripotent stem cell stage, providing a promising strategy for stem cell therapy to treat neurointestinal diseases. Human dental pulp-derived mesenchymal stem cells (DPSCs), similar to the ENS, are neural crest-derived cells found in adult teeth. Our primary aim is to use transdifferentiated DPSCs for intestinal transplantation to restore the enteric nervous tissue in the congenital aganglionic colon.
Methods
We initiated our experimental work by generating neural cell aggregates (neurospheres) from DPSCs transdifferentiated to neural phenotype using viral transfection. Immunocytochemical methods were used to characterize the neurospheres, and their nervous tissue forming capacity was studied by transplanting the neurospheres into aganglionic segments of 5-day-old chicken embryonic hindgut.
Results
Serial sections of neurospheres generated from transdifferentiated human DPSC demonstrate ubiquitous TUJ1+ neuronal expression and scattered SOX10+ precursors. Cells from neurospheres transplanted to the aganglionic chicken hindgut and transplanted onto the chorioallantoic membrane of host E9 chick embryos or cultured in 3D collagen gel for 72 hours migrate out and differentiate to neurons.
Conclusions
Transdifferentiated postnatal DPCS behave like embryonic neural crest-derived cells. The avian hindgut environment is permissive to engraftment by human DPSCs and supports migration and neuro-glia differentiation of these cells following transplantation in vivo. Our findings suggest that neurospheres generated from DPSCs hold significant potential as cell-based therapy for future treatment of neurointestinal disease, but only in early stages of neural differentiation.

Understanding how microalgae cells remediate heavy metals using Atomic Force Microscopy (AFM)

Dr Cécile Formosa-Dague[1], MSc Victoria Passucci[2], Dr Maria Mar Areco[2]
[1]TBI, Université de Toulouse, INSA, INRAE, CNRS, Toulouse, France, [2]IIIA-UNSAM-CONICET, Universidad Nacional de San Martín, Buenos Aires, Argentina

IM-09, Lecture Theater 5, august 29, 2024, 14:00 - 16:00

Background incl. aims
Microalgae have recently emerged as a promising biomass for the biosorption of heavy metals from aqueous environments, by offering an efficient and cost-effective alternative compared to conventional remediation techniques. However, to date, the mechanisms by which microalgae can remediate these pollutants is still not entirely clear. In this work, we investigate the role of extracellular polymeric substances (EPS) of a green microalgae species, Parachlorella kessleri, isolated from the polluted Reconquista River in Argentina, in the biosorption of zinc.
Methods
For that, we use an original approach based on atomic force microscopy (AFM) experiments. This technique, developed in 1986, relies on the control of a force acting between a sharp tip and a surface, while scanning a sample. In force spectroscopy mode, AFM can record force-distance curves, where the force experienced by the probe is plotted as a function of the probe-sample separation distance (typically from 0.5 to 6 µm). These curves can then be analyzed to extract several information on the sample morphology, on its nanomechanical properties, and on the physico-chemical nature and strength of interactions that can take place between the tip and the sample. In addition, while the tip used can be bare, it can also be functionalized with any type of molecules or particles, making it possible to access specific interactions between these functionalized tips and cell surfaces.
Results
A first step in the study was to optimize a culture medium favoring the production of EPS by cells. It was showed that cells cultivated in the presence of nitrates could produce EPS while the cells had much less EPS when cultivated with ammonium as a nitrogen source. This was confirmed by nanomechanical experiments performed with AFM that showed that cells cultivated with nitrates were covered by a thick layer of a soft material (200 Pa approximately), corresponding to the EPS layer. Then, our hypothesis is that EPS play a key role on the biosorption of metals. To test this hypothesis, AFM force spectroscopy experiments were performed using zinc-functionalized AFM tips, this way allowing to probe directly the interactions between zinc and cell surfaces at the molecular level. The results obtained showed that zinc could interact with the EPS present at the surface of cells cultivated with nitrates with a force of up to 1 nN. Since no interactions were recorded when cells cultivated with ammonium were probed, this confirms that the EPS of P. kessleri can interact directly with and absorb zinc, thereby remediating it from the medium.
Conclusion
Overall, these experiments provide a new understanding of biosorption mechanisms using an original biophysical approach, and show the potential of P. kessleri for heavy metal biosorption.

Revealing foliar nanoparticle uptake dynamics: integrating nano-CT, confocal microscopy and LA-ICP-MS insights
Andrea Pinna1, Emil Visby Østergaard2, Rajmund Mokso2, Noémie Thiébaut1, Søren Husted 1
1 University of Copenhagen, Copenhagen, DK, 2 Technical University of Denmark, Lyngby, DK
Background incl. aims
The agriculture sector calls for urgent action on novel strategies that can enhance fertilizers' efficiency in order to increase crop production while reducing its environmental footprint. Conventional soil fertilization methods often suffer from low efficiency due to nutrient immobilization, leaching, and volatilization. Foliar fertilization presents key advantages as it bypasses soil limitations but encounters obstacles such as leaf scorching and limited nutrient translocation1. Recent progress in bionanotechnology offers potential solutions by utilizing nanoparticles (NPs) with tailored properties to improve nutrient delivery to plant tissues. Comparably bigger than their ionic counterparts, yet small enough to penetrate all the relevant plant barriers e.g. cuticle, stomata, cell wall and vasculature, NPs can deliver plant mineral nutrients right where needed, overcoming the limitations of ions mobility and enhancing nutrient use efficiency1. However, unravelling the intricate fate and behavior of NPs within plants hampers the potential implementation of a nano-approach into foliar fertilization. Employing advanced bioimaging techniques can provide valuable mechanistic insights regarding plant interaction with and assimilation of NPs, which can positively contribute to our understanding and strengthen the case for nanotechnology adoption in plant production.
The objective of our research is to develop an NP-based system that allows for efficient delivery of Mn, one of the essential plant mineral nutrients, via foliar fertilization. To this end, formulation and NP physicochemical properties are optimized to enable effective penetration of the leaf surface, securing the delivery of adequate amounts of bioavailable Mn, whilst reducing the risk of scorching. At the same time, we want to characterize NP uptake pathways, distribution and assimilation of NPs in Mn-deficient barley plants. In this poster, we present a comprehensive investigation employing confocal imaging, nano-computed tomography (nano-CT) and laser-ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) to elucidate the dynamics of foliar-applied NPs.
Methods
25 nm poly(acrylic acid)-coated Mn oxide (PAA-MnO) NPs were produced via one-pot polyol method2. NP physicochemical properties such as size, shape, surface charge, dissolution and Mn oxidation state, were characterized using different techniques, including dynamic light scattering, TEM, ICP-MS and XPS. Fluorophore-labelled (DiI-PAA-MnO) and Ce-spiked (Ce-PAA-MnO) NPs were produced for confocal and LA-ICP-MS applications, respectively.
Mn-deficient 21-day-old barley plants were used for the NP application experiments. To study the NP leaf uptake, fluorescent DiI-PAA-MnO NPs were imaged 2 to 5 hours after the leaf application using a confocal microscope (Leica Stellaris 8). A small portion of the dosed area was excised with a scalpel, placed on a microscope glass slide, and submerged into perfluorodecalin 95% (Sigma-Aldrich) before imaging.

The nano-CT experiments were performed at the European Synchrotron Radiation Facility id16b beamline in Grenoble (FR). For these, pristine PAA-MnO NPs were dosed on barley leaves. 5 hours after treatment, a small leaf cut was placed inside a 200 µL pipette plastic tip and mounted on top of a rotating sample stage. The beamline was then set up in a projection geometry with a 29 keV pink beam focused to 50 x 50 nm^2. Each sample was scanned at four sample-to-detector distances with 900 angles over 360 degrees of rotation. The phase was retrieved using an iterative contrast transfer function (CTF) approach. Finally, the data was reconstructed and post-processed in Dragonfly, which was also used for visualizations.
For the LA-ICP-MS experiment, Ce-PAA-MnO were used. 5 hours after the application, a small portion of the leaf exposed area was cut, embedded in OCT mounting media and frozen in dry ice-cooled liquid hexane. The OCT molds were sliced at -30°C using a cryotome (Leica CM3050S) and freeze-dried overnight. Thin 14 µm cross-sections were ablated using a nanosecond LA unit (Iridia 193 nm excimer laser ablation system, Teledyne CETAC technologies).
Results
Our experiments document the early stages of NP uptake in plant leaves. Confocal analysis showed that NP uptake in barley leaves occur as early as two hours after the application and that stomata appear to be the main gateway for NP entry into the leaf. To validate the confocal imaging findings, nano-CT was used to study the uptake pathway of pristine PAA-MnO NPs. Nano-CT results corroborates the data obtained via confocal imaging, as NPs were detected inside the mesophyll below the stomata area. Despite nano-CT high resolution, NP clusters were visibile only when the leaf was pre-treated with a CaCl2 solution allowing for NPs aggregation inside the mesophyll. Finally, the correlation of nanoparticle distribution patterns observed via confocal imaging and nano-CT was determined by LA-ICP-MS, which confirmed the stomatal pathway as the main gateway for NP entry into the mesophyll, and highlighted the potential presence of NPs inside the leaf vascular tissue.
Conclusion
Our research highlights the strengths of three different, yet complementary, bioimaging techniques. Easy procedures for sample preparation and cellular resolution make CLSM a powerful technique to visualize NP uptake and distribution within plant cells and tissues. However, the imaging depth of confocal microscopy is limited to the superficial layer of the sample. Scattering, photobleaching and noise are few factors that restrict its use to study processes occurring a few hundred microns below the leaf surface. To overcome some of these issues, we integrated nano-CT imaging to obtain high-resolution, real three-dimensional images of pristine NP clusters inside the leaf. Complementing this, laser-ablation ICP-MS was used for elemental mapping, allowing us to study NP concentration gradients and NP spatial distribution at the whole leaf level. By combining these complementary techniques, we gained a comprehensive understanding of the processes occurring in the early hours after the leaf application of NPs.
This poster underscores the pivotal role of cutting-edge bioimaging techniques for unraveling the complex dynamics of foliar-applied NPs within plant systems, paving the way for the rational design and implementation of nanoparticle-based agricultural innovations.

Streamlining Graphene Liquid Cell Preparation: VitroTEM's Naiad

Mr Hans Radhoe[1], Dr Sina Sadighikia[1]
[1]Vitrotem, Amsterdam, Netherlands

Poster Group 1

Graphene Liquid Cells (GLCs) offer unprecedented capabilities for imaging samples in their native hydrated state, providing insights at atomic resolution [1]. However, manual assembly of GLCs presents significant challenges, limiting their widespread adoption. This poster presents VitroTEM's Naiad system, a revolutionary approach to GLC preparation. By employing a layered structure consisting of monolayer graphene sheets on standard TEM grids, the Naiad system rapidly constructs GLCs, encapsulating liquid samples for imaging [2]. Our poster showcases images of ferritin particles in their native environment, demonstrating the system's efficacy in biological materials research. Additionally, we present atomic resolution images of Au nanoparticles, highlighting its utility in nanomaterial science. The Naiad system simplifies GLC assembly, enabling researchers to focus on sample imaging rather than grappling with graphene preparation. This poster emphasizes the Naiad system's potential to accelerate discoveries in diverse fields reliant on high-resolution imaging of liquid-phase samples.

PS-10, Lecture Theater 5, august 26, 2024, 15:00 - 16:00

In this talk I will discuss the discovery of two-dimensional heavy fermions (2DHF) made of 5f electrons with an effective mass 17 times the free electron mass. These 2DHF present quantized states at terraces. The energy separation between quantized levels is of a fraction of a meV and the level width is set by the interaction with correlated bulk states [1]. Interestingly, we find a new connection between bulk and surface features. I will also describe recent new insight in the Josephson effect of ultra small Josephson junctions, which lead to an improved Josephson microscopy, called feedback Josephson microscopy.

Poster Group 2

Introduction Lead halide perovskite nanocrystals (LHP NCs) with composition $CsPbX_3$ (X = Cl, Br, I) have been widely studied due to their high photoluminescence quantum yield (PLQY) and narrow emission bandwidth, covering the whole visible spectral range. These properties, together with a remarkable tolerance to surface defects, make LHP NCs quantum dots (QDs) promising candidates for various light-emitting applications. Emission tunability in such materials is typically achieved by halide alloying, produced either directly during synthesis or as a result of post-synthetic halide (anion) exchange reactions. Cl-Br and Br-I exchanges are now well understood and we have recently provided a clearer view of the $CsPbCl_3$ → $CsPbI_3$ halide exchange [1]. Another way to tune outstanding optical properties of such QDs is to bond them with other semiconductors – metal chalcogenides (MC), which also adds the possibility of employing post-synthetic cation exchange. Here we present a detailed structural and compositional study of the interfaces between LHPs and MCs and their role during post-synthetic anion/cation exchange. Methods High resolution scanning transmission electron microscopy (STEM) studies were performed in an aberration-corrected ThermoFisher Spectra 300 operated at 300 kV. Samples were prepared by drop-casting diluted solutions of NCs onto ultra-thin carbon film grids. Atomic resolution images were acquired in both HAADF and iDPC modes. Compositional maps were obtained with a Dual-X EDX detector using Velox and rapid rastered scanning of the beam. Results Figure 1 shows HR STEM HAADF images of two colloidal epitaxial LHP-MC heterostructures used as a basis for post-synthetic anion/cation exchange: $CsPbCl_3$–$Pb_4S_3Cl_2$ and $CsPbCl_3$-PbS. The Cl-I halide exchange in $CsPbCl_3$–$Pb_4S_3Cl_2$ makes it possible to stabilise two perovskite domains ($CsPbCl_3$ and $CsPbI_3$) within one colloidal NC, despite the huge difference in lattice parameters (9%). HAADF, iDPC and GPA analysis revealed a complex 3D strain distribution and key role for the LHP-MC interface during halide exchange. The newly synthesised $CsPbCl_3$-PbS epitaxial heterostructure is shown in Figure 1b,c. Based on it we could prepare, by post synthetic anion exchange, heterostructures in which the perovskite domain is either $CsPbCl_3$, $CsPbBr_3$ or alloyed $CsPb(Brx/Cl1\text{-}x)_3$. HRSTEM confirmed that anion exchange only affects the perovskite region and does not affect the PbS domain. Next, through post-synthetic cation exchange, we created heterostructures in which the MC is either PbS or Cu_2S. HR STEM and STEM-EDX data were used to construct 3D atomic models of all heteroepitaxial NCs before and after post synthetic anion/cation exchange reactions. Conclusion Using STEM, we constructed atomic models of a series of recently discovered LHP-MC heteroepitaxial colloidal QDs and linked them to the optoelectronic properties, in particular emission tunability by post synthetic anion/cation exchange reactions.

Poster Group 1

Background incl. aims:
Silicon-based HeteroJuncTion solar cells (HJT or SHJ) are a family of photovoltaic cells based on the heterojunction formed between two materials with different bandgaps. They are hybrid devices combining the technology of classical crystalline silicon-based cells and thin-film cells.
HJT are now a well-established reality as they guarantee high efficiency and mass production [1], however they suffer of slight losses of the cell integrity when they are cut and assembled with a shingled structure. In this study, a mass-produced HJT cell surface was scribed for half of its thickness employing an ns-IR laser. Subsequently, the cell is separated in sub-cells by mechanically cleaving. This process is both stressful for the cell structure due to the high level of thermalization and is also locally removing the passivation layer of the newly cut edges. These mechanisms induce a drop in performance at the edges of the cell, hindering the advantages of shingled technology [2].
In this study, defects induced by the cut were characterized using different multi-scale techniques to identify the technological solution that would allow the cell structure to be protected as much as possible.
Methods:
The sample object of the study is a HJT cell with a bulk structure based on n-type silicon and a multi-layer passivation surface composed of 3 thin layers of intrinsic amorphous silicon doped with hydrogen (15-20 nm), n-doped amorphous silicon doped with hydrogen (15-20 nm) and indium thin oxide (ITO) (70-80 nm) provided by Applied Materials. The cut was performed with an ns-IR laser (Rofin Powerline F50) on an entire wafer (156,75 mm side) on several lines, while a second pristine wafer was used as a comparison.
The techniques used were X-Ray Diffraction (Bruker D8 ADVANCE), Raman and Photo-Luminescence spectroscopy (Renishaw InViaTM), Scanning Electron Microscopy (Zeiss Auriga) equipped with EdX Spectroscope (Bruker Quantax) and with Focused Ion Beam (Physics d'Orsay Cobra) and Atomic Force Microscopy (Oxford Instruments Cypher VRS).
Results:
The analyses, focused on the detection and identification of defects in the pristine and post-cut wafer, were initially concentrated on the physical-chemical characterization of the basic structure. The XRD analyses show that after laser cut, the ITO main peak disappears or consistently decreases its intensity, thus indicating a loss of crystallinity or even a detachment from the surface. Moreover, the silicon beneath ITO layers seems affected by the high energy laser treatment and in particular the strongest peak of Si (400) shows an increase in the strained component. In fact the pristine HJT sample shows, by means of XRD, a double peak of Si (400) with two relative maximum values at 30.3 deg and 30.4 deg (with a Mo tube). The relative amount of strained silicon (i.e. the intensity of the

peak at lower angle and therefore higher interplanar distance) appears increased, such behaviour might indicate an annealing of the sample due to the high energy treatment.
Through Raman and PhotoLuminescence (PL) analyses, it was then possible to assess the presence of crystalline defects within the silicon of both the pristine and post-cut wafers, with a clear splitting of the silicon peak in the case of Raman spectroscopy and a decrease in the Band To Band transition of the silicon in the case of PhotoLuminescence spectroscopy.
The morphology and chemical composition of these defects were then studied using scanning electron microscopy and atomic force microscopy. The surface structure is composed of square-based pyramids necessary to maximize the active surface of the cell. The pristine wafer presents mechanical defects derived from the production phase which cause the removal of the surface layer of ITO and thus an initial random decrease in the cell's performance. Once the laser cut has been performed, however, a complete destruction of the structure can be seen in the proximity of the cut. Moving away from the cut up to about 1 mm, a gradual improvement of the integrity of the structure can be seen until its complete recovery. Afterwards, in addition to the vast damage to the structures around the cut area due to the very high temperatures, the presence of silicon-based particles of various sizes scattered throughout the sample was observed causing a masking effect which decreases the cell's efficiency. Finally, viscoelastic and EDX maps were made on both the intact and cut zones unveiling that the ITO is not completely ablated; on the contrary, it tends to follow the reorganization of the silicon-based substrate, as also demonstrated through FIB-SEM. The viscoelastic maps revealed that the hardness of the sample strongly depends on the size of the ITO layer and, in the areas away from the cut, there is also a clear directional trend in hardness and thus in ITO thickness. This variation in thickness, although not critical, causes a heterogeneity that makes it easier to ablate the ITO in areas close to the cut.
Conclusion:
A complete characterization and identification of defects within HJT cells (both pristine and post-cut) was conducted. Several defectivities, of structural, mechanical and thermal nature were identified and characterized. The defects on the pristine wafer show that there is still room to optimize the synthesis of these materials in order to improve their final performances. Finally, through the study of the cut-induced defects, it was possible to demonstrate the causes of the decrease in the performances of this type of cell after the cutting and shingling process, something which has been already widely reported in literature.

3D imaging, visualisation, and analysis services at Lund University Bioimaging Centre

Dr Sebastian Wasserstrom[1], Dr John Stegmayr[1], Dr Nils Norlin[1]
[1]Lund University Bioimaging Centre, Lund, Sweden

Poster Group 1

Background and methods
Recent advances in optical clearing methods, which render tissues transparent by homogenization of the reflective index throughout the sample, allow for deep imaging into organs and even entire animals [1]. Optical clearing can unveil spatial relationships within tissues, providing a new dimension of understanding across various fields of biology and medicine. Light-sheet fluorescence microscopy (LSFM) offers an unparalleled combination of spatio-temporal resolution, ideal for imaging large biological samples [2].

Results and conclusions
Lund University Bioimaging Centre (LBIC) has made strategic investments in LSFM and optical clearing since 2019, currently possessing two LSFM systems and employing multiple clearing techniques, including the recent acquisition of a high-throughput commercial clearing system [3]. Here, we introduce LBIC's lineup of service offerings related to 3D-imaging and subsequent customised visualisation and analysis workflows.

Poster Group 1

Background
For decades, the fruit fly Drosophila melanogaster has served as a model organism for studying the molecular and genetic basis of many human diseases, including neurodegeneration. In this study the comparative analysis was performed using the Drosophila model that mimics the human pathological condition associated with spinocerebellar ataxia type 1 (SCA1), which is characterized by progressive problems in movement (3). In Drosophila, such anatomical evidence can be obtained by viewing serial paraffin sections of the mutant brain under a light or fluorescence microscope. This method was originally developed by Heisenberg and Böhl (2). The extent of brain damage was determined subjectively based on the frequency of brain neuropathology on the 6-point scale from "none" to the highest level of neurodegeneration (1). Our study aimed to address this limitation by developing a novel method for accurate quantifying of brain damage in Drosophila models of SCA1, using Fiji (ImageJ) and Imaris 3D modeling software on Z-stacks of whole adult Drosophila brain.
Methods
Flies were anesthetized under CO2 and prefixed in 4% paraformaldehyde (PFA) in phosphate buffer (PB). The prefixed flies were then washed in PB and the brains were dissected in PB. The dissected brains were fixed in 4% PFA. After fixation, brains were rinsed in PB-Tween and were blocked with 5% normal goat serum in PB-Tween for 2 hours as blocking solution. After thorough rinsing with PB-Tween (four times for 15 min at room temperature), the preparations were transferred to the goat anti-mouse IgG secondary antibody conjugated with Alexa Fluor 448 diluted 1:200 in the blocking solution and incubated overnight at 4 ºC. Preparations were rinsed with PB-Tween and mounted on microscopic slides (Figure 1). The confocal laser scanning microscope (FV 3000 Olympus) was used to acquire images of the Drosophila brain using a high sensitivity detector with a resolution of 1024x1024 pixels and a pixel acquisition time of 8 µs. To match the size of the Drosophila brain, the UPLANSApo 20XO objective was used. Serial Z-stack images were acquired with the optimal thickness. The data in oir format obtained with the confocal microscope were uploaded to the Fiji software and subjected to analysis by Threshold and Analyse particles modules. The obtained data were summed and multiplied by the layer thickness to obtain the exact volume of neurodegeneration in µm3.Three-dimensional models of areas of neurodegeneration were reconstructed in Imaris software (Bitplane) using the Surpass module - > Contour Surface. We correlated the obtained values to the volume of the whole brain thus determined the percentage loss of the brain volume caused by the neurodegeneration.
Results
In this study, two analytical approaches are presented to determine the degree of brain tissue damage in the Drosophila adult brain, and they are compared in terms of the time required and the accuracy of the measurements. The first method of raw data analysis was primarily based on the use of the publicly available software Fiji. The second method of brain damage extent analysis uses the

commercial image software Imaris. In both types of analyses (Fiji and Imaris), statistical analyses using Student t-test confirmed a significant difference in the degree of neurodegeneration between mutant and control brains, p-value was $P < 0.001$. To compare results obtained by these two analytical methods, the extent of neurodegeneration in mutants measured by Fiji and Imaris software was subjected to statistical analysis using Student t-test and linear regression. The results showed no significant differences.

Conclusion

In Fiji software, the Analyze Particles function enables automatic selection of neurodegenerative holes. However, subjective adjustment of the Threshold level may introduce measurement error. Conversely, Imaris software requires manual selection of each hole across all optical sections of the Z-stack using the Contour Surface module, which is time-consuming. Thus, the choice between the two methods depends on the degree of neurodegeneration. For low levels, Imaris is recommended for its 3D visualization capabilities, albeit at the expense of time and effort. Conversely, for high levels of neurodegeneration, Fiji is more efficient.

Vacuum ultra violet emission spectra observed by newly designed grating with improved diffraction efficiency

Takanori Murano[1], Dr Shogo Koshiya[1], Dr Masaru Takakura[1], Dr Masato Koike[2,3], Professer Masami Terauchi[3]
[1]SA Business Unit, JEOL Ltd., Akishima, Japan, [2]Kansai Institute for Photon Science, National Institutes for Quantum Science and Technology (QST), Kizugawa, Japan, [3]Institute Multidisciplinary Research for Advanced Materials (IMRAM), Tohoku Univ., Sendai, Japan

Poster Group 1

Introduction

In the research and development of new functional materials, obtaining information on their chemical bonding states is one of the most important subjects for understanding the physical properties of the materials. In the soft X-ray and vacuum ultra-violet (VUV) energy regions, various characteristic X-ray emissions owing to electronic transitions from the valence bands (bonding electron states) to the inner-shell electron levels are observed. In other words, the analysis of these emission spectra will lead to an understanding of the chemical bonding states and the physical properties of the materials. For the purpose described above, Terauchi et al. fabricated a soft X-ray emission spectrometer (SXES) accommodated to a transmission electron microscope (TEM) and demonstrated a high energy resolution of 0.22 eV for Al L-emission spectrum [1]. Based on their work, JEOL Ltd. commercialized a SXES, which can be mounted on a general-purpose scanning electron microscope (SEM) / electron probe micro analyzer (EPMA) using newly developed varied-line-spacing laminar-type gratings in 2013. This model, named SS-94000SXES, accepted the energy range of 50–210 eV. SS-94000SXES has been applied successfully to analyze battery materials and contributed to a trendy discussion of Li bonding with Si anode materials [2]. On the other hand, in Li oxides, the Li spectrum is predicted to shift significantly to the lower energy side compared with that of Li metal. However, it has not been accessed with SS-94000SXES due to its limitation of acceptable energy range.
To overcome this difficulty, a new diffraction grating which covers an energy range of 35–100 eV and a larger reflection efficiency with a coating was developed [3]. This grating system allows the observation of the whole band-spectrum of Li in the compounds with high sensitivity [4]. In addition, this energy range accepts to measure whole Mg L-emission spectrum. In this paper, some preliminary results obtained with the new grating system are presented.

Experiments

The modified SXES with the new grating was installed to an EPMA (JEOL JXA-8230 and JXA-iSP100). Samples used for the present experiments were selected for emphasizing the fascinating detection of lower-energy emission, The energy axes of these spectra shown in this paper are calibrated by C K-emission (277.0 eV) [5] and its higher order diffracted lines of HOPG.

Results

Figure 1 shows Al L-emission spectra of aluminum metal obtained by using the new grating (hereafter called as NEW) and SS-94000SXES system (hereafter called as CONVENTIONAL). Labels of L_3-M, L_2-M and L_1-$L_{2,3}$ are the assignments of related electronic transitions between shells. This shows that the intensity of NEW is more than two times larger than that of CONVENTIONAL. Besides, an intensity enhancement of approximately 5-times is obtained for Mg L-emission [4]. Inset (a) is the

enlargement of Fermi-edge region of Al L-emission, where intensities of the two spectra are normalized by L_3-M peak for comparison. It is seen that the energy resolutions of NEW and CONVENTIONAL are the same. The L_2-M intensity, which is separated from L_3-M by 0.4 eV, is clearly observed. Inset (b) is the enlargement of Al L_1-$L_{2,3}$ emission region, which is out of the energy range of SS-94000SXES. Furthermore, the spectrum of NEW shows the second-order Al $L_{2,3}$-M spectrum because of the extended performance of NEW down to 35 eV. This means that NEW covers the energy region of shifted Li K-emission intensities of compounds.
Figure 2 shows $M_{2,3}$-$M_{4,5}$ emission spectra of Manganese and Cobalt. These transition metals were selected to show the applicability to battery cathode materials. Spectral intensities of Mn and Co are normalized by peak intensities at 46.2 eV and 58.1 eV, respectively. The vertical dotted line is the lower limit of the detection energy of CONVENTIONAL. Then, the Mn $M_{2,3}$-$M_{4,5}$ emission spectrum shown here can only be measured by using NEW. Furthermore, this Mn $M_{2,3}$-$M_{4,5}$ emission spectrum shows asymmetric intensity profile with an additional structure in the high energy side (49.0 eV) indicated by a red vertical line, which reflecting the chemical bonding state of the material.

Conclusion
VUV region emission from 35 eV could be observed by using the NEW grating system. Compared to CONVENTIONAL, the intensity of Al L-emission has improved more than 2 times (more than 5 times for Mg L-emission [4]). Furthermore, Mn $M_{2,3}$-$M_{4,5}$ emission spectrum, which could not be observed with CONVENTIONAL, reflecting the chemical bonding state was observed by NEW.

Visualization of surface plasmon propagation and emissions by cathodoluminescence

Izzah Machfuudzoh[1], Sotatsu Yanagimoto[1], Researcher Naoki Yamamoto[1], Supervisor Takumi Sannomiya[1]
[1]Tokyo Institute of Technology, Yokohama, Japan

Poster Group 1

- Background -
Plasmonic materials are capable of manipulating light-matter interactions at nanoscale dimensions through the control of material morphology. Metallic plasmonic waveguides with extended geometrical nanostructures, such as planar surfaces, periodical gratings, and nanowires, can support eigenmodes of surface plasmon polaritons (SPPs), which are defined as surface electromagnetic waves propagating along the interface between a metal and a dielectric medium. The intrinsically two-dimensional nature of SPPs provides flexibility in engineering integrated nanophotonic circuits, facilitating the transfer of optical information across given distances due to their confined and enhanced fields near the interface [1]. However, despite the importance of SPP modes in applications such as optical communications and photonics, detailed studies on their propagation and emissions upon excitation are relatively underexplored. In this work, we present an extensive study on the behavior of SPPs on one-dimensional plasmonic crystals (1D-PlCs), delving into their propagation properties as well as the simultaneous correlation of their emission positions relative to the beam irradiation spots.
- Methods -
A 1D-PlCs with a periodicity of 600 nm and terrace dimensions of 420 nm width and 100 nm height, patterned on an otherwise flat 200 nm-thick silver surface, served as the samples. Mode excitation and data acquisition were both performed in cathodoluminescence-based scanning transmission electron microscopy (STEM-CL) at an accelerating voltage of 80 kV. This modified STEM-CL system is capable of resolving the emission angles θ and energies E of the detected CL radiations, providing full post-access on the fields of the excited modes [2]. The vertically-polarized emissions from different sample setups were analyzed, namely the “flat at front” and “flat at rear” setups with half-grating-half-flat structure oriented symmetrically along the x-direction (see Figure 1).
- Results -
Distinctive dispersion curves with predominantly opposing slopes were observed. The “flat at front” setup exhibits negative-slope dispersion lines attributing to backward-propagating SPPs (in the negative x-direction), while the “flat at rear” setup with a geometrically symmetric flip shows positive-slope dispersion lines referring to forward-propagating SPPs (in the positive x-direction), as shown in Figure 1(a,b). These differences are due to the presence of periodic structures on only one side of the samples, causing the SPPs propagating towards the planar surface to experience no SPP-scattering structure. Moreover, the effect of the interference of the outcoupled SPPs as photons with transition radiation (TR) generated at the beam impact position was also clearly observed as additional dispersion lines appearing in-between, as marked by numbers in Figure 1(a,b) [3].
Photon maps analysis further elucidates the characteristics of the excited modes and spatially visualizes the interference phenomena. Two modes with distinguished hotspot distributions were observed at θ = 20°±5°: the symmetric mode (S-mode) at around E = 2.50 eV (Figure 1(d,f)) and the antisymmetric mode (A-mode) at E = 1.47 eV (Figure 1(c,e)). The former S-mode has opposite sign charges located alternatively at the terrace and groove centers, while the latter A-mode distributes

the charges along the terrace edges. Additionally, periodic-like fringes with varying spacings were observed on the planar surface, depicting a spatial image of the interference of SPP-induced radiation with TR. For the A-mode, for instance, given the measured fringe spacings of 645 nm and 1190 nm respectively for the “flat at front” and “flat at rear” setups, the average SPP wavelength was estimated to be around 838 nm [4]. Such a wavelength, close to but less than its free-space wavelength of the A-mode at 843 nm, indicates the bound nature of SPPs on a flat surface.
A study on the optical emission spots was also performed to evaluate the positions of the photon emissions from the propagating SPPs upon scattering by grating structures. By synchronizing emission imaging with beam scanning on the sample, signals of the emitted CL light were captured and digitally mapped as emission spots, with each pixel in the emission space storing information about spatial emission positions in the sample space [5]. Depending on the sample setups (i.e., the “flat at front” or “flat at rear” setups) and beam excitation positions (i.e., at the terrace, groove, or flat area), the obtained emission spots varied in number (i.e., one, two, or three spots). By extracting the signals of these emission spots, known as emission-spot-decomposed CL maps, it was uncovered that photons emerge not only at where the beam is irradiated but also at more delocalized locations, providing strong evidence of the scattering of propagating SPPs. Moreover, shifts of the emission spots with beam irradiations across the samples show a nonlinear trend, depicting a modulation of the emission spots by the presence of the surface charge distributions.
- Conclusions -
In conclusion, our studies uncover how SPPs interact with 1D-PlCs through their propagation behaviors, as revealed by dispersion curves with opposing slopes, CL photon maps with differing fringe widths, and optical emission spots with emission-spot-decomposed CL maps showing emission positions. This work, with in-depth details on the SPP propagation, could provide valuable insights for designing nanophotonic devices.

Nanocrystals with dilated interplanar distances in the carburized surface case of Inconel-718 gas-processed at 570°C

Dr Corneliu Sarbu[1], Phd Student Marian Cosmin Istrate
[1]National Institute for Materials Physics, Magurele, Romania

Poster Group 1

It is utterly important to find appropriate methods of surface processing with the aim of enhancement of the properties of engineering interest of the stainless alloys (SS) and even of superalloys, as are hardness, wear resistance and even corrosion resistance. At Swagelok Co. Ltd. (Solon, OH, USA) it was invented the surface carburization processing at low temperature (LT) in gas-atmosphere (LTC) which matches the engineering requests for many SS alloys and for Inconel-718 (IN-718) Ni-Fe based superalloy [1]. The effect of LT gas-carburization consists in the formation at the alloy's free surface of a so-called carburized case (tens of µm-s thick) which is suggested to consist in crystallographically slightly modified alloy grains having properties that are matching the engineering requests. The theory currently accepted for explanation of the modified crystalline structure is based on a supposed supersaturation with carbon (CSS). It is claimed that carbon diffuses in the interstitial locations of the initial alloy grains (of face centered cubic structure (FCC)), leaving unchanged the initial grain structure and crystallography of the alloy, except for a dilatation of cubic lattice parameter due to the colossal-stuffing with carbon [2]. This theory is currently considered as valid for explanation of the enhancement of all the surface properties of the carburized IN-718 at carburizing temperatures of 843K, 803K and 783K [3]. We report that the low-temperature carbon supersaturation theory (LTCSS) is not valid in the case of IN-718 carburization at 843 K even when a surface carburized case is formed and revealed through chemical etching. We herewith report that the initial micrometer sized grain structure is replaced by a nanostructure located at least in the uppermost layer 1-2 µm thick, generated by the gas-carburization of the surface at LT.
The uppermost layer 1-2 µm thick of the free carburized surface at 843K of IN-718 was investigated by HRTEM by using a JEM-ARM200F aberration corrected (HR)(S)TEM microscope. In view of reaching the highest achievable precision in our measurement of the interplanar distances by using the HRTEM images of the observed nanocrystals, the Fourier transform of the Bragg reflections - mainly of the alloy matrix (111) reflections which have the highest structure factors in transmission electron diffraction (TED) - were analyzed. The usual disk samples of 3 mm diameter were prepared for TEM by following the usual steps: (a) mechanical cutting of a ≈1.5 mm thick sheet along a plane parallel to the free carburized surface of a bulk piece of carburized alloy, (b) mechanical polishing until a ≈80÷100 µm thickness is achieved, (c) ultrasonic punching of Ø=3mm disks, (d) dimpling of the disks until a remaining minimum thickness of ≈20µm is reached at the carburized face and (e) final dual beams milling with Ar+ ions in a Gatan PIPS device. The operations (b), (d) and (e) were done only at the uncarburized face of the disk samples.
A Cu contamination of the free carburized surface was our permanent mark for checking that the observed nanostructure belongs to the uppermost layer of the carburized case, whose entire thickness was reported as ≈20µm [3]. We have investigated the same IN-718 material sample as the one reported in [3], where no mention is made concerning the existence of a surface nanostructure due to the LT gas carburization. We collected a large number of directly measured d(hkl) values from HRTEM images of atomic resolution, regarding mainly the d(111) interplanar distances. We measured d(hkl)-s also for other observed nanocrystalline orientations. Interplanar distances of carbides were also measured, but they are not the object of our interest here. The distribution of the directly

measured d(hkl) values revealed that most of the observed matrix (austenite) nanocrystals have enlarged crystallographic interplanar distances in comparison to the uncarburized crystalline FCC structure of the IN-718 austenite matrix. The values measured by us are higher far beyond the errors that could affect our measurements. A much lower number of IN-718 austenite nanocrystals with non-modified lattice constant was observed. We took as a reference value the IN-718 lattice constant measured via neutron diffraction in a fully aged IN-718 superalloy [4].
Fig-1(a) is a negative inverted photo (used for better visibility of the nanostructure details) and shows the direct HRTEM image of an area located at the rim of a hole resulted by ion milling. It reveals the presence of nanocrystals embedded in an amorphous phase located in the uppermost layer of the carburized case. Fig-1(b) - not allowed by the template of the abstract text - was a reverse Fourier filtered image generated by mask selection of only the (111) reflections in the Fourie transform (FT) of the image shown in Fig-1(a). In many areas similar to the depicted one (Fig-1(a)) we measured several surprising values of the interplanar distance d(111), as for example 2.07, 2.08 , 2.11, 2.18 Å which correspond respectively to the FCC lattice cell parameter of the matrix nanocrystals of 3.58, 3.60, 3.65, 3.77 Å. These are as a rule largely higher than the most precisely measured lattice constant - done by means of neutron diffraction - of 3.5954÷3.6005 Å [4] - in a fully annealed IN-718 alloy.
The image shown in Figure (1a) (the FT of Fig-1a was not allowed by the template of the abstract text) is only an example taken from a wealth of HRTEM recorded images showing similar nanostructures. We got similar d(hkl) values also by measurements done at the recorded transmission electron diffractograms. This large collection of directly measured d(hkl)-s are clearly evidencing that the FCC crystalline cells of the nanosized fragments of the carburized IN-718 matrix are most probably generated via a massive diffusion of carbon in the alloy grains, as claimed by the LTCSS theoretical model, which instead of simply dilating the crystalline cell of the initial alloy grains, is inducing the fragmentation of them. The ultimate evidence concerning the occurrence, the mechanism and the crystallography of this fragmentation process - occuring deeper in the alloy - is obtainable only by means of neutron diffraction or by synchrotron XRD. Furthermore, it should be revisited the original evidence supplied via classical XRD which supports the claimed basic idea of the LTCSS model.

Poster Group 1

Background incl. aims
Continual advances in methods development for single particle imaging in cryogenic electron microscopy (cryo-EM) have paved the way towards ever-increasing resolution for three-dimensional (3D) particle reconstruction. For thicker particles, one must further correct for the effects of multiple scattering within the particle. This is commonly associated with the correction of the Ewald sphere curvature, and existing algorithms have recently successfully pushed the resolution limit beyond what was possible. However, the physics of cryo-EM image formation is better understood as in-line holography. This implies that the phases of the complex-valued field arriving at the detector are lost upon the measurement of particle images. Therefore, the Fourier coefficients inferred from these phase-less images, which are subsequently used in Ewald sphere curvature correction, cannot fully remove the effects of multiple scattering. This results in ghost-like artifacts in the reconstructed particle. Our developed algorithm, Ghostbuster [1], aims to minimize these artifacts by accounting for multiple scattering in cryo-EM particle refinement through phase retrieval.

Methods
Ghostbuster refines the 3D particle through batch stochastic gradient descent by minimizing the error between the estimated images from a multislice-based forward model and actual cryo-EM measurements. Our algorithm implicitly recovers the lost phases of the measured particles, enabling the inversion of the multislice method through wave backpropagation. Particle refinement is further accelerated through the inclusion of a sparsity constraint as well as symmetry priors.

Results
Here, we compare Ghostbuster's reconstructed particle against state-of-the-art software such as CryoSPARC and RELION. Using a simulated dataset of Methanococcoides burtonii Rubisco (PDB: 5MAC), Ghostbuster demonstrates improved resolution beyond that of CryoSPARC's Ewald sphere curvature correction algorithm based on Fourier shell correlation (Fig. 1). Preliminary tests on experimental datasets deposited on EMPIAR show that Ghostbuster performs close to, if not, similar, to both CryoSPARC and RELION (Fig. 1).

Conclusion
In the absence of confounding noise sources in experiments, we show that the effects of multiple scattering can be minimized using Ghostbuster, even for particles previously assumed to be thin. Further work is to be done to investigate the efficacy of Ghostbuster under experimental conditions.

Poster Group 1

Background incl. aims
Better synthesis control of nanostructured catalysts and their durability in electrochemical systems can be achieved by an in-depth understanding of the electrochemical deposition and dissolution processes. Electrodeposition and electrodissolution studies of nanomaterials are conventionally investigated over large specimen areas. The thermodynamics and kinetics of both NP nucleation and dissolution are affected by the specific surface interactions between NPs and substrate, which depend on the heterogeneous substrate's chemical, structural, and morphological properties. Although some high-sensitivity electrochemical techniques allow recording electrochemical signals of the growth or dissolution of single NPs, a direct visualization of these processes at high-spatial resolution can provide invaluable information on the underlying mechanisms. Recently developed liquid-cell transmission electron microscopy (LC-TEM) holders allow in-situ study of materials reactions on a nanoscale. Such specialized holders contain liquid cells that can withhold the liquid in a confined environment, allowing the imaging and spectroscopy of samples in the reaction media. Combining the capabilities of LC-TEM holders with micro-size electrodes printed on a chip enables us to study dynamic phenomena during electrochemical reactions. In this work, we have employed the LC-TEM to directly visualize the dynamic dissolution of electrodeposited gold nanoparticles (NPs) on an electrode and tap into the durability and stability of Au electrocatalysts. Combining the in-situ electrochemical LC-TEM, ex-situ nano-scale, and macro-scale measurements provided a unique perspective on the interaction between the metallic particles and the substrate during the electrochemical process [1,2].
Methods
The in-situ EC-LTEM experiments were performed using a JEOL JEM 2100 TEM at a 200 kV accelerating voltage in the bright-field mode. Experimental images and videos were recorded at the standard illumination conditions for real-time imaging with controlled electron beam damage effects. The electrochemical measurements in the TEM were carried out using a Protochips Poseidon 500 liquid holder, which allows observation of dynamic electrochemical processes in the liquid. The electrodeposition process of Au NPs was conducted from 1 mM HAuCl4 + 0.1 M NaCl solution in ultrapure deionized water. The electrochemical dissolution of these Au nanoparticles was observed under a constant applied potential during a potentiostatic regime at 1.5 V vs Pt pseudo reference.
Results
The in-situ electrochemical deposition of Au NPs from the HAuCl4 electrolyte resulted in fairly homogeneous particles of around 20 nm in size. The real-time observation of the dynamic electrochemical dissolution of these particles revealed that these Au NPs were dissolved heterogeneously and consecutively (one after another) during anodic polarization in a time span of

more than 30 seconds. Moreover, it was shown that Au NPs form a core-shell structure, with the shells being more resistant to the dissolution process.

Conclusions

The unprecedented combination of in-situ electrochemical LC-TEM and the macro-scale experiments revealed important information from the electrochemical deposition and dissolution of supported metal NPs. This approach opens up new opportunities for the rational design of functional nanostructured materials for catalytic applications and for evaluating their durability under electrochemical polarization from the perspective of their resistance to electrochemical dissolution.

Tracking the Ultrastructure of Life with Serial Block-face Scanning Electron Microscopy

Dr. Alexandra Elli[1], Dr. Nathalie Braun[2], Dr. Dieter Lauer[2]
[1]Carl Zeiss Microscopy GmbH, Jena, Germany, [2]Carl Zeiss Microscopy GmbH, Oberkochen, Germany

Poster Group 1

Background incl. aims
Life happens in 3D. To unlock the secrets of life we must consider and understand different aspects. Images acquired with an electron microscope reveal insights into the ultrastructure with highest resolution. Scanning electron microscopy (SEM) is a versatile method to obtain high-resolution information on the nanometer scale. While traditionally used for topography measurements, modern SEMs in biomedical research are utilized increasingly to obtain large volume data of biological samples. Single images are snapshots of a complex three-dimensional architecture reduced to a 2D image. The acquisition of volume data is necessary to understand this complex architecture. New developments in hardware and software as well as in electron optics enable an ever-larger range of applications in 3D. Different techniques like serial section tomography (Array Tomography), Serial block-face SEM (SBF-SEM) and focus ion beam SEM (FIB-SEM) allow us to understand these volumes. On this poster, we present the latest developments in Serial block-face imaging realized as ZEISS Volutome. ZEISS Volutome enables the acquisition of large volumes at nanometer resolution in an automated, unattended way. Regardless of which biological sample is to be analyzed - whether individual cells surrounded by pure, non-conductive resin or large, densely packed tissues such as brain - ZEISS Volutome is developed to image any type of resin-embedded biological sample.

Methods
Serial block-face SEM (SBF-SEM) was first developed and communicated by Denk et al. in 2004 [1]. In SBF-SEM, an ultramicrotome inside the SEM chamber can cut down to 25 nm thick sections from a resin-embedded sample block. The exposed sample surface is imaged with an electron beam, then new sections are cut away with a diamond knife, and the newly exposed block-face surface is imaged. This cutting and imaging process is repeated until the structure of interest is completely imaged. The acquired EM images are processed and digitally aligned into a 3D data set. Cell compartments can be easily identified and segmented from this z-stack. The segmented 3D data set can be visualized, investigated, and statistically analyzed.

Results
Serial block-face Imaging is the appropriate solution to image and follow neurons with long and thin protrusions, such as dendrites and axons. It is well suited to trace neurons within the large volumes necessary to capture the often-unpredictable paths of these cells. ZEISS Volutome enables acquisition of large mosaic images over all three dimensions at high resolution. This is supported by the stability of the ultramicrotome stage solution. Once the cutting and imaging parameters are set-up, the experiment runs automatically and autonomously. Sections as thin as 25 nm with pixel sizes as small as 3 nm can be cut to follow the dendrites and axons precisely over long distances (Figure 1A).
Going beyond image acquisition, ZEISS arivis, the software for image processing, segmentation, and visualization, facilitates the analysis of your ultrastructural 3D data set to elucidate the path of the individual neurons and the network of cell organelles (example shown in Figure 1B). High resolution

image acquisition is crucial for the identification of different cellular components; this is possible with ZEISS Volutome (Figure 1C).

Conclusion
In recent years a range of technical hurdles have been overcome and have extended the applicability of SBF-SEM. Most notably, a technique called Focal Charge Compensation has been developed to enable imaging of charge-prone biological samples [2] as well as the new high-sensitivity Volume BSE detector for high quality imaging at low kV. Unattended sectioning and imaging make this technique a convenient way to acquire large, ultrastructural 3D data sets.

Self-assembled nanoparticles in a thin film of water

Dr Crispin Hetherington[1], Dr Dmitry Baranov[2], Dr Katarzyna Makasewicz[3]
[1]nCHREM, Lund University, Lund, Sweden, [2]Chemical Physics and NanoLund, Lund University, Lund, Sweden, [3]Institute for Chemical and Bioengineering, ETH Zürich , Zürich, Switzerland

Poster Group 1

Background including Aims
Metal nanoparticles that are functionalised may be used as markers in Cryo-EM studies on soft materials (Ahmad 2022). An observation has been made where these particles have self-assembled into remarkably regular 2-dimensional lattices in a thin water layer, and where the interparticle separation is large. The aim is to investigate this phenomenon, the role of the water thickness, and to link it to similar observations

Methods
Au nanoparticles functionalised with NH2 groups were obtained from a commercial supplier and mixed with small unilamellar vesicles in a series of aqueous samples. TEM grids were prepared in the Leica GP1 grid plunger and transferred to the TEM in a Cryotransfer holder (Fischione Model 2550). Observations were made on a JEOL 2200FS TEM adapted for cryogenic studies and operated at 200 kV. While the main study was aimed at the interaction of the functionalised NPs with the vesicles, this presentation concerns the observation of the interaction between the functionalised NPs themselves.

Results
Functionalised NPs were found to have self-assembled into a 2D hexagonal lattice. The interaction occured only within thin layers of water. Note that the observations were made when the sample was frozen and the thin layer transformed to vitreous ice. The distance from one particle centre to another is in the 50 nm range, while the gold nanoparticle diameter is around 14 nm. Hence the gap between NP surfaces is around 36 nm, indicating a chain length of the functionalising ligand of around 18 nm.

Conclusions
Low density ordered arrays of particles forming spontaneously from various solutions are an interesting phenomenon. Previous work (Kanie 2012) found assemblies with 7 nm gaps between particles, which the authors commented was rather larger than typical gaps of 3 nm or even less. This observation of a 36 nm interparticle gap, which can still result in a particle array having a highly regular hexagonal packing, is intriguing. Further work will investigate the role of the thickness of the water/ice layer.

Figure 1 Micrograph showing self-assembled Au NPs in several patches of thin vitreous ice (200kV, TEM magnification 10kx). The distance between these NPs is around 50 nm. NPs can also be seen in thicker ice in random arrangements, and attached to the strands of lacey carbon film. Some small unilamellar vesicles appear (with low contrast in this image) in the thicker ice with sizes 70 - 100 nm; 6 are outlined in white.

Poster Group 1

Background incl. aims
Neisseria meningitidis are Gram-negative bacteria responsible for life threatening sepsis and meningitis and are human-exclusive pathogens. Disease is driven by polymeric fibers at the surface of bacteria called type-IV pili (T4P), assembled by a multi-protein molecular machine known as type-IV pilus machinery (T4PM). Only the outer membrane and peptidoglycan segment of the T4PM, the PilQ secretin, allows the T4P to be secreted to the extracellular medium and thus it is of great interest for therapeutical approaches and bacterial model design. Because PilQ is reported to be widely different among bacteria, the structure and assembly of this secretin in Neisseria is not known. We therefore aim to solve not only the high-resolution model of PilQ but also describe the proteins involved in its assembly. We finally use this information to develop a piliation-trapped bacteria for cryo-ET.

Methods
For electron microscopy purposes, PilQ was natively purified from N. meningitidis (Strain 8013) ΔsiaD under Biosecurity II conditions. Proteins were loaded into custom carbon-coated Au-CFlat grids and images were collected in a Titan Krios microscope equipped with a Falcon 4i camera (Thermo Fischer Scientific), then processed using diverse processing software, most notably Relion 4 and CryoSPARC 4. Modelling and refinement of PilQ and its associated proteins was performed with Coot and Phenix using information from MS, Alphafold2, deep-etch EM and cryo-EM. Peptidoglycan-binding and protein-protein interaction assays were carried out to support the working model.
Mass spectrometry was performed on cross-linked samples of N. meningitidis pellets harvested from plate cultures. Membranes were crosslinked using UV-aided click-chemistry with NNP9 and digested. Eluted peptides from Photocleavable alkyne agarose beads were analyzed by nanoLC-MS/MS using a Vanquish Neo UHPLC system coupled to an Orbitrap Eclipse Tribrid mass spectrometer fitted with an EASY-Spray Source (Thermo Scientific). Peptides were separated on an EASY-Spray PepMap Neo.

Results
Our cryo-EM map of native NM PilQ at 2.14 Å resolution allowed to fully build an atomic model of all domains of the protein, including its highly-dynamic gate but excluding the flexible AMIN1 and AMIN2 peptidoglycan region. It is a 14-fold symmetry dynamic molecule as opposed to the previously reported C12. This structure allowed to design NM strains with locked conformations of the T4PM for subtomogram averaging purposes.
Both in vitro and crosslink data, combined with knowledge from literature allowed to build the AMIN regions, which tend form dimers, thus pointing to a heptamer-of-dimers structure. Similarly, MS data on NM membranes pointed to three proteins that interacted with PilQ in-situ: TsaP, RmpM and

BamA. This data, along with PGN-binding and BLI assays, allowed to build a working model of the assembly. Crosslinks of interactor-deficient mutant strains also enabled to describe the functionality of the interacting proteins in the assembly of PilQ. TsaP dimerizes PilQ protomers and anchors them to the peptidoglycan, while BamA interacts with RmpM which in turn localizes the PilQ protomers and keeps the secretin on top of the peptidoglycan.

Conclusion
Neisseria meningitidis PilQ is a 14-mer secretin, assembled as a heptamer-of-dimers, driven by TsaP and the propensity of the AMIN region to dimerize. Transitory interactions with BamA and RmpM help localize protomers for oligomerization and position the secretin on top of the peptidoglycan. The structure of PilQ shows a highly-dynamic gate that can be blocked with mutations, thus enabling T4PM-driven piliation steps to be studied in-situ by cryo-electron tomography. Further understanding piliation may enable novel approaches to inhibiting the process and thus, disease.

Parent grain reconstruction of martensitic microstructures: a comparison of different methods

Dr. Barbara Šetina Batič[1]
[1]Institute of Metals and Technology, Ljubljana, Slovenia

Poster Group 1

Background
Metallographic techniques have traditionally been used for primary austenite grain analysis. In this study, we compare conventional metallography with selective etching to reveal primary austenite grains within the microstructure and two different parent grain reconstruction software packages, which reconstruct the primary austenitic grains based on orientation relationships between (child) martensitic phase and (parent) austenite phase.
Methods
The samples were prepared following standard metallographic procedures. The samples for optical microscopy were etched with different etchants to reveal the primary austenite grain boundaries. For EBSD analysis the samples were finished with 5 min OP-S final polishing.
For light otical microscopy, we used Microphot FXA, Nikon with 3CCD-videocamera Hitachi HV-C20A and analySIS software. For scanning electron microscopy, two different microscope set-ups were considered: Zeiss CrossBeam 550, with EDAX Hikari Super EBSD detector and OIM 8 software for data processing and ThermoFisher Apreo 2, with Oxford Instruments Symmetry 2 EBSD system and Crystal software for data processing was used.
Results
The etching process highlights grain boundaries, facilitating the identification and measurement of primary austenite grains, and providing valuable information about their size, distribution, and orientation. Complementing the metallographic approach, EBSD can also be used to determine primary austenite grains through crystallographic orientation mapping. EBSD data is processed to reconstruct parent grains, offering high spatial resolution and insights into the crystallographic characteristics of the primary austenite phase.
Conclusion
The presented work shows and compares different ways to reconstruct primary austenite grains from martensitic microstructure.
Light microscopy is by all means a much faster technique, while scanning electron microscopy and electron backscatter diffraction require advanced equipment, additional sample preparation and additional post processing of the acquired data; but can give more impartial results that are not as dependent on the skill of metallographer.

Poster Group 1

TiO_2 is known for its photoactivity and chemically inert behavior. It is widely used in many applications as a pigment or as a UV light absorber. We were interested in what happen when the particle of TiO_2 is in contact with the wood matter and irradiated by UV light. For the experiments, two wood species were chosen: beech (Fagus sylvatica) and pine (Pinus sylvestris). Molecular and physical modifications in coated and uncoated wood exposed to UV radiation were investigated with Fourier transform infrared spectroscopy with attenuated total reflectance (FTIR-ATR) and transmission electron microscopy (TEM). UV-VIS spectroscopy was used to describe the absorption of UV light by the TiO_2 planar particles chosen for the experiment. It was demonstrated that TiO_2 coating protects wood against photodegradation to a limited extent. TEM micrographs showed fissures in the wood matter around clusters of TiO_2 particles in beech wood.

Poster Group 1

Global BioImaging mobilizes imaging scientists and facilities from 60 countries and 13 networks, accelerating resource exchange and championing the global impact of imaging. Through inclusive programs, Global BioImaging transcends barriers to foster innovation and community building under the banner of "Imaging 4 All," spanning bioimaging, biomedical, and material sciences.

Global BioImaging offers comprehensive training, job shadowing, and advocacy to empower imaging scientists and influence policy. Collaborative papers and working groups advance topics from career pathways to infrastructure development. Key discussions focus on fair career paths, funder communication, network building, training courses, showcasing core values, and data management.

Imaging networks connect researchers with advanced instruments, enhancing data quality, fostering collaboration, and improving resource efficiency. Shared facilities reduce costs and expand access to cutting-edge technologies.

The synergy between open access and imaging networks drives scientific progress. Open access disseminates high-quality data widely, while imaging networks contribute to openly accessible research, enhancing reproducibility, fostering global collaboration, and driving technological advancements.

Global BioImaging and partner imaging networks are reshaping the scientific community by democratizing knowledge and providing unparalleled tools for exploration and analysis. As anticipation grows for the annual meeting in Japan (#GBI_EoE2024), Global BioImaging continues to accelerate exchange and foster collaboration in imaging science.

Visualization of the Endosomal Fate of mRNA-Lipid Nanoparticles Reveals the Reason for Low Escape Rate

Anke Kaltbeitzel[1], Johanna Simon[2], Kai Speth[1], Volker Mailänder[1], Ingo Lieberwirth[1]
[1]MPI Polymer Research, Mainz, Germany, [2]Merck KGAA, Darmstadt, Germany

Background incl. aims
During Covid-19 pandemic, lipid nanoparticles (LNPs) have proven an indispensable drug for fighting viral infections[1]. They also bear potential as drugs against cancer and in many other fields[2]. They are formed of ionizable cationic lipids, helper lipids, PEGylated lipids and mRNA. They assemble at low pH during manufacturing, taking advantage of electrostatic interaction of cationic lipids with negative charges of the phosphate backbone of mRNA. The LNPs are taken up by cells into endosomes. Transfer of mRNA from the endosome to the cytosol is a prerequisite for the transcription of mRNA into drug effective proteins. Ionizable cationic lipids are thought to hold a crucial functional role because at low pH in late endosomes they should interact with and destabilize the endosomal membrane[3].
Despite vaccines being efficient, it is known that endosomal escape of mRNA is a bottle neck for this technology, being in the low percent range[4]. Visualization of endosomal processing of LNPs is crucial to understand the inefficiency of release.

Methods
Using correlative light and electron microscopy (CLEM) we were able to visualize the LNPs within endosomes for 2 different LNP formulations: lab scale LNPs with mRNA encoding for Firefly Luciferase and the COVID-19 vaccine Comirnaty® produced by Pfizer/Biontech. During administration to dendritic cells, the LNPs were exposed to an RNA stain to confer fluorescence for the correlation. Cells were incubated with LNPs for 6, 16-18 and 24h. Subsequently, cells were high pressure frozen (HPF), OsO_4 and Uranyl-acetate stained, embedded in EPON and sectioned. Confocal images and EM images (SEM and TEM) were registered.

Results
After 6h incubation with lab scale LNPs, we see fluorescently stained particles of ~100nm size in endosomes on the verge of aggregation. After 16-18h the proportion of LNPs in endosomes has increased, coalescence took place resulting in dense layered structures. These structures clearly differ from endogenous multilamellar bodies but resemble TEM images of LNPs[5]. After 24h, endosomes are packed with large aggregates. Disentanglement of the dense stratified layers in some parts of the aggregates is observed. Despite filling > 90% of the endosomes, the aggregates rarely touch the endosomal membrane. However, at few places local ruptures of the endosomal membrane are visible.

Conclusion
We were able to visualize processing of LNPs in endosomes after uptake. We see massive accumulation of LNPs in endosomes over a time period of 24 hours, resulting in coalescence of LNPs. This process has rather been considered to limit the lifetime for storage of vaccine formulations. However, it also has crucial impact on endosomal escape. Release of mRNA is thought to occur via local breakup of the endosomal membrane after contact with cationic lipids followed by release of single LNPs to the cytosol[3]. Our images reveal a different scenario: PEGylation of LNPs minimizes contact with the endosomal membrane in early endosomes. Yet, coalescence of LNPs takes place due to massive accumulation of LNPs in endosomes leading to concentrations orders of magnitude above those in the formulations. Coalescence also increases the density of PEG-groups on the surface, thus further reducing contact between LNP agglomerates and the endosomal membrane. Maturation of the endosomes causes a drop of pH so that ionizable cationic lipids get increasingly positively charged. This leads to electrostatic repulsion of the lipids resulting in the observed disentanglement of the lipid layers in the agglomerates. On the surface of the agglomerates there is local breakup of the lipid layers. Helped by their positive charge, loose strands locally interact with and perforate the endosomal membrane. However, the agglomerates are too bulky to pass through the membrane with their mRNA load and diffusion of single mRNA strands is hampered by their electrostatic attraction to the cationic lipids. Only a complete breakdown of the endosomes would reincrease the pH to levels allowing for efficient mRNA diffusion to the cytosol. Our findings indicate that the very concept of LNP assembly finally limits the mRNA release. Careful adjustment of the apparent pKa value of the ionizable cationic lipids can optimize the release rate.

Poster Group 1

Background incl. aims
3D imaging is helpful for revealing the internal structure of biological tissues, microbes, and plants. This technique, especially for soft materials in micromorphology, has traditionally been performed using the tomography method with a transmission electron microscope (TEM). In recent years, scanning electron microscopes (SEM) have been used for 3D imaging by array tomography [1, 2], focused ion beam SEM (FIB-SEM), and serial block-face SEM (SBF-SEM). These SEM tomography methods are expected to be useful for many biological specimens because SEM can observe a wider region than TEM. Especially, the array tomography method is very useful due to the following features: fewer limitations on specimen size, the ability to re-observe sections, and the capability to perform correlative light electron microscopy (CLEM).
The array tomography method requires long acquisition times because it involves taking large number of photos over a wide area and through many sections. This method is generally performed using a high-resolution SEM, which is expensive and has a large footprint. Since benchtop SEMs are cheaper and have a smaller footprint, using multiple benchtop SEMs can be expected to increase throughput for large microstructures within a limited budget. Additionally, efficiency can be improved by first using 3D images obtained from benchtop SEMs to narrow down regions of interest. These selected regions can then be analyzed in detail with high-resolution SEMs.
The array tomography method using benchtop SEMs, which are manually operated to acquire images one by one, has been reported [3]. Modern benchtop SEMs, which have a motorized stage, can automatically perform array tomography similarly to high-resolution SEMs. In this report, we compare the 3D image quality between benchtop SEMs and high-resolution SEMs and discuss the possibility of the array tomography method using benchtop SEMs. Furthermore, we introduce the stage position linkage between both SEMs for the purpose of the efficient detailed analysis.

Methods
Paramecium was used as the model sample. Paramecium was cultured in water with gold, silver, and silica nanoparticles for 1 hour. The specimen was fixed with glutaraldehyde and OsO4 and then stained with uranyl acetate. The specimen was embedded in resin and sliced to a thickness of 200 nm. Three hundred sixty-six serial sections were placed on a carbon substrate (Ultra Flat Carbon: UFC, JEOL Ltd.). The serial sections were observed using a benchtop SEM (JCM-7000, JEOL Ltd.) and a high-resolution SEM (JSM-IT800<SHL>, JEOL Ltd.).

Results
3D reconstruction from the images of the serial sections was successful even with the benchtop SEM. The 3D reconstructed image obtained by the benchtop SEM is shown in Fig.1. In the cross-sectional image from the 3D reconstructed image, the paramecium (approximately 150 µm) and the phagosomes (approximately 10 µm) inside the paramecium were clearly recognized. However, in the benchtop SEM 3D image, the aggregation (approximately 1 µm) of nanoparticles in the phagosomes could not be clearly identified. This is because the spatial resolution of the benchtop SEM is poorer

than that of the high-resolution SEM. Despite this, the benchtop SEM was able to perform array tomography and identify the macrostructure of the paramecium.

Conclusion
We succeeded in automatically capturing the images of the serial sections and demonstrated the effectiveness of array tomography on the benchtop SEM. The stage position linkage system between the benchtop SEM and the high-resolution SEM makes it possible to re-analyze the region of interest in detail and effectively.

Electrochemical sensors for detection of benzotriazole in water

Assist. Prof. Kristina Žagar Soderžnik[1,2], Neža Sodnika[1], Melanija Hadolin[3], Zoran Samardžija[1]
[1]Jožef Stefan Institute, Ljubljana, Slovenia, [2]Jožef Stefan International Postgraduate School, Ljubljana, Slovenia, [3]Faculty of Chemistry and Chemical Technology, Ljubljana, Slovenia

Poster Group 1

Background incl. aims
Benzotriazole (BTA) and its derivatives are extensively utilized in various industries for their properties as corrosion inhibitors, UV radiation filters, and plastic stabilizers. BTA is, therefore, found in food packaging, dishwashing detergents, textiles, lubricants, antifreeze, aircraft de-icing fluids, and other commercial and industrial products. [1,2]
Due to its solubility in water and resistance to biodegradation, BTA can persist in the environment. The inclusion of BTA as an additive in dishwashing detergents and tablets leads to its direct discharge into wastewater treatment plants, where it is only partially removed during the treatment process. As a result, BTA is prevalent in natural waters at nanomolar concentrations. While these concentrations may not pose an immediate threat to human health, the persistent nature and potential bioavailability of BTA can lead to long-term environmental consequences, which have yet to be sufficiently investigated. [1,2]
Currently, the primary methods for analyzing BTA in environmental samples involve solid-phase extraction followed by gas chromatography-mass spectrometry or liquid chromatography-mass spectrometry. However, there is a need for cost-effective, fast, reliable, in-situ detection of BTA for real-time monitoring of environmental samples. Given that BTA and some of its derivatives can be electrochemically reduced at low potentials, electrochemical detection on screen-printed electrodes (SPE) emerges as a promising approach. SPEs offer a more cost-effective, portable alternative to traditional electrochemical setups, which use conventional electrodes such as glassy carbon and mercury drop electrodes. In this work, a sensor based on carbon nanotube-Nafion-modified SPE is proposed for the detection of BTA. The modification of SPE was fully characterized via electrochemical and electron microscopy techniques.
Methods
1 mg/mL dispersions of carboxyl-functionalized single-walled or multi-walled carbon nanotubes (SWCNT, MWCNT) were prepared in a 1:1 (v/v) mixture of DMF and water containing 1 wt.% Nafion. The sensor was fabricated by drop-casting 4 µL of the CNT suspension on the working electrode of the SPE (DRP-150, Dropsens, Metrohm) and allowing it to dry at room temperature overnight.
BTA solutions were prepared in Britton-Robinson buffer (pH 2.4) and analyzed using cyclic voltammetry (CV) and square wave voltammetry (SWV). The electrochemical measurements were carried out by the PalmSens4 potentiostat.
The surface morphologies of the commercial SPE-C and modified SPE-SWCNT and SPE-MWCNT electrodes were investigated by using scanning electron microscopy (SEM) and transmission electron microscopy (TEM). The samples for SEM were embedded in metallic sample holders using conductive, carbon adhesive tape and observed at various magnifications in a field-emission-gun scanning electron microscope (FEG-SEM Verios G4 HP, Thermo Fisher Scientific, USA). Preliminary examinations of the samples showed that they were sufficiently electrically conductive for the SEM analysis. The experimental conditions for imaging were set to an accelerating voltage of 4 kV, a beam current between 20 pA and 50 pA, and a working distance of 3 mm. The electron micrographs were recorded with two detectors: (i) a through-the-lens detector (TLD) for secondary electrons (SE) and

(ii) a mirror detector (MD) for backscattered electrons (BSE) positioned within the objective lens. To observe the SWCNT and MWCNT structure and size, transmission electron microscopy (TEM) with energy-dispersive X-ray spectroscopy (EDS) was used (JEOL JEM-2100, Jeol Ltd., Tokyo, Japan). The samples for TEM observations were prepared by dispersing the nanoparticles after ultrasonic deagglomeration in water onto lacey carbon-coated Cu grids.

Results

The sensors' receptor element was based on modified commercial screen-printed electrodes (SPE). The drop-casted material's coverage of the working electrode (SWCNT or MWCNT) was assessed using electron microscopy to observe the morphology, composition, and conductivity of the material. As seen in Fig. 1a, the SWCNTs are anchored to the working electrode by a Nafion membrane, resulting in satisfactory surface coverage and conductivity. The MWCNT showed similar results with a grass-like structure and Nafion presence.

At the next step, the electrochemical behavior of BTA on the SPE-C/SWCNT was evaluated via CV. BTA exhibited a single reduction peak around –1,4 V with no observable oxidation peak during the reverse scan. The SPE-C/SWCNT exhibited significant adsorption capacity for BTA. As a result, SWV analysis was performed after a 60 s preconcentration period at –1 V. With this approach, a limit of quantification (LOQ) was determined, and the limit of detection (LOD) was calculated from the calibration curve (Fig 1b). The LOQ was 10 2 µM and LOD of 2 µM. This LOD is comparable to that obtained for BTA detection using commercially available SPE with a SWCNT working electrode [2], indicating that homemade modified SPEs offer a versatile alternative to commercial counterparts. Furthermore, by adjusting the composition, it may be possible to achieve an even lower LOD, comparable to those achieved using modified glassy carbon electrodes [3], making the proposed sensor suitable for real sample monitoring.

Figure 1. a) SEM image of the working electrode surface modified with SWCNT and Nafion and b) Calibration curve of the reduction peak current recorded on SPE-C/SWCNT.

Conclusion

Benzotriazole and its derivatives are ubiquitous in industries due to their diverse applications, yet their persistence in the environment poses ecological concerns. This study proposes a carbon nanotube-Nafion-modified screen-printed electrode for electrochemical BTA detection, addressing the need for cost-effective and rapid monitoring methods. Electrochemical analysis revealed a single reduction peak, leading to an LOD of 2 µM with square wave voltammetry. This approach offers a comparable alternative to commercial electrodes, underscoring its potential for environmental monitoring.

Poster Group 1

Tungsten, as a candidate material for the plasma-facing component of the ITER reactor, will endure severe operational conditions. Recent studies have reported radiation-induced hardening and DBTT profiles for various tungsten grades, which needs to be supported by microstructural analysis.
In this study, neutron-irradiated, various tungsten grades are investigated using transmission electron microscopy (TEM) in order to comprehend the microstructural stability of tungsten under fusion-relevant conditions. Irradiation experiments were conducted at BR2 reactor at temperatures 600 C and 1000 C with 1 dpa dosage, which is the expected lifetime in ITER. Characterization of the three main radiation-induced defects (dislocation loops, nanovoids and transmutation precipitates) includes defect density, size, morphology, decoration and spatial distributions for each tungsten grade. Chemical analysis provides insights into the decoration of ODS precipitates and radiation-induced defects. The observed trend of increased radiation-induced hardening from irradiation temperatures of 600 C to 1000 C is attributed to changes in defect densities and chemical composition.
This research enhances our understanding of tungsten's microstructural response to neutron irradiation, offering valuable insights for the development and performance assessment of plasma-facing materials in fusion reactors.

Volume Electron Microscopy: A Powerful Tool for Studying Embryonic Pineal Organ Development in Birds

Prof. Bogdan Lewczuk[1], Dr Natalia Szyrynska[1], Dr Magdalena Prusik[1]
[1]University Of Warmia And Mazury In Olsztyn, Olsztyn, Poland

LS-07 (2), Lecture Theater 5, august 28, 2024, 14:00 - 16:00

The structure of the pineal organ in birds exhibits significant species variability, with three main types identified: saccular, tubule-follicular, and solid, along with several intermediate forms. The parenchyma of the most commonly observed tubule-follicular type includes the pineal canal, a primary evagination of the neuroectoderm of the diencephalon roof, and numerous follicles. Three types of pinealocytes (receptor pinealocytes, rudimentary-receptor pinealocytes, and secretory pinealocytes) and two types of supporting cells (ependymal-like and astrocyte-like cells) have been identified in the avian pineal organ at the electron microscopy level. However, two-dimensional studies have been insufficient to answer many questions about the spatial organization of pineal parenchyma.
This study utilized volume electron microscopy to investigate the structure of the embryonic pineal organs of the domestic turkey and the domestic goose, chosen for their substantial differences in pineal parenchyma organization. The embryonic turkey pineal organ features follicles with a large lumen surrounded by a thin layer of parenchymal cells, resembling pseudostratified epithelium. In contrast, the pineal parenchyma of goose embryos consists of two distinct parts: follicular areas composed of elongated cells surrounding the follicular lumen and parafollicular areas, which are peripheral to the follicular region and consist of several layers of cells.
The pineal organs of 18-day-old turkey and goose embryos were fixed and contrasted according to a modified protocol by Deerinck et al. (1). Serial block face imaging (SBFI) was performed using 3View 2XP (Gatan, USA) and OnPoint detector (Gatan, USA) operating in EF-SEM Gemini 450 (Carl Zeiss, Germany) with the focal charge compensation system. Stacks of 300-1000 images (15,000 x 15,000 pixels, pixel size 5 nm, section thickness 50 nm) were manually segmented using MIB software (2), and the models were visualized using Amira 3D (Thermo Fisher Scientific, USA).
In the embryonic pineal organ of the domestic turkey, two types of parenchymal cells were identified and classified as embryonic rudimentary receptor pinealocytes and ependymal-like supporting cells. These cells were present in both the pineal follicles and the pineal canal, with structural differences depending on their location. SBFI revealed that rudimentary receptor pinealocytes typically do not contact the basement membrane limiting the follicles and the canal. The basal parts of rudimentary receptor pinealocytes in the follicles had the shape of an inverted cup, with their outer surfaces in contact with ependymal-like supporting cells. In the pineal canal, pinealocytes formed long basal processes that created flattened fragments lying in invaginations of ependymal-like supporting cells. Up to five flat parts of different rudimentary receptor pinealocytes were found in one invagination. Ependymal-like supporting cells had a broad basal portion resting on the basement membrane. Both rudimentary receptor pinealocytes and ependymal-like supporting cells had regular internal organization. In pinealocytes, the organelles were distributed as follows: 1) nucleus in the basal part of cell, 2) accumulation of endoplasmic reticulum cisterns on the upper pole of the nucleus, 3) Golgi apparatus, and 4) mitochondria. The apical protrusion of pinealocytes had a 9+0 cilium and contained endoplasmic reticulum and mitochondria. A key feature of rudimentary receptor pinealocytes was the accumulation of mitochondria in the upper part of the cell, with SBFI showing these mitochondria as elongated and parallel to the cell's long axis. Some mitochondria formed long strands from the cell

apex to the perinuclear region. In supporting cells, mitochondria were present throughout the cytoplasm, including the basal process. Secretory pinealocytes and astrocyte-like supporting cells were not found in the turkey pineal organ.
Special attention was given to mitotic cells since precursor cells of pinealocytes and supporting cells have never been described in the avian pineal organ. Cell divisions were more numerous in the pineal canal than in the follicles. Mitotic cells always contacted the canal lumen by short apical processes and had long basal projections ending in numerous fine, parallel-running processes that did not attach to the basement membrane. Daughter cells maintained contact with the lumen and remained connected by a thin cytoplasmic bridge near the canal lumen for an unknown period. These cells lacked a polarized distribution of organelles, leading us to hypothesize that differentiation results in the characteristic distribution of organelles seen in pinealocytes or supporting cells.
Rudimentary receptor pinealocytes in the pineal canal varied in the proportion of cell body length to basal process length. Cells with short bodies and long basal processes exhibited numerous deep invaginations of the nuclear envelope. Occasionally, large parts of the cytoplasm of these pinealocytes, connected to the cell body by a narrow band, were located in the lumen, suggesting that the upper parts of these cells are removed into the lumen. The same process was observed in the pineal follicles. Since undifferentiated precursor cells were not found, we hypothesize that old pinealocytes lose the upper part of their cytoplasm and re-enter the cell cycle.
In the goose pineal organ, follicular areas were mainly composed of cells resembling rudimentary receptor pinealocytes, which created long processes penetrating into the parafollicular areas. Parafollicular areas were primarily composed of embryonic secretory pinealocytes. Supporting cells were exclusively found close to the basement membrane and were largely infrequent due to the parenchyma's poor division by connective tissue, resulting in the majority of cells not contacting the basement membrane. The cells of the parafollicular region formed specific contact sites bordered by tight junctions, created by both cell bodies and cell processes. Secretory pinealocytes showed significant variability in shape and the presence of very long processes. Their cytoplasm often contained three zones with the Golgi apparatus, endoplasmic reticulum, and mitochondria, though not arranged in series.

TEM strain measurement methods on SiGe/Si films for accuracy tests

Dr. Roberto Balboni[1], Prof. Matteo Ferroni[1,2], Dr. Fabiola Liscio[1], Dr. Anacleto Proietti[3], Dr. Chiara Mancini[3]
[1]CNR-IMM, Bologna, Italy, [2]University of Brescia, Brescia, Italy, [3]University of La Sapienza, Roma, Italy

Poster Group 1

Background incl. aims
Transmission electron microscopy (TEM) is still considered a key analysis technique when high spatial resolution is required, even considering the generally lengthy, difficult and sometimes troublesome sample preparation. Such important advantage applies to imaging, structural and diffraction analysis and analytical investigations. The analysis and quantification of strain fields in crystalline materials also takes advantage of the TEM spatial resolution and over the last decades several TEM based techniques were developed [1].
In the framework of the CHALLENGES project financed by the EC (Grant agreement 861857 [2]), several methods have been used to validate the results of Tip Enhanced Raman Spectroscopy (TERS) in the characterisation of semiconductors (Si based) wafers and structures. Strain was one of the physical quantities measured in either thin film or patterned structures and TEM methods were used as standard reference. A series of three Si1-xGex heterostructutres, deposited as thin films onto a Si substrate, at different Ge concentration and thickness (see Table I), were used as 'standard strain' samples in order to compare all the techniques adopted (that includes optical based as well as diffraction based ones, such as TEM and X-ray Diffraction, XRD) onto the same samples. The Ge nominal concentration and SiGe film thickness were #1: 20%/45 nm, #2: 30%/29 nm and #3: 40%/22nm, respectively.
We therefore took this opportunity to test different standard TEM strain analysis methods, namely Convergent Beam Electron Diffraction (CBED), Geometric Phase Analysis (GPA) and standard Selected Area Diffraction (SAD), in such samples using a conventional TEM, with the aim of evaluating the accuracy of the measurements with particular reference to the strain relaxation related to the lamellae thickness.

Methods
Thin cross-sectioned lamellae for TEM analysis have been prepared from the wafes using a Zeiss XBeam 340 FIB, with Ga ions accelerated at 30 KeV, then at 5 and 2 KeV for a final polishing to reduce the amorphous and crystal damaged layers thickness at the thinned surfaces. In each lamella a series of 3 thin regions at different thicknesses were prepared. The local crystal thickness in each region was evaluated by means of two-beams (004) CBED and resulted of about 100 nm, 200 nm and more than 450 nm, from the thinner to the thicker ones in each lamella.
The TEM measurements were performed in a FEI Tecnai F20T equipped with a Schottky emitter and operated at 200 kV accelerating voltage.
The samples film strains have also been measured with high resolution XRD using a Rigaku SmartLab X-ray diffractometer.

Results
CBED strain analysis was performed in STEM mode by obtaining diffraction pattern along several lines proceeding from the substrate to the surface after having oriented the sample along the <230> zone axis [3]. The CBED measurements were performed only in the thicker (>450 nm) regions of the

sample. It was possible to obtain good and measurable patterns only up to regions close to the Si/SiGe interface. In the centre of the film the High Order Laue Zones (HOLZ) lines split or blurred out, thus preventing any measurement.
Since strain values were of the order of 10-2 and the film thicknesses were at least 20 nm it was possible to use also conventional SAD that showed comparable results with those obtained with the more sophisticated and instrumental requiring Nano Beam Diffraction (NBD). The SAD measurements showed a split of the (400) reflection family, corresponding to the Si and the SiGe regions, confirming that the crystal deformation was uniaxial in all samples, i.e. along the growth direction, as expected in a tetragonally distorted crystal. The mismatch values obtained vary considerably in the same sample at different thicknesses of the lamella: in Table 1 the mismatch values obtained in the thicker regions are reported.
Finally, good quality HREM images were recorded only in the thinner area of the samples, in both film and substrate, and from these we obtained the corresponding mismatch values from GPA analysis. From this analysis too the distortion showed an uniaxial behaviour but also smaller mismatch values if compared with those obtained by SAD in thicker regions.
All the results obtained are summarised in Table I, together with the measured Ge concentration (as obtained by energy dispersive x-Ray spectroscopy) and High Resolution XRD (HRXRD) measurements. From the results shown in the table it is quite evident that phase analysis gives lower values for the measured mismatches, and it reasonable to assume that a larger strain relaxation occurs here since the sample should be thinned to a lower thickness value to collect HREM images. Moreover, samples #1 and sample #2 show a similar residual strain, while sample #3 keeps a much higher value. This could be due an increased rigidity in sample #3 related to the much smaller film thickness. The small discrepancy between SAD and HRXRD results suggests that small strain relaxation could still occur even in thicker areas.

Conclusion
The application of well established TEM techniques for crystal strain evaluation in simple SiGe/Si heterostructures showed some limitations. Despite the High strain sensitivity, CBED confirmed to be ineffective in samples regions were an high strain gradient or a strong strain relaxation occur. Both GPA and conventional diffraction were able to measure the uniaxial deformation, but best results were obtained in thick lamellae (>450 nm), thus confirming that the relation between strain vs. local sample thickness plays an important role in measurement accuracy.

Poster Group 1

Background incl. aims:
Multiplex immunostaining has become an increasingly important approach in current biomedical research. However, the availability of directly labeled primary antibodies often poses a bottleneck for multiplex methods. Here we aimed to develop an antibody-labeling process that enables fast and easy conjugation of primary antibodies to fluorophores at a microgram to milligram scale, e.g. for the amount needed for one immunostaining experiment.
Methods:
For the development of this labeling procedure, we employed a broad range of methods including in silico protein design, molecular cloning, protein expression, protein purification, site-directed conjugation, BLI, DLS, cell culture, IF, IHC, flow cytometry and X-ray crystallography. Successful application of the developed labeling technique takes around 10 minutes and does not require any special equipment or proficiency in chemical conjugation or antibody purification.
Results:
We designed peptide-based multivalent linkers that bind to primary IgGs from rabbit, mouse, rat or human species with an apparent dissociation rate koff (1/s) below 0.0001 and covalently conjugated them to different fluorophores (CL+405/488/555/647/750). We validated the specificity of the binding between the linkers and their target IgGs and confirmed the proposed molecular arrangement with X-ray crystallography. Since these linkers are fluorescent, they offer a simple and convenient tool to functionalize primary IgGs from the aforementioned species with the desired fluorophores. We called this labeling approach FlexAble labeling because it embodies the simple steps of mixing and briefly incubating linkers and primaries. This procedure can be performed virtually in any laboratory for any amount of primaries right before applying the antibodies in the desired assay. Moreover, primary antibodies can be in any buffer, since glycerol or other additives do not interfere with FlexAble labeling.
Here, we show that FlexAble-labeled antibodies are suitable for immunofluorescence stainings, especially when multiplexing of primaries from the same species is required. Also, we present examples of FlexAble applied to flow cytometry, WB, tissue IF, live time-lapse imaging, cyclic IF, and other more advanced experiments employing immunofluorescence detection of the target molecules.
Conclusion:
We have established FlexAble, a novel antibody labeling process that enables rapid conjugation of primary antibodies to fluorophores and facilitates multiplex immunofluorescence experiments. We are expanding this method further to expedite labeling of primary antibodies with reporter proteins (HRP, PE, APC), biotin, DNA oligonucleotides, rare-earth metals etc. to support multiplex flow cytometry, nucleotide barcoding (e.g. 10x Genomics) and IMC (e.g. CyTOF).

Comparative Analysis of Sample Preparation and Imaging Methods for Metallographic Examination of Archaeological Silver

Dr Alexandra Suvorova[1], Prof Walter Bloom[2]
[1]The University of Western Australia, Perth, Australia, [2]Western Australia Museum, Fremantle, Australia

Poster Group 1

Background
There are two principal considerations for metallographic examination of historical metal artefacts: first, the selected portion of the material must be representative of the object; second, the sample preparation procedure must ensure minimal destruction to the archaeological object. Sample preparation is a critical step in the metallographic analysis of archaeological metals and is a prerequisite for accurately determining the microstructure and elemental composition using SEM, SEM-EDS, EPMA, and EBSD techniques. The quality of the sample surface is crucial for accurate metallographic analysis: surface damage, surface contamination, and limited material availability are key factors that limit the reproducibility and accuracy of structural and analytical results. The sample state (corrosion), area of interest (surface vs. bulk), analytical technique, and intended purpose (information required) play major roles in selecting the optimum sample preparation.
Methods
The 17th century silver coins and artefacts from the Batavia shipwreck of the Dutch East India Company's (VOC) flagship from Western Australian Museum collection have been analysed using STEM and SEM detectors in FEI Verios 460 SEM and FEI Helios FIB-SEM. The samples for SEM examination have been prepared by ultramicrotomy (Leica EMFC7 Ultramicrotome Microsystem equipped with Diatome diamond knife), focused ion beam milling (the FEI Helios Nanolab G3 CX DualBeam FIB), and laser micromachining tool (3D Micromac microPREP).
Results
Various sample preparation methods and their outcomes have been compared to reveal their advantages and limitations for metallographic applications in the archaeological silver artefacts. The outcomes are demonstrated below in Figure(a) 100nm slice prepared from a silver alloy using ultramicrotomy, imaged at 30kV using the TLD detector; Figure(b) sectioned and polished silver alloy sample with the laser micromachining tool, imaged at 20kV using CBS detector; Figure(c) cross-section prepared by focused ion beam milling, imaged at 5kV, 1.4nA, using the ICD detector.
Conclusion
All methods are excellent sample preparation options for archaeological metal samples, such as silver objects and coins when the best surface quality and minimal destruction is required. Additionally, the most suitable protocols for sample preparation, imaging, and analytical studies have been found specifically suitable for historical silver alloys.

Poster Group 1

Background
Germanium dioxide (GeO2) is an advanced semiconductor material characterized by an ultrawide band gap ranging from approximately 4.6 to 6.2 eV [1], depending on its concrete crystal phase and doping level. This wide gap renders GeO2 well-suited for high-power and high-frequency electronic devices. Establishing precise correlations between thermal processes, structure evolutions, and electrical properties is essential for understanding fundamental mechanisms and achieving high-performance semiconductor materials.
This study utilizes SEM, XRD, and TEM to investigate the phase transformations of GeO2 from amorphous to crystalline phases triggered by a controlled annealing process.
Methods
An approximately 1 µm thick amorphous GeO2 layer was deposited on c-plane sapphire (Al2O3 {0001}) wafers at 300 °C by plasma-assisted molecular beam epitaxy (PAMBE). These layers were subsequently subjected to annealing in an oxygen environment at temperatures of 1000°C, 1100°C, and 1200°C for a duration of six hours. The resulting samples were directly analyzed by SEM and XRD. And the cross-section samples were prepared by FIB for TEM investigations.
Results
The figure depicts bright field TEM images, high-resolution TEM images, and corresponding fast Fourier transition (FFT) patterns of GeO_2 layers subjected to thermal treatment at temperatures of 1000°C, 1100°C, and 1200°C, respectively. After annealing at 1000°C for 6 hours (figures a-c), mainly circular, with occasional hexagonal crystalline grains of quartz phase GeO2 (α-GeO2) emerged in the amorphous matrix, typically between 10-20 nm in size. With further heating to 1100°C, these nanograins, as seen in figures d-f, evolved within the amorphous matrix to larger crystals between 10 and 60 nm. Further annealing under 1200°C (figures g-i) completely transformed the amorphous phase into crystalline. Meanwhile, a phase transition from the hexagonal quartz to the tetragonal rutile was observed. This transition coincides with non-homogeneous grain growth in GeO2, i.e. one grain grew to over 20 times the mean grain size depicted in figures (g, h). Such grain growth highlights the dynamic nature of the phase transformation process within the GeO2 layers when subjected to elevated temperatures. Further results, such as the XRD patterns and ESD analysis, will be presented on-site.
Conclusion
This comprehensive investigation provides insights into the structural evolution and phase transformations of GeO_2 under varying thermal conditions. It offers valuable information for further understanding of the properties and behaviors in different temperature regimes.

Computational analysis of the anisotropy of SEM images to quantify nanowire verticality and surface roughness

Eleni Stai[1]
[1]National Centre For Scientific Research Demokritos , Athens, Greece, [2]NKUA Department of Physics, Athens, Greece

Poster Group 1

Background incl. aims
Surface texturing on micro and nanoscale plays a fundamental role in many applications of nanotechnology due to its effects on almost all surface properties such as wetting, wear, reflectance, bioactivity to name just a few. A chief feature of surface texture is its isotropy/anisotropy. Anisotropy (i.e. directionality of surface texture) is encountered in a wide gamut of cases since it can be caused by a plethora of processes on different scales and can have strong impact on applications at a variety of scales. Based on its importance, the characterization of surface texture anisotropy has been incorporated in the ISO 25178-2 and two parameters have been proposed to characterize the degree and directionality of anisotropy using the autocorrelation function and Fourier transform respectively. The ISO characterization assumes full measurement of 3D topography by 3D profilometer or AFM. However, since height information is not critical in anisotropy identification, SEM images can also be used and provide a straightforward way to surface anisotropy characterization.

Moreover, surfaces with nanowires have been used in various fields of applications from electronics and photonics to bio-devices and energy harvesting systems. One of the critical properties of nanowire patterns is their alignment and verticality since it tunes the contact area with the attached body and hence their performance in their applications.

The aim of this work is firstly to implement a methodology for the quantification of SEM image anisotropy based on 2D Fourier spectrum analysis to conclude about surface anisotropy and secondly to characterize indirectly the verticality of nanowires (NWs) developed on substrates.

Methods
Here, we propose a fast and easily implemented method to characterize the degree of surface anisotropy1, which can also be applied to surfaces with nanowires to assess their verticality. First, we apply a threshold to the Fourier spectrum values to identify the low-frequency region in the 2D Fourier space with amplitudes higher than this threshold. Then, we calculate the anisotropy ratio A by dividing the smallest radius of this region by the largest one and then substract it from 1 (see Fig. 1). An A value close to 0 indicates an isotropic surface, whereas a value close to 1 indicates an anisotropic surface.
A top-down SEM image of a fully vertical nanowire (NW) with a cylindrical shape is isotropic, as it displays the circular shape of its cross-section. When the NW is tilted from verticality, the SEM image shows a portion of its axis, indicating local anisotropy. Therefore, the deviation from full verticality can be quantified by an index characterizing the anisotropy of NW spots in top-down SEM images.

Results
Our methodology was applied to SEM images of inclined polymer surfaces after plasma etching with oxygen gas. We observed that at the bottom part of these surfaces, near the electrode plate of plasma reactor, anisotropic morphologies were emerged, forming horizontal ripples at large

inclination angles2 (see Fig. 2). As we are moving upwards, there is a noticeable transition from anisotropy to isotropy with ripples qradually replacing by nanowire bundles. Using Fourier-based anisotropy indices, we can quantify this transition and establish a link to plasma etching conditions and inclination angles. Figure 2 illustrates the change in low-frequency Fourier contour lines (blue for bottom areas vs. red for top areas), from which we calculated the anisotropy index A increase from 0.13 at the top to 0.82 at the bottom.
To study the change in the verticality of the nanowires, Figure 3 presents the anisotropy index used to assess the verticality of nanowires on the polymer surface before and after water condensation. The anisotropy index, A, decreased from 0.51 to 0.26, indicating degradation of nanowire verticality by nearly 50%.

Conclusion
In conclusion, we developed a fast and easily implemented method to characterize surface anisotropy, which is also applicable to assessing the verticality of surfaces with nanowires. This method successfully quantified the transition from anisotropic to isotropic morphologies on inclined polymer surfaces after plasma etching with oxygen gas, linking these changes to etching conditions and inclination angles. The anisotropy index proved to be an effective tool in determining nanowire verticality, demonstrating significant sensitivity and accuracy. These findings pave the way for optimizing plasma etching processes and enhancing the design and fabrication of nanowire-based materials and devices.

Poster Group 1

By unlocking previously unattainable scales, microscopy proved pivotal for our today's understanding of the fundamental processes in living systems and enabled future-shaping discoveries. However, understanding the interactions of biomolecules at the nanoscale and putting them in a cellular context remains a major challenge as light diffraction events limit the achievable resolutions. Electron microscopy (EM), unlike light-based techniques, gives access to the cellular ultrastructure yet results in grey-scale images and averts unambiguous (co-)localization of biological targets without electron-dense labels or correlative approaches.
This work presents multimodal nanoparticle-based protein labels for correlative cathodoluminescence electron microscopy (CCLEM) and energy-dispersive X-ray spectromicroscopy (EDX-SM). By incorporating rare-earth dopants in a low phonon host lattice and shielding them from their environment using an inert shell, the characteristic cathodoluminescence (CL) and characteristic X-ray emissivity of sub-20 nm nanoparticles were utilized as unique spectral fingerprints for precise label identification and localization. The core/shell nanoparticles were decorated with either folic (terbium-doped) or caffeic acid (europium-doped), bridging the single-particle response to a biological entity. Their potential for (protein-)labelling was examined using HeLa cells expressing different surface receptors that bind to folic or caffeic acid, respectively.
Single-particle cathodoluminescence along with a distinctive energy-dispersive X-ray signal was successfully presented for both populations, with the latter outcompeting CL as response for ColorEM. EDX-SM persuaded with swift imaging times well below 2 mins per µm² while offering high resolution with a pixel size of 2.78 nm, enabling the observation of biological relevant areas.
Taken together, these results pave the way for multi-color labelling based on electron spectromicroscopy and show its unleashed potential for the study of structure-function relationships.

Observation of spontaneous fluctuations in product selectivity of the acetylene hydrogenation reaction in operando TEM

Dr. Christian Rohner[1], Mr Eugen Stotz[1], Dr. Alexander Steigert[2], Dr. Daniel Amkreutz[2], Prof. Dr. Rutger Schlatmann[2], Prof. Dr. Beatriz Roldan Cuenya[1], PD Dr Thomas Lunkenbein[1]
[1]Fritz Haber Institute of the Max Planck Society, Berlin, Germany, [2]Helmholtz-Zentrum Berlin für Materialien und Energie, Berlin, Germany

Poster Group 1

Background incl. aims
The selective hydrogenation of acetylene to ethylene is an important step in the purification of feed streams for the production of polyethylene.¹ A key finding from Teschner et al. describes the beneficial influence of subsurface C species on the selectivity of the reaction.² In that study, spontaneous fluctuations of the product selectivity were also observed under adiabatic conditions. The aim of our ongoing study is the detection of dynamic motifs and structural changes, which govern the occurrence of the fluctuations in the product selectivity. Specifically, we focus on the detection and elucidation of the role of transient and non-transient C species, as mediator for the catalytic performance.
Methods
In the framework of the CATLAB project, the development of thin film catalysts are conducted using existing preparation tools previously employed for thin film photovoltaics. Using a sputter deposition technique results in open networks of aggregated nanocrystals of the catalyst metals of interest, termed laterally condensed catalysts (LCCs). In this fashion, nominally 3nm thick Pd or Pd₆₀Au₄₀ alloy LCCs were deposited on DENS Solutions climate chips (SiNx windows). Using a home built gas-feeding station coupled to a quadrupole mass spectrometer, the reaction and product composition can be followed in real-time.³ Simultaneously, the structural parameters of the LCC are observed by TEM, electron diffraction (ED), and pair distribution function analysis of ED (ePDF).⁴
Results
To the best of our knowledge, the (semi)-hydrogenation of acetylene has not been observed in an operando TEM study prior to our experiments. A surprising result of our first experiment conducted at 150 °C was the observation of the aforementioned fluctuations in selectiviy and activity. and, second, that the product composition did not change, when the chip temperature was reduced to 20 °C (Figure 1). The observation of the fluctuations was confirmed by a second experiment conducted entirely at RT, while the absence of any product formation or fluctuations was confirmed in a blind experiment conducted with the empty operando cell. The high rate of conversion at RT exemplifies the exceptionally high activity of the LCC. However, this also indicates that catalyst material present in the non-heated and non-observable areas of the operando cell may have a significant contribution to the signal detected by the MS. Further, the results of supporting operando TEM experiments are discussed. These show the high potential of the ePDF method for operando measurements on nanocrystalline and amorphous catalysts in showing the formation/decomposition of the beta-PdH phase, and the measurement of crystalline domain growth, sintering and dewetting of the LCC.
Conclusion
In conclusion, the LCC seems to present itself as a highly promising platform for operando TEM, as its preparation is highly reproducible, the particle distribution very homogeneous, the metal layer very thin, and due to the high activity in the acetylene hydrogenation reaction, the product detection is

facile. So far, we could not detect structural changes that correlate with the fluctuations in the MS data. However, this raises the question about how local the origins of these effects are. Our future experiments aim to limit the sputter-deposited LCC to the heatable and observable region of the operando chip by using a specifically designed sputter mask.

A systematic study on PtRu alloy composition for catalytic applications

Tonya Kloos[1], Dr. Ningyan Cheng[1], M.Sc. Miquel Vega Paredes[1], M.Sc. Alan Savan[2], Prof. Dr.-Ing. Alfred Ludwig[2], Prof. Dr. Christina Scheu[1]
[1]Max-Planck Institute for Sustainable Materials, Düsseldorf, Germany, [2]Ruhr-Universität Bochum, Bochum, Germany

Poster Group 1

Background incl. aims
In order to reduce CO2 emissions in the areas of energy supply and consumption the use of fuel cells (FC) is inevitable. The choice of the catalyst material for the electrochemical reaction to convert H2 in electricity plays a major role. For this reaction the system of PtRu catalyst nanoparticles is well studied and already used in commercial application. However, for the PtRu phase diagram at ambient temperatures empirical data is not available. Thus, only Thermo-Calc generated phase diagrams down to room temperature exist.
Until now just few compositions of the PtRu nanoparticles are investigated in terms of structure and their performance since it is challenging and time consuming to synthetize nanoparticles with different specific compositions. In this work we perform a systematic investigation on the different chemical compositions of PtRu alloys and the influence on their micro- and nanostructure using a thin film.

Methods
The thin film was deposited on an oxidized silicon wafer via combinatorial magnetron sputtering. With positioning the Pt target and the Ru target in an 180° angle to each other a geometrical concentration gradient is generated. The surface of the thin film was analyzed in a Scanning Electron Microscope (SEM) followed by Energy dispersive X-ray Spectroscopy (EDXS) to determine chemical composition and distribution of the elements. Using a focused ion beam (FIB) lamellae were lifted out on specific targeted areas. Theses were analyzed with a Transmission Electron Microscope (TEM) to obtain the local structure and composition. The software Thermo-Calc was used to generate a phase diagram of the PtRu alloy down to room temperature.

Results
The deposited thin film had a smooth surface with no macroscopic defects. The atomic concentration range goes from Pt:Ru 58:42 at % - 17:83 at % along the sample. The thickness of the thin film was determined to be 115 nm ± 3 nm based on TEM micrographs. Additionally, the TEM micrographs taken from cross sections of the thin film showed columnar grains with 13 nm ± 4 nm width and the height of the thin film. With lamellae from areas of targeted positions EDXS was performed in the TEM to verify the validity of the calculated phase diagram. EDXS maps revealed that a two-phase material exists in regions where the calculation suggests a single phase material.

Conclusion
Combinatorial magnetron sputtering can be used to create thin films with a concentration gradient. A systematic study on the influence of the chemical composition on the structure was performed. This is necessary for a follow-up investigation of the electrochemical performance and its dependence on the composition and atomic structure. Correlation of structure and electrochemical experiments is key for future catalyst design.

Correlative light electron microscopy for improved investigation of subcellular GLUT4 distribution in human skeletal muscle

PhD student, MSc Kaspar Wredstrøm Persson[1], Christian T. Voldstedlund[1], Chris Neal[3], Judith M. Mantell[2,3], Erik, A. Richter[1], Paul Verkade[2], Thomas E. Jensen[1]
[1]August Krogh Section for Molecular Physiology, Department of Nutrition Exercise and Sports, University of Copenhagen, Copenhagen, Denmark, [2]School of Biochemistry, University of Bristol, Bristol, UK, [3]Wolfson Bioimaging Facility, University of Bristol, , UK

Poster Group 1

Background incl. aims
Insulin stimulated glucose uptake into skeletal muscle tissue is facilitated by translocation of the Glucose Transporter Type 4 (GLUT4) from intracellular storage sites to the cell surface, a well-established site of impairment in obesity linked insulin resistance. Despite impaired GLUT4 translocation, canonical signal transmission via the Insulin receptor substrate-1 is frequently observed to be normal, and human fractionation studies indicate that intracellular GLUT4 is missorted in individuals with insulin resistance. Exercise acutely promotes skeletal muscle glucose uptake by insulin-independent GLUT4 translocation and improves skeletal muscle insulin sensitivity independent of present insulin resistance in the hours following exercise - a phenomenon coexisting with the redistribution of GLUT4 to well-known insulin responsive subcellular compartments in metabolically healthy individuals. Whether the subcellular localization of GLUT4 is distorted in obesity linked insulin resistance and is corrected by a single insulin-sensitizing bout of exercise has not yet been investigated by high resolution microscopy-based approaches.
The aims of this study were 1) to establish and apply a quantitative correlative light electron microscopy (CLEM) workflow on human skeletal muscle biopsies, and 2) to investigate the subcellular distribution of GLUT4 in skeletal muscle single fibers of metabolically healthy vs. insulin resistant individuals prior to, immediately after and 3 hours into recovery from a single exercise bout.
Methods
Skeletal muscle biopsies were obtained from m. Vastus Lateralis of normal weight (BMI: 22.8 ± 1.7) and obese (BMI: 36.2 ± 3.1) young men (age 25-35y) (n=5) before, immediately after, and 3 hours into recovery from an acute bout of bicycling exercise (65% VO2max, 30 min). Immediately after excision, biopsies were chemically fixed for light and electron microscopy. Muscle fiber bundles were teased apart to single fibers, labelled with a GLUT4 antibody and subsequently FluoroNanogold, counterstained with Hoechst, embedded in agar on a glass slide, sealed with a coverslip and imaged using a Leica SP8 confocal microscope equipped with a 40x oil objective. For each muscle fiber, a full fiber surface tile scan was obtained using transmitted light followed by a single-tile 10µm z-stack for the wavelengths of interest. The specific tile was chosen based on visual landmarks (bends, curves, non-fiber substances etc.) for optimal recognition of the area in the subsequent electron microscopy imaging. Following gentle removal of the coverslip, in-agar fibers were further processed directly on the glass slide for electron microscopy. The procedure included silver enhancement of the FluoroNanogold particles, chemical post-fixation, lipid and nucleic acid staining and graded resin infiltration and polymerization. The specific areas of interest from confocal imaging were identified under a stereomicroscope and targeted for in-resin ultrathin (70 nm) sectioning. The sections were mounted on grids and imaged on a Tecnai T20 transmission electron microscope. Tile imaging was performed blinded along the edges of the fiber prior to low-magnification, full-section overview imaging. Overview images containing bleached areas were used in combination with confocal and

stereomicroscope images to overlay the corresponding light and electron microscopy images and confirmed by the shape, size and distance between nuclei.
Results
Insulin resistance was confirmed in participants with obesity both in the fasting state by the homeostasis model assessment 1 of insulin resistance (HOMA1-IR) (obese: 3.7 ± 2.1 vs. lean: 0.7 ± 0.1, p=0.02) as well as in response to an oral glucose tolerance test by the Matsuda Index (obese: 3.4 ± 1.5 vs lean: 15.7 ± 3.6, p=0.0001). The CLEM workflow was successfully implemented, and data are currently being analysed for the accumulation of GLUT4 in various subcellular compartments prior to, immediately after, and 3 hours into recovery from a single insulin-sensitizing bout of exercise.
Conclusion
In this study, we successfully established a novel quantitative CLEM workflow to investigate the subcellular distribution of GLUT4 in human skeletal muscle fibers with high spatial precision, achieving resolution down to the nanometer scale while ensuring ultrastructural integrity. Our methodology enabled detailed information on the localization of GLUT4 in single muscle fibers from both metabolically healthy and insulin-resistant individuals, and ongoing analyses aim to elucidate whether insulin resistance is associated with distorted subcellular distribution of GLUT4 and whether this is corrected by a single bout of exercise. This research advances our understanding of GLUT4 dynamics and provides a foundation for potential therapeutic strategies targeting insulin resistance through exercise. Moreover, this advanced imaging approach can be utilized to investigate various other subcellular processes in muscle tissue, expanding its applicability in muscle biology research.

Background incl. aims
To reduce the problem of global warming, alternative eco-friendly energy sources such as solar cells or fuel cells should be used. For fuel cells, hydrogen is an attractive energy carrier.1) To produce hydrogen in a sustainable way, we need to improve the efficiency of hydrogen generation in electrolysers. For this, efficient and stable electrocatalysts are required. One promising class are Ir-based catalyst which are known to speed up the oxygen evolution reaction (OER) but its stability needs to be improved. 2) In our work, we want to improve the stability of Ir and reduce the amount of Ir by using TiO_2 support.
Methods
Ir/TiO_2 nanostructures were synthesized on fluorine doped tin oxide coated glass slide (FTO) using a facile hydrothermal approach. After synthesis, films were prepared for scanning electron microscopy (SEM) by using copper tape attached to an aluminum SEM holder. ZEISS Gemini SEM 500 and ZEISS Merlin FE-SEM (field emission gun) were applied for examining the morphology of samples. For the (scanning) transmission electron microscopy ((S)TEM) analysis, the nanostructures were collected on a TEM holey carbon-copper (C/Cu) grid. A JEOL 2100 and an image Cs-corrected Titan Themis 80-300 from Thermo Fisher were used for the examination.
Results
Electrochemical characterization of the films showed that higher contents of Ir lead to an improved oxygen evolution reaction activity. SEM and (S)TEM analysis revealed that Ir/TiO_2 films consist of an assembly of facetted nanowires on the FTO substrate with the facets in according to the Wulff shape. The width of the individual nanowires was evaluated and it was observed that it increased from 95 nm to 114 nm with increasing amount of Ir used during the synthesis. Electron diffraction in TEM shows that Ir/TiO_2 maintains a rutile structure independent of the Ir content. Finally, energy dispersive X-ray spectroscopy (EDS) demonstrates that small Ir clusters with a size of less than 1 nm form which are homogenously distributed. However, until now it is not yet clear whether Ir is placed on top of the TiO_2 or embedded in the TiO_2 lattice.
Conclusion
To reduce the amount of Ir catalyst for the OER, TiO_2 is used as support. By changing the amount of Ir during the synthesis, the width of the nanowires increased in proportion to the amount of Ir. It is found that Ir/TiO_2 has a rutile structure but further studies are needed to determine whether Ir is incorporated into the lattice or adsorbed on the surface.

Poster Group 1

Background incl. aims
Understanding the mechanisms involved in nanoparticle formation, especially at the initial stages, is a significant challenge in materials science. The knowledge of early stages provides essential information regarding design strategies during nanomaterial synthesis1; silver is one such material of interest. This metal is significant for catalysis2 and sensing3 applications. Different silver nanoparticle synthesis strategies were investigated previously through chemical and electrochemical routes. However, there is a lack of comprehensive dynamic knowledge regarding the mechanisms of its reactions in solution. The control of essential parameters such as nanoparticle size, size distribution, and morphology will benefit from proper description and direct observation of nanoscale reactions. In-situ Liquid-Cell Transmission Electron Microscopy (LCTEM) is an experimental microscopy technique that allows observation of these nanoscale processes close to the native environment, directly in the liquid. Electrochemical reactions, in particular, can be studied and imaged using a miniaturized three-electrode electrochemical cell setup MEMS chip. Therefore, in this work, we are employing a correlative methodology for in-situ electrochemical LCTEM experiments to study the electrodeposition of silver nanoparticles.
Methods
The in-situ EC-LCTEM experiments were performed using a JEOL JEM 2100 TEM at a 200 kV accelerating voltage in parallel beam mode. The electrochemical measurements in the TEM were carried out using a Protochips Poseidon 500 liquid holder, which allows observation of dynamic electrochemical processes in the liquid. Cyclic voltammetry (CV) technique was used to obtain the characteristic curve for the electrolyte/electrode deposition system, potential window between -300 mV to 200 mV vs. Pt. A chronoamperometry (CA) experiment at -300 mV vs. Pt was carried out to study the growth of silver nanostructures in liquid. The electrolyte solution containing 2 mM AgNO3 + 50 mM KNO3 in ultrapure deionized water was used for the electrodeposition experiments. The electron beam dose was estimated to be below 1000 e-/A2·s.
Results
The in-situ LCTEM CV measurements pinpointed the peak potentials for nucleation of Silver onto the clean electrode measured at -150 mV vs Pt, and the potentials for reduction and oxidation of Ag, which were measured to be around -60 mV vs Pt and 70 mV vs. Pt. Due to this overpotential value, a potential of -300 mV vs. Pt was selected. The growth of small nuclei was recorded immediately after biasing started. The size of this first nuclei was around 6 nm. The growth rate of these particles was observed to be much higher at the beginning of the experiment due to the higher availability of electrolytes. As the electrolyte was not as available to the particle's growth, diffusion-limited growth of needle-like nanostructures extended from these nuclei shortly after.

Conclusion
The LCTEM technique is a powerful experimental method for probing dynamic chemical processes at the nanoscale. Electrochemical deposition, in particular, exhibits mechanisms that are still unclear and might follow non-classical phase transformation routes. This study allowed us to explain the mechanisms of silver nanostructure's electrochemical nucleation and growth.

Analysis of transcription dynamics via single cell imaging of chemically inducible system in S. Cerevisiae

Yujie Zhong[1], Maximilian Gehri[1], Gamze Dogali[1], Heinz Koeppl[1]
[1]Self-organizing Systems, Darmstadt, Germany

Poster Group 1

Background incl. aims
Transcription is stochastic switching between an active and an inactive state, known as bursting. Advances in microscopy and imaging methods have enabled visualization and quantification of transcription cycles in single living cells, enhancing our understanding of transcription regulation. It is well-studied how the native inducer, for example, GAL1, regulates the transcription activation. Recently, many synthetic transcription factors (TFs) have been used in synthetic biology, for example, the GEV system and zinc finger proteins, which can rapidly regulate gene expression by simply supplying chemical inducers. In most research projects, it has been shown that by using different inducer concentrations, different translation levels could be observed. However, it is still unknown how the chemical inducer concentration affects transcriptional bursting.
In addition to the inducer dependent transcriptional bursting, it is also unclear whether the GC content of the gene of interest will directly influence the initiation rate, elongation rate, or pausing during the transcription. It has been shown that in different organisms, the elongation rates differ. By using our synthetic GOI oin combination with MS2/PP7 system, we could visualize and analyze the promotor state and the elongation rate under identical conditions by using the same concentration of inducer and inserting at the same genomic integration site. This helps to directly understand the dynamic changes caused by varying the GC content of the GOI.
In the future, we intend to use moment-based variational inference for approximate Bayesian estimation of transcription rate parameters from time-lapse observations of the MS2/PP7 system in identical living cells. Utilizing the totally asymmetric exclusion process with extended particle size (l-TASEP) and a switchable promoter state, we model the transcription dynamics in detail. The model accurately describes parameter regimes of high polymerase density, as expected for high GC content. Given the computational intractability of the full model, we investigate principled approximations.

Methods
To test how chemical inducers affect the transcription dynamics, a chemical inducible LexA-ER-AD system was used, combined with the MS2-PP7 system. Before adding the chemical inducer beta-estradiol, LexA-ER-AD is constitutively expressed in the cytoplasm. Beta-estradiol can bind to the LexA-ER-AD estrogen receptor domain, and form a complex causing LexA-ER-AD relocalization, receptor binding and activate transcription through the VP16 domain. By using the LexA-ER-AD system, we can easily control the transcription at any time without toxic effects. Once the transcription starts, the MS2 and PP7 stem loops up- and downstream of the GOI will begin to be transcribed and form hairpin structures. The PP7 and MS2 coat proteins, fused with fluorescence reporters will bind to the specific loop structures and show as a bright spot.
To quantify the number of fluorescence proteins in one spot, an absolute calibration tool using self-assembling nanocages was applied, which has never been tested in S. Cerevisiae. Each monomer of the nanocage was tagged with one or two fluorophores, leading to 60- or 120mers, and was tethered to the outer membrane of the endoplasmic reticulum (ER). To avoid aggregation, an aTC-inducible system was used to control the expression level.

To image all the dynamics at a single cell level, we used a microfluidics chip, containing a custom designed cell trap. This allows us to image the same cell over a long time period, supplying fresh media and inducing the cell at any time point.

Results
To visualize the transcription dynamics in living cells, the MS2-PP7 system is crucial, especially the repeat numbers. To ensure that the transcription site can be visualized under a widefield microscope, we used yeast-optimized GFP fused with the PP7 coat protein and mScarlet fused with the MS2 coat protein. We tested different numbers of stem-loops up and downstream of the GOI and found that we could visualize the transcription sites with 24 repeats of PP7 stem loops and 16 repeats of MS2 stem-loops.
Additionally, the absolute calibration using nanocages was successfully established in S. cerevisiae, where the 120mer nanocage has exactly twice the fluorescence intensity compared to the 60mer.

Conclusion
- Chemical inducible LexA-ER-AD system can quickly respond to beta-estradiol
- Stem loops upstream and downstream of the GOI enable analysis of elongation rate
- MS2-PP7 system allows to assess rate parameters of transcription for different inducer concentrations and thus facilitates the analysis of transcriptional bursting
- Absolute calibration applying self-assembling nanocages allows to separate detection noise from system fluctuations

Poster Group 1

Background incl. aims
Mixed-anion compounds are much less explored than monoanionic materials such as oxides. However, the possibility of forming heteroleptic coordination polyhedra can result in significantly different emergent properties and the different anion properties such as charge, ionic radii, electronegativity, and polarizability add new degrees of freedom to control and tune the electronic and atomic structure of materials. We have recently succeeded in preparing Ca_2MnO_3Cl (powder) which adopts a novel structure type. However, obtaining the structure of this new compound was tricky because of the powder's extreme sensitivity to humidity, and because of the presence of secondary phases, which made indexing the powder X-ray diffraction pattern particularly hard.
Methods
Particularly well-suited to the study of nanomaterials, Transmission Electron Microscopes (TEMs) have recently become indispensable in nanoscale crystallography, thanks to major technological advances such as the invention of spherical aberration correctors, the development of fast, sensitive pixel detectors, cryogenic methods, beam precession, etc... which have led to the advent of 3D Electron Diffraction (3D-ED) methods for solving nanocrystal structures. The microscopist now has reliable diffracted intensities at his disposal, enabling him to calculate a structural model ab initio, then refine it on the basis of dynamic theory, thanks to the development and constant updates of dedicated crystallography programs [1-3], or use X-ray or neutron diffraction. He can also compare the resulting structure with atomic resolution images and maps, recorded in parallel in a state-of-the-art TEM. We performed 3D-ED, Z-contrast imaging and Energy Dispersive X-ray Spectroscopy (EDX) to determine the crystallographic structure of the new mixed anion oxyhalide Ca_2MnO_3Cl. Then the structural model was refined using powder X-ray and neutron diffraction [4].
Results
Ca_2MnO_3Cl crystallizes in a novel structure type stabilized by the small ionic radius of Ca and the strong Jahn-Teller effect of $Mn^{3}+$. The resulting structure (9.752 Å × 6.4946 Å × 6.5763 Å, space group Cmcm) contains 1-dimensional chains of MnO4 square planes, with an angle ~120 ° between neighboring planes. At low temperatures, this material adopts magnetic arrangements with ferromagnetic chains coupled antiferromagnetically. On applying a magnetic field, it experiences a spin flop transition leading to a magnetic unit cell four times larger than the nuclear one.
Conclusion
We will describe the process leading to the structure of the new oxychloride Ca_2MnO_3Cl, emphasizing the importance of the TEM part to solve ab initio its crystal structure, which opened the doors to the comprehension of its magnetic state.
Acknowledgments

Sub-4-Å cryo-EM structure of apoferritin from a basic 120 keV TEM with thermionic electron gun

Dr. Alexander Neuhaus[1], Dr. Anja Blanque[1], Prof. Dr. Christos Gatsogiannis[1]
[1]Institute for Medical Physics and Biophysics and Center for Soft Nanoscience, Universität Münster, Münster, Germany

Poster Group 1

Background incl. aims: Cryogenic electron microscopy (cryo-EM) has developed into one of the most powerful techniques in structural biology since direct electron detectors (DEDs) became available some 10 years ago. High resolution cryo-EM structures are usually solved with high-end microscopes (e.g. the Thermo Fisher Titan Krios) or well-equipped medium range microscopes (e.g. Thermo Fisher Galcios). These microscopes operate at 200 kV or 300 kV and are equipped with field emission guns (FEGs), DEDs and often with energy filters. Here we analyzed the performance of a current entry-level transmission electron microscope (TEM) with an up-to-date scintillator camera.
Methods: We used a Thermo Fisher Talos L120C with a Gatan 698 Elsa cryo-transfer holder to solve the structure of mouse heavy chain apoferritin (mFTH1) by single particle cryo-EM. This microscope is equipped with a thermionic LaB6 electron source and a Thermo Fisher CETA-F scintillator camera. It does not have an energy filter and is usually used for conventional EM, negative staining EM and only for very basic screening of cryogenic samples.
Results: Here we present a 3.8 Å structure (FSC = 0.143) of apoferritin solved by single particle cryo-EM using a Thermo Fisher Talos L120C. At this resolution the protein backbone is clearly visible and most amino acid side chains produce recognizable densities. To our knowledge this is by far the highest resolution for a single particle cryo-EM structure solved with an entry-level 120 kV TEM. We claim that the decent detector quantum efficiency (DQE) and fast readout speed of the CETA-F camera contributed to achieving high resolution.
Conclusions: A resolution below 4 Å for single particle reconstructions was first achieved about 15 years ago and this resolution range was reserved for high-end and medium range microscopes until now. Our results show that a modern compact and affordable electron microscope can reach near-atomic resolutions in single particle cryo-EM and can be used for much more than analyzing particle distribution and ice quality.

Poster Group 1

Developing new materials for battery energy storage is a significant challenge and a key factor in technology. Among the limitations, new materials for more efficient cathodes have been required, but until now there is no perfect candidate. Sodium ion batteries have emerged as a promising solution, although they still present some disadvantages. In addition to new cathode materials, fabrication routes also need to be improved, and economically and environmentally friendly synthesis routes are desirable. When new candidates were sought, in this study, a promising transition metal oxide cathode for Sodium-Ion Batteries (SIBs) was characterized. The synthesis was performed following a variant of an organic synthesis approach developed within the research group [1]. This method uses metal acetates, and Vaseline (hydrophobic component) and oleic acid (surfactant). To further test this route, different combinations of hydrophilic and surfactants have now been employed to validate the use of this route for the synthesis of the cathodes. Notably, the use of non-polluting, economically and safe reagents and the generation of non-contaminant reaction by-products render this approach environmentally friendly. Moreover, it has shown speeds and efficiency higher than those of conventional dry-milling or sol-gel methods, with significant potential for scalability. Preliminary X-ray diffraction and transmission electron microscopy results confirmed the structure of the materials, similar to those obtained by other fabrications routes.

Methods
To achieve the emulsions studied in this work, metal acetates were mixed for 4 minutes in a shear mixer with the other organic compounds to be tested. Products such as coconut oil or mineral oil were used as the hydrophobic component. Whereas glycerol or, sodium dodecyl sulphate (SDS), were tested as surfactants. The achieved emulsion was heat treated for 10 hours at 900 ° C. The crystallinity of the obtained Na compounds was studied by X-ray diffraction (XRD) and the microstructure, morphology and size of the particles as well as the composition by (Scanning)Transmission Electron Microscopy ((S)TEM).

Results
After sintering, XRD was performed to investigate the structure of the synthesized particles, revealing the formation of the desirable products in all cases, similar to those obtained using other techniques, i.e., the stable P2 structure. Scanning electron microscopy revealed hexagonal-shaped particles, with sizes consistent with those in the literature [2]. EDS mapping in STEM mode was used to corroborate composition and the homogeneous distribution of elements which the particles.

Conclusions

In summary, the use of economical and common products to fabricate cathodes following this organic route is a suitable and environmentally friendly technique as well as a scalable route, while drastically decreasing mixing times down to a few minutes. Furthermore, the use of organic products guarantees that the side products are non-contaminant.

Poster Group 1

LiNi1-x-yMnxCoyO2 (NMC) belongs to a class of layered oxide materials renowned for their solid energy storage performance, making them ideal for use as cathodes in lithium-ion batteries. NMC's structure consists of a two-dimensional layered arrangement where lithium and transition metal ions layers alternate, affecting how lithium ions move from the bulk to the surface within the crystal structure. These materials have already reached the stage of commercial performance with Tesla currently utilizing the NMC622 ($LiNi_{0.6}Mn_{0.2}Co_{0.2}O_2$) formula. However, the performance of NMC cathodes tends to degrade with battery cycling, which is linked to structural deterioration of NMC, although the precise degradation mechanisms remain poorly understood. To explore the performance and structural integrity of NMC cathodes and to understand the directional transport properties of Li ions, we created a thin film model cathode system using NMC111 ($LiNi_{0.33}Mn_{0.33}Co_{0.33}O_2$).

NMC111 thin films were grown on $SrRuO_3$/0.5% wt. Nb-doped $SrTiO_3$ (SRO/Nb) substrates with varying surface terminations by means of the pulsed laser deposition (PLD) technique. X-ray diffraction was used to confirm their epitaxial nature, showing distinct out-of-plane orientations (104), (118), and (003) corresponding to the (001), (110), and (111) substrate orientations. Detailed microstructural analysis through conventional and high-resolution transmission electron microscopy (TEM) showed twinned domains in films on (001) and (110) SRO/Nb substrates due to angled layer growth, with no twinning observed on the (111) SRO/Nb substrate. Electrochemical behavior of the produced thin films with different orientations was tested via galvanostatic cycling at different cycling rates. It revealed that crystal orientation markedly influences NMC's electrochemical performance, especially at higher charge and discharge rates, highlighting the anisotropic nature of lithium ion movement within NMC.

Background: With a growing demand of viral products for gene therapy and as oncolytic agents, understanding the production process of viruses in the biopharmaceutical environment becomes increasingly important. For this, besides controlling classical bioprocess parameters like infectious titer, there is a need for additional methods to characterize the Drug product. Up to now, electron microscopy (EM) remains the only way of directly visualizing cellular processes during virus replication. Here, we aimed at the development of a protocol using high pressure freezing and subsequent freeze substitution for studying manufacturing of VSV-GP, a recombinant vesicular stomatitis virus (VSV) pseudotyped with the glycoprotein of lymphocytic choriomeningitis virus (LCMV-GP).
Methods: Transmission electron microscopy (TEM) and scanning transmission electron microscopy (STEM) tomography were used to characterize VSV-GP replication kinetics. Samples were prepared by high pressure freezing and subsequent freeze substitution. The ultrastructure was compared with the number of viral genomic copies, quantified by qPCR.
Results: High pressure freezing and freeze substitution of chemically fixed VSV-GP infected cells yielded a good ultrastructural preservation. At 8 hours post infection, inclusion bodies and bullet shaped virions budding from the plasma membrane could be observed. TEM and STEM tomograms indicate a colocalization of inclusion bodies and rough endoplasmic reticulum.
Conclusion: A hybrid fixation by chemical inactivation and subsequent high pressure freezing proved feasible for VSV-GP infected cells. Three-dimensional reconstruction of STEM tomograms yields information on VSV-GP replication that is otherwise not accessible by TEM imaging and that improves the scientific understanding of viral genome replication and virion morphogenesis.

ExpertPI: A Comprehensive Tool for Automated 4D-STEM Multimodal Analysis and Method Development

Mr. Petr Mareš[1], Mr. Vojtěch Homola[1], Dr. Robert Hooley[1], Dr. Zhongbo Li[1], Mr. Branislav Hesko[1], Dr. Daniel Nemecek[1]
[1]TESCAN Group, Brno, Czechia

Poster Group 1

Background including aims
The advancement of analytical techniques, particularly in scanning transmission electron microscopy (STEM), necessitates sophisticated tools that can balance ease of use for routine applications and flexibility for method development. The TESCAN TENSOR is a new analytical scanning transmission electron microscope (STEM) that is optimized for electron diffraction experiments, both by unique hardware and software. Specifically, the Expert PI package is an innovative solution designed for development and implementation of new methods and approaches in (multimodal) analytical STEM, 4D-STEM, and 3D-ED techniques.

Methods
ExpertPI is a Python-based library integrated into the TESCAN TENSOR platform, enabling full access to the microscope's functionalities. Unlike the traditional user interfaces that simplify the microscope control and operations at the cost of limited advanced capabilities, the ExpertPI enables direct and unconstrained utilization of all components and modules to their full potential. The core functions of ExpertPI include: i) full instrument control including EM optics, stage, detectors, etc., ii) customizable User Interface with powerful access to all functions via Python console, iii) possibility of integration with third-party libraries, iv) automated data acquisition and processing, v) advanced analytical techniques (such as DPC), vi) customized method development environment, and vii) AI-assisted workflows.

Results
Consequently, such comprehensive control over all electron-optical parameters, beam scanning and acquisition settings, sample stage movements, and synchronized readout of all detectors facilitates unparalleled experimental control, thereby empowering researchers to innovate and refine their techniques, thereby driving forward the capabilities of STEM analysis in material sciences and semiconductor research.

Conclusions
The TESCAN TENSOR therefore represents a highly versatile platform for both routine and advanced 4D-STEM applications. By providing full control over the microscope functionalities and integration with third-party analytical tools, ExpertPI bridges the gap between ease-of-use of routine measurements and the need for advanced method development. This dual capability ensures that the TESCAN TENSOR remains at the forefront of STEM technology, meeting the evolving demands of both application-focused users and method developers.

Poster Group 1

Structural steels suffer from hydrogen embrittlement (HE) at various stages of its value chain. Versatility of steel microstructures necessitates detailed investigation about how HE occurs at various microstructural hierarchies and interfaces. In this study, we examine the role of various boundaries in two key steel microstructures, i.e., direct quench martensitic steel (DQ1600) - consisting >99% martensite, and quench-partitioned martensitic steel (QP1900) - consisting up to 10% retained austenite and 90% martensite.
We used in-house built bellow-devised fatigue testing set up, to examine fatigue behaviour in pressurized hydrogen atmosphere. Fatigue tests of these microstructures were carried out using 100 bar gaseous H2 (pre-charged + in-situ charging) using 0.03 Hz frequency, under ambient condition using 86 Hz frequency, using stress ratio of -1 under variety of stress amplitudes. Tests were carried out until fracture and fracture surfaces of the selected specimens were investigated using scanning electron microscope. Selected fracture surfaces were cut across the cross-section along the primary crack propagation direction. After standard metallographic polishing, we examined the cross-sections using electron backscatter diffraction (EBSD).
We observed up to 3 orders of deterioration in fatigue life under the influence of 100 bar H2 environment compared to ambient atmosphere in both the steel microstructure. Effect of these microstructures on the fracture events, during HE, is widely different. In ambient conditions as well in pressurized N2, both steels demonstrate similar fracture behaviour, depicted by occurrence of fatigue striations. In hydrogen, on the other hand, DQ1600 steel shows prevalent plasticity mediated intergrannular (IG) fracture, whereas, QP1900 steel exhibits dominant quasi-cleavage (QS) transgrannular (TG) fracture event. Image analyses from the cross-section of the selected samples indicate that depth of secondary cracks (SCs) at 1 mm from the initiation point is twice in case of DQ1600 steel compared to QP1900 one. EBSD-assisted analyses in determining the contribution of various boundaries towards SCs propagation suggests that compared to ambient condition, in case of HE, SCs activated along different lath interfaces in both steels. Using Kurdjumov-Sachs relationship, we showed that in case of DQ1600 steel subjected to HE, block boundaries dominated the fracture events; whereas, in case of QP1900 steel, the sub-block boundaries and lath interface fracture were more prevalent.
In conclusion, local plasticity mediated decohesion, also known as hydrogen induced local plasticity (HELP) mediate hydrogen enhanced decohesion embrittlement (HEDE) is observed to be more dominant in DQ1600 steel compared to QP1900 steel, in which decohesion is more prevailing at microstructural hierarchs.

Poster Group 1

The development of soft X-ray emission spectrometer (SXES) significantly enhances the capabilities of scanning electron microscopy (SEM) in elucidating the electronic structure of material [1]. In SEM, the primary electron beam excites inner electrons of the sample, resulting in the emission of X-rays due to energy transitions as electrons move from higher to lower orbitals to stabilize the sample. For detecting soft X-rays, a mirror and diffraction grating are employed to focus and guide the X-rays to a CCD camera within the SEM, enabling subsequent signal analysis [2]. Soft X-rays, originating from electron transitions from the valence band to the core level, provide valuable information about the bonding energy states, such as the 2s, 2p electrons from carbon. This makes SXES a promising tool for analyzing energy materials. In 2024, the installation of a new JEOL IT-800 SEM in Tumint-Energy Research GmbH, equipped with SXES, will support our efforts to characterization electronic structure of various materials. With an energy resolution 0.3 eV and the non-destructive nature of the technique, SXES holds potential for analyzing a wide range of energy materials.
Electron energy loss spectroscopy (EELS) is well-established for detecting the density of states (DOS) from the conduction band. The combination of SXES with EELS provides electron microscopists with a comprehensive approach to analyzing the total electronic structure of materials. Our goal is to integrate these two methods to gain a deeper understanding of the electronic structure of different materials.
We utilized two samples for the preliminary assessment of SXES determination. Fig.1(a) shows the SEM image of diamond crystals on a silicon wafer. Fig.1(b) presents the soft X-ray results: the black curve responds to the diamond sample, while the red curve represents soft X-ray obtained from carbon tape. A notable small peak in the circled area of Fig.1(b) distinguishes the diamond sample from the carbon tape successfully.

Structural studies of the cross-link mutant, ABC transporter BmrA by cryo electron microscopy

Sepideh Valimehr[1], Margot Di Cesare[2], Elise Kaplan[2], Jean-Michel Jault[2], Cédric Orelle[2], Eric Hanssen[1]
[1]Ian Holmes Imaging Centre and Department of Biochemistry and Pharmacology and ARC Centre for Cryo-Electron Microscopy of Membrane Proteins, Bio21 Institute, University of Melbourne, Melbourne, Australia, [2]Bacterial Nucleotide-Binding Proteins Team, Molecular Microbiology and Structural Biochemistry (MMSB), UMR 5086 CNRS/University of Lyon, Lyon, France

Poster Group 1

ATP-binding cassette (ABC) transporters are the membrane proteins that use the energy from ATP hydrolysis to undergo some conformational changes and transport a variety of substrates across biological membranes. The flexible nature of these transporters enables them to adopt various conformation, hence accommodate different substrates. Certain ABC transporters provide multidrug and antimicrobial resistance in cancer cells and pathogenic microorganisms.
These transporters mainly function by alternating between inward-facing and outward facing conformations. ATP binding creates an outward-facing conformation that facilitates drug release, while ATP hydrolysis resets the transporter to its inward-facing conformation. The opening and closing conformation of the nucleotide-binding domains (NBDs) directly cause movements in the transmembrane helices, leading to changes in the substrate-binding pocket. Various degrees of the opening and closing of the nucleotide binding domain has been reported.
Although the amount of the structural information has been increased over the past years, there are still some missing information.
To study the effect of the separation of the NBDs on catalytic cycle, we introduced a Cysteine near the C terminal of the NBD. The structural impact of the mutation on conformational changes of the transporter was investigated by cryo electron microscopy. The mutant did not affect the function of the BmrA and there was no structural difference between mutant and WT BmrA. Two structures were highly similar, showing intermediate opening between their NBDs while their C-terminal extremities remain in close proximity. This data suggests that the NBDs of BmrA function with a tweezers-like motion.

Poster Group 1

Background incl. aims
Functional oxides are ubiquitous and exhibit a wide range of electric, magnetic, optical, and structural properties. Controlling the defects and interfaces in thin-film devices is the new challenge in multifunctional oxides. Antiphase boundaries are the interfaces between two crystallographically identical regions with shifted phases. Based on previous studies, the correlation between the existence of antiphase boundary and decreased saturation magnetization in oxides has been discussed [1]. Due to the resolution limitation of magnetism measurement, it is difficult to investigate the structure-property relationship at high spatial resolution.
Methods
EMCD, first experimentally verified by Schattchneider et al. [2], is a magnetism measurement method in a transmission electron microscope and is confirmed with the ability to reach spatial resolution better than 2 nm using a convergent beam [3]. This significant breakthrough enables us to study the magnetic properties of interfaces and boundaries on the nanometer scale. In the meanwhile, our group has developed site-specific EMCD [4] and atomic plane resolved EMCD [5] in complex oxides such as spinel and double perovskite.
Results
Intensity analysis of antiphase boundary (APB) in HAADF (high angle annular dark-field imaging) STEM (scanning transmission electron microscopy) images suggests that only half of the octahedral interstices are occupied at the rock salt structure interlayer of a new type APB in $NiFe_2O_4$ with a relative translation of (1/4)a[011]. High-spatial-resolution EMCD has been used to demonstrate experimentally reductions of ~46.8%±8.2% and ~38.8%±14.5% in the EMCD strengths of Fe and Ni in APB, respectively, compared to perfectly ordered $NiFe_2O_4$ [6]. DFT and dynamical diffraction calculations suggest that the reduced EMCD strengths result from the fact that Fe ions at the APB interlayer are antiferromagnetically coupled with each other. In contrast, Ni ions show a significant decrease in magnetic moment as a result of the formation of low-spin state Ni^{4+} (d^6) ions.
Conclusion
Our combined approach of using element-specific EMCD under high-spatial-resolution and first-principles calculations to resolve and identify the atomic structure and magnetic coupling of an individual APB in spinel ferrite is applicable to studies of a broad spectrum of other defects in magnetic materials.[7]

Unveiling the Mechanisms of Structural Reconstruction and Magnetic Evolution in NiFe2O4 During Phase Transition

Dr. Qi Wang[1,2,3], Prof. Xiaoyan zHONG[1,2,3]
[1]Department of Materials Science and Engineering, City University of Hong Kong, Hong Kong, People's Republic of China, [2]City University of Hong Kong Matter Science Research Institute (Futian), Shenzhen, People's Republic of China, [3]Nanomanufacturing Laboratory (NML), City University of Hong Kong Shenzhen Research Institute, Shenzhen, People's Republic of China

Poster Group 1

The phase transition from spinel to rock salt structure has significant implications for information storage and energy conversion applications. Previous studies have employed various techniques, such as X-ray diffraction (XRD), neutron scattering, and X-ray absorption spectroscopy (XAS), to investigate the mechanism and pathway of this transition.[1] However, due to technical constraints, a comprehensive understanding of the transformation of local structures during this transition remains elusive, particularly regarding how local lattice and chemical environments influence the process. Moreover, the role of local structural order and chemical environment in this transition process has not been fully elucidated.[2] To bridge this knowledge gap, our study utilizes advanced transmission electron microscopy (TEM) and electron energy loss spectroscopy (EELS) techniques to monitor atomic migration and electronic structure alterations in real-time during the phase transition. By employing TEM and EELS, we aim to provide new insights into the mechanism and pathway of the spinel to rock salt phase transition, shedding light on the influence of local lattice and chemical environments on the process. These enable us to gain a deeper understanding of the local structural and chemical changes occurring during the transition, which have not been fully explored in previous studies.

Methods

This study employs a combination of advanced scanning transmission electron microscopy (STEM) techniques to investigate the phase transition in NiFe2O4's spinel structure under electron beam irradiation. Specifically, we utilize high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM) and annular bright-field scanning transmission electron microscopy (ABF-STEM) to dynamically observe the migration of Fe atoms within the spinel structure. In addition to the structural analysis, we employ a nanobeam electron magnetic circular dichroism (nanobeam-EMCD) method to observe the variation in magnetic information during the phase transition. This technique enables us to probe the local magnetic properties at the nanoscale and correlate them with the structural changes observed through HAADF-STEM and ABF-STEM.

Results

Through the integration of STEM image simulations and quantitative image analysis, we have unraveled the reconstruction dynamics of octahedrally-coordinated Fe/Ni atoms during the phase transition in NiFe2O4. Our findings provide valuable insights into the lattice dynamics and Fe atom rearrangement pathways across varying coordination environments. By tracking the movement of these atoms in real-time, we have gained a deeper understanding of the atomic-level mechanisms driving the phase transition.Simultaneously, we have employed real-time electron energy loss spectroscopy (EELS) to monitor the changes in the chemical valence states of Fe, Ni, and O throughout the various stages of the phase transition. This approach has allowed us to correlate the structural changes observed through STEM with the electronic structure evolution, providing a comprehensive picture of the phase transition process.Furthermore, we have investigated the

magnetism evolution during the phase transition using EMCD.[3] By correlating the structural information obtained from STEM with the magnetic information derived from EMCD, we have gained insights into the interplay between the atomic structure and magnetic properties of NiFe2O4 during the phase transition.[4]

Understanding and modifying cell wall permeability to facilitate cellular nanoparticle uptake

Tommaso Angeletti[1], Grmay Lilay H[1], Søren Husted[1]
[1]PLEN, Frederiksberg, Denmark

Poster Group 1

Background incl. aims
The green transition of agriculture requires an increased crop productivity accompanied by a low environmental impact. However, poor nutrient use efficiency (NUE) and the environmental footprint of conventional fertilizers hamper this process.
The advances within nano-biotechnology have paved the way for the development of next-generation nanofertilizers. Foliar application of nanofertilizers allows farmers to bypass the soil matrix, where a large fraction of nutrients becomes unavailable to the plant due to chemical fixation, microbial immobilization, leaching to water bodies or volatilized to the atmosphere. Moreover, these nanofertilizers can be tailored with a range of smart properties, which enable them to deliver nutrients more efficiently to the plant.
In order to increase the efficiency of foliar nanofertilization, fundamental understanding of how these nanoparticles (NPs) interact with plant tissue is essential. After foliar application, NPs can cross the leaf surface through stomata to reach the apoplast. Here, NPs must remain intact to deliver their nutrient cargo inside mesophyll cells or travel through the phloem towards developing plant tissues. Further cellular internalization of NPs requires passage through the cell wall (CW) and plasma membrane. The CW has a size exclusion limit of 10-20 nm and, thus, it represents a major barrier for NP cellular uptake.
Zwitterions have been shown to loosen the tight cell wall networks of plant tissue in a biocompatible manner. Zwitterions destabilize hydrogen bonds in the cellulose matrix of CW's and thereby enhancing its permeability.
We hypothesize that CW porosity is the major barrier for NP uptake at the single cell level. Therefore, our aim is to utilize zwitterions to enhance CW porosity and facilitate internalization of polyacrylic acid coated manganese oxide (PAA-MnO) NPs.
In this innovative approach, the impact of zwitterions on NPs uptake is investigated in single-cell cultures with a combination of Confocal Laser Scanning Microscopy (CLSM), Transmission Electron Microscopy (TEM) and Laser Ablation Inductively Coupled Plasma Mass Spectometry (LA-ICP-MS).
Methods
For the single-cell experiments, Tobacco BY-2 cells (Nicotiana Tabacum cv. Bright Yellow 2) were used.
PAA-MnO NPs were synthesized according to an established protocol and labeled with Dil dye. PAA-MnO NPs exhibited a hydrodynamic dyameter of ~ 20 nm and a zeta potential of -20 mv.
BY-2 cells were either incubated with only PAA-MnO NPs or pre-incubated (30 minutes) with PAA-MnO NPs and then treated with zwitterions. Cells were imaged with CLSM after several time points of interest. The same experimental setup is repeated to image the interaction between BY-2 cells and Ce spiked PAA-MnO NPs, using TEM and LA-ICP-MS.
Results
BY-2 cells treated only with PAA-MnO NPs for 3 hours exhibited a pronounced fluorescent signal around the cell edges. Additionally, a faint fluorescent signal was also visible within the cells, with a halo-like pattern surrounding the cell nucleus. The intensity of the signal inside the cell increased

when cells were imaged after 4 hours of incubation with PAA-MnO NPs. Interestingly, BY-2 cells incubated with a combination of PAA-MnO NPs and zwitterions for 3 hours were characterized by a strong fluorescent signal inside the cell, localized in the cytosol, around the cell nucleus and tracing actin filaments. A mild fluorescent signal was also observed around the cell perimeters. The intensity of the fluorescent signal inside the cell increased when the incubation time was prolonged to 4 hours.

Conclusions

Our findings suggest that the CW is a significant barrier to NPs internalization as it limits the uptake of 20 nm spherical NPs, while zwitterions facilitate NPs uptake in BY-2 cells. The mechanism of plasma membrane penetration is still unclear and warrants for further investigation. Furthermore, CLSM, TEM and LA-ICP-MS are powerful techniques to study the processes of NP internalization at the single cell level.

Poster Group 1

Carbon, as the element of many different forms, is in the center of attention of many physicists for quite some time. In the last decade, carbon science and technology have enlarged its scope thanks to the discovery of 1D and 2D carbon forms (nanotubes and graphene), and the newest 2D materials – MXenes. Numerous technological applications are rising and will still arise in the foreseeable future, from these newly discovered carbon forms. Indeed, the development of these new materials and nanostructures requires the emergence of new surface-sensitive techniques for their characterization. As regards the surface sensitivity, the ultra-low-energy electron microscopy/spectroscopy can become a very powerful tool for the true examination of these atom-thin materials, capable of confirming physical phenomena predicted to occur on their surfaces. The advantage of modern commercial scanning electron microscopes is the possibility to enable imaging and analysis by low-energy electrons even at very high magnification.

Nevertheless, the real surface studies of 1D and 2D nanomaterials in microscopes equipped with selected spectroscopic techniques are not common so far, which is due to significant problems associated with the sample contamination under the electron beam. Since the specimen contamination increases with increasing of the electron dose and decreasing landing energy, specimen cleanness is a critical factor in obtaining meaningful data by low-voltage SEM/STEM. A range of various surface cleaning methods can be applied to selected samples. Typical cleaning methods, such as solvent rinsing, heating, bombarding with ions, and plasma etching have their limitations. Even a small amount of hydrocarbon contamination can severely impact the results obtained with low-energy electrons. During the scanning of surfaces by electrons, the image usually darkens because a carbonaceous layer gradually deposits on the top from adsorbed hydrocarbon precursors. This effect is called electron stimulated deposition. The surface diffusion of hydrocarbon molecules around the irradiated area serves as a source of additional precursors responsible for an even darker frame of the contaminated field of view. On the other hand, the effect of electron stimulated desorption occurs at the same time, especially at low energies. So, the fundamental question arises, whether the deposition of desorption will dominate, which depends on parameters settings in SEMs. We are using the slow electrons to electron-induced in-situ cleaning, which is gentle, experimentally convenient, and very effective for a wide range of specimens.

Detailed knowledge of mechanisms of electron scattering and its practical consequences for very low energies are of prime importance for not only measurement techniques but also development of new
materials for next-generation electronic devices. Determining inelastic mean free path (IMFP) of electrons in bulk materials is an ongoing topic in spectroscopy. Information on IMFP for very low electron energies, $E \leq 100$ eV, is not satisfactory and it is often missing in case of 2D materials, which are promising in the semiconductor industry. Low thickness of 2D crystalline materials motivated us to develop the unique UHV device analyzing samples via transmitted electrons in a standard

microscopic regime (energy range 0 – 5 keV), and also via time-of-flight (ToF) method (focusing on energy range E ≤ 300 eV). [1]

Graphene is one of the most well-known 2D materials, it is lightweight and strong, and its other unique
properties such as excellent electrical and thermal conductivity and transparency make it an ideal candidate for study at very low energies in the transmission mode of our device. We performed experiments with multilayered graphene to obtain electron energy loss spectra (EELS). Both plasmon peaks (π and π+σ) are present in the measured spectra for 2 layer and 3-5 layers graphene samples (Figure 1). The position of the plasmon peaks increases with both the number of layers of 2D samples and the momentum transfer value [2, 3]. The experimental EELS data are used to derive IMFP values. The measured data are supported by simulated momentum-resolved EELS spectra using many-body perturbation theory (Yambo code), on top of density-functional theory (DFT), Quantum Espresso [4].

We are focusing on the precise characterization of advanced 1D and 2D carbon-based nanomaterials (mainly graphene) and comparing the obtained data with theoretical DFT simulations. Moreover, we also examine possible surface damage by low-energy electron irradiation, which is a very important parameter in the electron analysis. We are using the low- and ultra-low-energy electrons for in-situ cleaning and even for already observed possible structure recovery. The influence of electron irradiation on sample quality (recovery/damage) is studied by Raman spectroscopy in detail.

Background
Knowledge of arthropod development is important for understanding morphogenesis, comparative embryology and the application of these concepts in various fields of bioscience. The processes of morphogenesis and differentiation during embryonic and postembryonic development of an organism are complex and interdependent at all organisational levels, which is crucial for the establishment of the functions of individual organs. The analyses of samples of isolated organs and of intact animals complement each other, particularly in terms of understanding the 3D structure at different levels, and require the combined use of complementary imaging techniques: micro-computed tomography (micro-CT), histology, fluorescence labelling and various electron microscopy methods, including array tomography (AT) and transmission electron microscopy (TEM) tomography. In addition, the study of developmental processes demands the analysis of temporally sequential developmental stages, which range in duration from a few hours to a few days. The basis for an integrative study of developmental processes is the establishment of a staging system for the species investigated. Accordingly, the first aim of our studies is to comprehensively characterise the morphology of the developmental stages in the investigated crustacean species. Next, in the context of comparative studies of arthropod development we aim to study morphogenesis of the digestive system and the integument in detail, focusing on the differentiation of epithelia, that is crucial for shaping of the organ and establishment of vital functions.
Methods
The morphological characterization of developmental stages in the crustacean species (Porcellio scaber and Asellus aquaticus) was performed by imaging of living organisms (embryonic and postembryonic stages) by light microscopy and fluorescence labelling of cell nuclei in fixed whole-mount embryos. To study morphogenesis of selected organs and differentiation of epithelia, the samples of P. scaber mid- and late-stage embryos, postembryonic stages (marsupial and postmarsupial mancae) and adults were analysed using micro-CT, histology, fluorescence labelling of selected structures and electron microscopy. For micro-CT imaging whole animals were chemically fixed and dried, and after imaging the segmentation of the digestive system was performed. Histological and ultrastructural analysis were performed on semithin and ultrathin sections, respectively, prepared from chemically fixed, dehydrated and resin-embedded samples of whole organisms or isolated organs.
Results and conclusions
Morphological analysis of sequential developmental stages is currently being used to characterise embryonic development of a freshwater crustacean A. aquaticus, a model organism in various fields, notably ecotoxicology and evolutionary ecology. The morphological characteristics of intact embryos and mancae (postembryonic stages) were analysed by light microscopy each day of the development. Fluorescence labelling of nuclei is particularly suitable for the analysis of early embryonic development, when the arrangement of cells follows a well-defined pattern (Fig. 1A). According to the main morphological modifications, the development of A. aquaticus was divided into 10 embryonic stages, the stage of marsupial manca and the stage of postmarsupial manca (Fig. 1B, C).

During the formation of the integument, gut and digestive glands the differentiation of epithelial tissues was described in P. scaber, including changes in cell shape and ultrastructure. Using micro-CT, we obtained 3D morphology data of the digestive system in intact organisms of distinct developmental stages (Fig. 2A). Data on the changes in epithelial cell shapes in different organs during development were obtained by analysing semithin sections (Fig. 2B). The elongation of the invaginated foregut and hindgut until they fuse into a single digestive tube and the gradual incorporation of the yolk into the developing digestive glands in embryos, as well as the differentiation of the gut regions in postembryonic stages, were clearly visible. At the ultrastructural level, the processes of cell junction differentiation, apical and basal plasma membrane remodelling, and apical extracellular matrix (cuticle) formation were characterised by transmission electron microscopy (Fig. 2C), supplemented with AT for the 3D context of the cell junctions. The combination of the described imaging analyses provides a broad spectrum of information on the structure of individual cells, tissues and whole organs at the same developmental stage in the context of the whole organism. This allows us to relate modifications in detailed cell ultrastructure and tissue differentiation to morphogenetic processes at the organ and organism level during development.

Li-rich metal oxide cathode materials for Li-ion batteries, such as Li1.2Ni0.13Mn0.54Co0.13O2 can make use of the redox reaction of oxygen anions and transition metal (TM) cations, delivering superior capacities of over 250 mAh/g, much higher than the conventional metal oxides. However, fading in the capacity and voltage and the sluggish kinetics are significant problems for the Li-rich oxides1,2. Understanding the Li+ ion diffusion pathway is crucial for understanding the sluggish kinetics in anionic O2- redox. Li diffusion within the alkali layers undergoes a well-known, low-barrier octahedral-tetrahedral-octahedral (o-t-o) pathway3, however, it is less clear how Li diffuses in and out of the TM layers, particularly given the complex structural rearrangements which take place during O2- oxidation.

Here, we perform electron ptychography and simultaneous annular dark field imaging to directly visualise the Li in Li1.2Ni0.13Mn0.54Co0.13O2. At the end of the TM-oxidation region and before the high voltage O oxidation plateau, we observe Li occupying alkali-layer tetrahedral sites on opposite sides of the TM layers, forming Li-Li dumbbell configurations. The presence of Li at these tetrahedral sites is demonstrated by mathematical processing of the quantitative ptychographic phase contrast, see Figure 1. Density functional theory (DFT) calculations support the observation showing that tetrahedral Li-Li dumbbell configurations are lower in energy than corresponding tetrahedral TM configurations. We also observe the in- and out-of-plane TM migration as well as a partial phase transition from O3 to O1 stacking. In the O1 stacking phase, tetrahedral Li is absent, consistent with our DFT calculations indicating the O1 phase is not thermodynamically stable to accommodate tetrahedral Li. Upon further Li deintercalation to 4.8V, most tetrahedral Li is removed and we only observe a small amount of residual tetrahedral Li. After discharging to 2 V, we do not observe the reformation of tetrahedral Li but observe permanently migrated TMs occupying the alkali-layer sites. These migrated TMs may suppress the Li re-population of some vacant TM-layer octahedral sites by disfavouring Li occupation of the face-sharing tetrahedral sites. To maintain the maximum number of accessible tetrahedral Li sites and minimise the blocking of tetrahedral Li diffusion pathways, strategies to mitigate the irreversible TM migration and the O1 phase change should be employed.

Figure 1 Quantification of ptychographic phase contrast of Li1.2Ni0.13Mn0.54Co0.13O2 at a charging state of 4.45 V. (a) Ptychographic phase image marked with the alkali-layer tetrahedral sites showing

contrast. The scale bar is 0.5 nm. (b) Squared phase image by squaring the ptychographic phase contrast in (a). The squared phase values around each atom are integrated using Voronoi cells to obtain the integrated squared phase (ISP). The ISP values at the alkali-layer tetrahedral site (AKtetra) and TM-layer octahedral site (TMoct) define an ISP ratio between these values. Two DFT models are used to simulate the ptychographic image and deliver the ISP ratios: (c) tetrahedral Li (Tetra_Li) model with Li ions at the tetrahedral sites. (d) tetrahedral Ni (Tetra_Ni) model with Ni ions at the tetrahedral sites. In the schematic representations of the models, grey is Ni, purple Mn, blue Co, red O and green Li. The ISP ratios calculated from the collected image in (a) and simulated images of the two DFT models within a range of thicknesses are compared in (e) and (f).

Background
Iron (Fe) alloys are fundamental to various industrial applications due to their diverse mechanical properties and structural versatility. Understanding these alloys' grain structure and crystallographic characteristics is crucial for optimizing their performance. Here, a newly developed laboratory-based Diffraction Contrast Tomography (LabDCT) was used for non-destructive three-dimensional grain mapping and crystallographic analysis of pure iron. LabDCT, within a commercial laboratory X-ray microscope (Zeiss Xradia 630 Versa), uses a synchrotron-style tomography detection system and, combined with conventional absorption tomography, enables analysis of defects, deformation, grain growth, and phase transformation. This study aims to evaluate the efficacy of XRD-CT in characterizing pure iron, comparing the obtained grain and crystallographic data. The aim is to use the data from pure iron as a reference point for the future characterization of more complicated Fe alloys. To validate the results obtained from LabDCT, this study also employs 3D Electron Backscatter Diffraction (EBSD) tomography on the same volume. This comparative analysis seeks to highlight the potential advantages and limitations of LabDCT, advancing its application in material science and industrial contexts.
Experimental Method.
A cylindrical piece of pure iron with a diameter and height of 450 µm and 1800 µm Lab-based Diffraction Contrast Tomography (DCT) scan and X-ray absorption tomography were performed using the Zeiss Xradia 630 Versa Micro X-ray Computed Tomography (Micro-XCT) system. A helical phyllotaxis Lab DCT (HP-DCT) scan was used to cover a larger field of view. The DCT Scan was performed using an accelerated voltage of 100 kV, a power of 14 W, A letterbox aperture of (375 µm × 375 µm), DCT 4X objective detector with 2.5 mm x 2.5 mm detector beam stop to block the transmitted X-rays. The specimen was rotated 360°, over which 181 projections with an exposure time of 60 s per projection were collected. To Satisfy the Bragg condition, the source and detector were positioned within an equal distance from the sample. A helical scan was used to cover a larger field of view. For serial sectioning tomography, a dual-beam TFS Helios G5 Xe PFIB system was employed. The sectioning and EBSD scans were carried out under the following conditions and controlled by the FEI Auto-slice-and-view software. The slice thickness was set to 2 µm, and EBSD was collected every other slice for a final z-resolution of 4 µm. A current of 0.2 µA was used for slicing the block, and a 5° rocking mill was used to prevent curtaining effects. 2D EBSD maps were collected at 20 keV with a current of 13 nA using an Oxford Symmetry detector and the Aztec control software. Each EBSD map covered the entire sample face with indexing at 4 µm step size to provide approximately cubic voxels for the 3D reconstructions. In total, 75 individual slices were collected on a sequence of X-Y planes.
3D Reconstruction

To reconstruct the DCT data and grain mapping, version 3.2.5 of the data reconstruction software, GrainMapper3D by XnovoTech® was utilized. Importing the raw data, thresholding, alignment, and clean-ups, were all carried out using DREAM.3D software to reconstruct the EBSD-FIB Tomography data. Following the reconstruction, 3D datasets were visualized using Dragonfly Pro and ParaView software.

Results

Fig 1a shows the DCT-reconstructed 3D volume of the pure iron and the three 2D cross sections of the grains in the XY, XZ, and YZ planes. Fig 1 b illustrates a 3D-EBSD reconstruction of the volume corresponding to the top 300 µm of the sample. To match the EBSD and DCT results, a slice-by-slice observation was carried out to reveal the internal microstructure of the material. The 3D variation of the grain morphology and crystallography was precisely tracked through the entire volume of the material using both 3D-EBSD and DCT datasets. After identifying the corresponding 2D slice in the lab-based DCT dataset, comparisons were made between lab-based DCT and EBSD techniques in terms of grain size, shape, and texture. A grain-by-grain comparison of the DCT and EBSD data is shown in Fig 1C. Although the LabDCT effectively determined the center of the mass position and large grains' shape, the EBSD data showed more accuracy in terms of the grain boundaries and grain shapes and detection of smaller grains. Furthermore, the DCT method was able to image larger volumes in a shorter time.

Conclusions

The quality of the 3D grain maps of pure iron obtained with LabDCT and 3D FIB-EBSD was compared in terms of grain size and shape. The centre of the mass position of grains in DCT was found very close to 3D EBSD. The grain size and number of grains in DCT were underestimated compared to the grain size obtained in the EBSD. The grains in the EBSD image are more complex than the DCT grains due to the higher resolution of the EBSD method. Overall, a promising agreement was observed between the DCT and EBSD data.

Poster Group 1

Background

Nature-inspired nanopillar surfaces have been shown to kill surface-attached bacteria by physical means, providing a novel route to potentially control bacterial colonisation on implant surfaces and thus combat implant-related infections. It is proposed that structural damage to the bacterial cell wall kills bacteria as they attach to the nanopillars[1,2]. However, more than a decade since this concept was introduced, the precise mechanism by which bacteria are killed remains an open question[1-4]. Using fluorescent staining, damage to the cell wall is predicted to happen at a single time point after the interaction. However, light microscopy cannot visualise damage to the cell wall, while traditional electron microscopy (EM) techniques associated with sample processing cannot characterise hydrated samples and may introduce artefacts during processing. This work aims to enable the native interaction between bacteria and nanopillars to be visualised at nanometre resolution and so better understand the bactericidal mechanism by establishing a cryo-correlative workflow to characterise the bacterial cell wall interacting with the surface nanotopography while maintaining a hydrated environment[5]. Here, we discuss our assessment of different vitrification techniques and different cryo-microscopy techniques to characterise bacteria within a hydrated state.

Methods

The project used silicon (Si) and titanium (Ti) as test substrata and Escherichia coli as a model bacterium to develop the workflow. Freshly grown bacteria, diluted into PBS, were incubated for 30 minutes on the test substrata at the room temperature. Samples were then vitrified using different techniques: 1) liquid nitrogen slush freezing; 2) plunge freezing (PF); or 3) high pressure freezing (HPF). Both fluorescently-labelled and non-labelled bacteria were vitrified by PF and imaged by cryo-SEM to identify surface-attached bacteria. Single bacterial cells in HPF samples were identified for further analysis after screening under cryo-fluorescence microscopy. Single bacterial cells were lifted using cryo-FIB/SEM and placed onto TEM grids for cryoET. After polishing the lamella, the presence of bacterial cells was confirmed using cryo-fluorescence microscopy.

Results

Slush frozen samples could allow the visualisation of surface-attached bacteria with minimal sample preparation. Both Si and Ti samples were successfully vitrified for cryoSEM. However, the technique could not be used for further investigations as the workflow was not set up for sample transfer between different microscopes. PF and HPF resulted in vitrification of the water layer on the substrate. Bacterial cells were not visible under cryoSEM when vitrified by HPF or PF as they were buried under the surface of the liquid phase. Therefore, bacteria could only be identified when they were fluorescently labelled. Some of the PF samples showed ice crystals as blotting was not optimal. Vitrification of samples by HPF was more reproducible without ice crystal formation. However, finding and isolating individual bacterial cells for further analysis was a challenge with both techniques. Therefore, cryo-fluorescence is an essential step in this workflow. For HPF samples, estimation of depth was a challenge as the test substrate surface could not be accurately measured on the micrometer scale under the cryofluorescence microscope. When a bacterium was selected in the XY plane, it was not necessarily attached to the substrate. This could only be verified after lift-out of lamella, followed by cryo-fluorescence imaging.

Conclusions

Nitrogen slush freezing is a rapid way of vitrifying the sample and suitable for cryo-SEM to study the morphology of bacterial cells interacting with nanopillar topography. Both HPF and PF are promising techniques to vitrify samples with bacteria attached to the substrate. However, identification of individual bacteria attached to the substrate is a challenge.

Poster Group 1

Background
Detailed knowledge of the dynamic nuclear architecture is indispensable for understanding important nuclear functions such as DNA replication and repair, RNA synthesis, maturation, and transport. These processes occur in non-membrane chromatin-containing domains. Generally accepted opinion is that chromosomes reside in a certain area of the nucleus known as the chromosomal territories (CT). On the other hand, there is still disagreement over the interchromatin compartment, which is the DNA-free or DNA-poor nuclear region surrounding each individual CT. Our volume electron microscopy (EM) study set out to examine the distribution of DNA and chromatin inside the nuclear region, taking into account its extensive organization and functional role.

Methods
Light microscopy and fluorescent labels can provide an estimate of chromatin compaction and organization. For an understanding of the structural and functional organization of the cell nucleus in higher resolution, analysis of chromosomal domains at the ultrastructural level is essential.
To differentiate chromatin from other, especially, ribonucleoprotein containing structures, in EM, the cells were treated by pre-embedding staining where chromatin is observed as a highly contrasted structure. NAMA-Ur is method based on the extraction of RNA and phosphate groups from phosphoproteins by a weak alkali hydrolysis (NA) which does not affect DNA, followed by blockage of the amino and carboxyl groups by methylation and acetylation (MA). Finally, samples were stained by uranyl (Ur), which can bind to DNA, dehydrated and embedded in epoxy resin. Structural 3D acquisitions were performed using focused ion beam scanning electron microscopy (FIB-SEM). The obtained data was analysed by using Amira, NIS-Elements, and Imaris softwares. Nuclear subcompartments considered for analysis were as follows: perinuclear chromatin, perinucleolar chromatin, intranuclear chromatin, chromocenters, and interchromatin area.
Another analyses, which are currently in process, are comprised of function visualization of chromatin. To reveal the chromatin domains where gene transcription or replication take place, cells were labelled by in vivo incorporation of the nucleic acid precursors marked with halogens such as fluorine or bromine and/or by stable isotope 15N or 13C. Incorporated nucleotides were then observed either by combination of FIB-SEM with time-of-flight secondary ion mass spectrometry (SIMS) or by TEM with nanoscale SIMS (NanoSIMS). Moreover, serial sectioning of labeled cell nuclei is in progress for SEM followed by NanoSIMS as well as for array tomography.

Results
We successfully obtained a 3D datasets of NAMA-Ur-labeled nuclei by FIB-SEM acquisition with sufficient resolution and contrast for further quantification of perinuclear chromatin, perinucleolar chromatin, intranuclear chromatin, chromocenters, and interchromatin volumes.

Conclusion
The results demonstrate that the volume EM approaches performed on mammalian cell nuclei with specifically contrasted chromatin and eventually combining with spectrometry methods offer an extraordinary opportunity for study of nuclear architecture in situ and show great promise for novel achievements.

Poster Group 1

Background
The Orsay virus (OrV) is a non-enveloped, icosahedral virus with a bipartite, positive-sense, single-stranded RNA genome (RNA1 and RNA2). It naturally infects the nematode Caenorhabditis elegans. Previous crystallographic studies have resolved the structure of an OrV-like particle (360 Å in diameter) at a resolution of 3.2 Å [1]. One hundred-eighty copies of the capsid protein (CP) assemble the icosahedral proteinaceous shell in a T = 3 lattice. Additionally, other studies have demonstrated the presence of a pentameric fiber, which may facilitate viral attachment and infection of the host cell [2-3]. Here we aim to elucidate the structure of the wild-type virus and to provide an understanding of its assembly mechanism and role played by the genome in this process.
Methods
Wild-type viruses obtained from the infection of C. elegans were purified, vitrified, and subsequently analyzed by cryo-EM using high-resolution microscopes. RELION, Chimerax, Phenix, and Coot software were employed for map analysis and localized reconstruction technique to study the structure of the fiber and the CP-genome interactions.
Results and Conclusion
We have determined the structure of the wild-type OrV virion by cryogenic electron microscopy to 2.5 Å resolution. The reconstructed 3D electron density, in addition to showing an ordered icosahedral capsid, unravels a previously unreported defined density network beneath the viral capsid that may be related to the interaction between the CP and the bi-partite RNA genome. Our efforts are currently focused on improving the resolution and implementing symmetry relaxation techniques, as well as biochemical techniques that will allow us to structurally elucidate possible sites of interactions between the bipartite genome and the CP and its evolutionary relationship with other RNA viruses. Additionally, we are studying the structure of a pentameric virion-associated fiber and its potential role in host cells infection.

Background
Exploitation of nanotopography found in nature with bactericidal properties was reported a decade ago as an alternative method to combat the emerging threat of bacterial antibiotic resistance.[1],[2] However, a consensus has yet to be reached on the mechanism(s) by which bacteria are killed upon contact with pillar-like nanostructures. Without knowing the mechanism by which the cell wall is damaged, it is unlikely that this concept can be further implemented for real-world applications. Using fluorescent staining, damage to the cell wall is envisioned to happen at a single time point after the interaction. However light microscopy cannot visualise the damage to the cell wall, and serial cross-sectioning and imaging in FIB-SEM can create a pseudo-3D image of bacteria, and is a destructive approach. Our FIB-SEM data shows that bacteria cell wall is in contact with nanopillars at random positions and many nanopillars under the bacterium is not touching the cell wall.[2]-[4]This project aims to investigate the use of lab based X-ray nanotomography to study the 3D volume of bacteria attached on to nanopillar surfaces non-destructively at nanometer resolution.

Methods
The project uses nanostructured Silicon (Si) as test substrate and E.coli as model organism to develop the workflow. Freshly grown bacteria sample diluted into PBS media, incubated for 30 minutes on test substrata and chemically fixed, dehydrated by ethanol series and dried by critical point drying to be compatible for electron microscopy. Then subsamples of 15 µm in size with bacteria centred was isolated and placed on a sharp needle tip using a plasma FIB, as in preparation for nanoCT. These samples are then imaged in Zeiss Xradia 810 nanoCT, with low X-ray energy, with a voxel size of 150 nm.

Results
Micro manipulation of the samples on to a needle top was successfully achieved by plasma FIB. Creating of these sub-samples of 10 µm in size is essential to enable nanoCT characterisation. Ultra-high resolution was not successful, but high-resolution imaging nanoCT data clearly shows the bacterium attached on the top of nanopillars of 50-70 nm in size. As 3D image of bacteria and it's immediate surrounding is visualised by a non-distrructive method, now TEM lamellas can be prepared from the positions where bacterial cell wall is interacting with nanopillars.

Conclusion
Use of plasma FIB/SEM to create subsamples compatible for nanoCT was successful. The analysis of the samples in nanoCT was successful as bacteria and nanopillars could be located using 100 nm voxel resolution. This allows to characterise the overall 3D shape of bacterium when they interact with nanopillars non-destructively. approach to find individual bacteria cells. This approach allows to pinpoint positions where bacterial cell-wall interact with nanopillar surface so that TEM lamellas can be prepared for high-resolution TEM tomography to study the cell-wall damages in detail.

Correlative X-ray and Electron Microscopy Workflow for Investigating Grey Matter Lesions in Multiple Sclerosis

PhD Alexandra Glasmacher-Kober[1], Susann Hesse[1], Prof. Dr. Fred Wouters[1], Dr. Gertrude Bunt[1]
[1]Research Unit Innovative Microscopy Technologies, Institute for Neuropathology, University Medical Center Goettingen, Goettingen, Germany

Poster Group 1

Background: Multiple sclerosis (MS) is a complex neurological disease characterized by a heterogeneous distribution of lesions within the brain, making their investigation challenging. Currently, the treatment of MS primarily focusses on white matter pathology. However, it is increasingly recognized that injuries in the cortex, i.e. grey matter lesions, play a critical role in progressive disease outcome. Unfortunately, these grey matter lesions are poorly understood. In order to gain a better understanding of these lesions and their underlying pathological mechanisms, we pursue an ultrastructural study. We have established a correlative microscopy workflow that combines X-ray microscopy (XRM) and electron microscopy (EM). This workflow enables us to track and analyse the diseased regions in human brain samples throughout the different stages of tissue preparation up to their ultrastructural investigation.

Methods: we apply a correlative multiscale approach based on XRM, scanning electron microscopy, and transmission electron microscopy to analyse MS lesions in human brain samples.

Results: XRM is used to identify the diseased regions during the tissue preparation process for ultrastructural imaging, starting from fixed brain tissue to the final EM samples. Through XRM, we are able to identify lesions in the brain samples. Using a coordinate system, specific regions of interest within resin-embedded EM samples are then targeted for detailed ultrastructural examination by electron microscopy. This targeted approach enables us to directly visualize and analyse the ultrastructural changes of grey matter lesions.

Conclusion: The combination of X-ray microscopy (XRM) and electron microscopy (EM) offers a systematic approach for analysing the spatial distribution and the ultrastructural changes of heterogeneously localized diseased areas.

AI-driven microscopy for analysis of xenotransplantation models

Dr Courtney Wright[1], Professor Deniz Kirik[1]
[1]Brain Repair and Imaging in Neural Systems (B.R.A.I.N.S), Department of Experimental Medicine, Lund University, Sweden, Lund, Sweden

Poster Group 1

Background and Aims
Accurate visualization and quantification of immunohistochemical data is critically important in biological applications, particularly when requiring nuance within disease models and paradigms. Manual and single threshold methods are prone to bias, inaccuracy and are wholly inefficient over a large scale. The increased demand for accurate analysis of high throughput data acquisition becomes even more critical when modelling disease as results can influence the development of treatments and new therapeutics. Therefore, the aims of this work were to develop a highly accurate pipeline for image analysis of xenografted human cells to determine how pathology may develop in Parkinson's disease (PD) mouse models, utilizing AI-driven machine learning to accomplish these aims.
Methods
Immunofluorescent stained mouse tissue grafted with human derived cells were imaged using a widefield slide-scanner solution to train a deep neural network (DNN). Individual slides were loaded and scanned automatically using a 20x overview and target cells manually labelled to create initial training datasets. Of these datasets, 80% were used to train the DNN and 20% used for internal validation. Utilising instance segmentation with the ResNet50/FasteRCNN DNN we generated, this first trained iteration was applied over new datasets for automated tissue and cell detection with manual approval/quality control checks. Additional training and optimisation of the DNN was applied until a level of accuracy and acceptability was reached with low (<5%) errors detected.
Results
All grafts within scanned tissue were able to be accurately detected and cells of interest quantified. Initial training had accuracy at approximately 84% and required alterations to the scanning parameters to ensure high quality input data was used to train and improve the DNN accuracy. The developed DNN was additionally able to provide several critical readouts important for the analysis of pathophysiology as it relates to xenotransplantation models in PD. Area and size of grafts, migration of cells from the injection site, phenotyping and quantification of cells within the graft were able to be automatically detected and accurately analysed with the developed DNN.
Conclusion
Development of this AI driven microscopy solution for analysis of grafted cells within the brain has allowed for greater efficiency, accuracy and decreased bias within this animal model. By developing and training the above DNN, we were able to efficiently and accurately provide robust commentary on large dataset using a mouse model of human disease, improving our confidence in the results. This method could be applied widely to other models and similarly improve the accuracy and efficiency of data analysis as it applied to biological questions and potential downstream therapeutic development.

[2]Chemical Engineering (AVT), RWTH Aachen University, Aachen, Germany

Poster Group 1

Background incl. aims
Replacing conventional high energy consuming chemical syntheses by a carbon-neutral route is in high demand for the future chemical industries. Especially the electrochemical synthesis of ethylene through the reduction of carbon dioxide instead of cracking intermediates of mineral oil at high temperatures allows sustainable value chains with a carbon circular economy [1]. Copper turned out to be the only pure metal that reduces carbon dioxide to products requiring more than two electrons transfers with substantial Faradaic efficiencies like hydrocarbons, aldehydes, and alcohols [2]. In order to prevent agglomeration of nanoparticles and improve adhesion to the substrate material, ionomers like Nafion (perfluorosulfonic acid, PFSA) are added to the ink. The combination of hydrophobic PTFE chains and terminal hydrophilic sulfonic acid groups promotes a homogeneous dispersion of the copper nanoparticles resulting in an overall high chemical activity and serves as a robust binder between the copper nanoparticles and the gas diffusion electrode [3]. However, any variations in the catalyst layers like thickness, porosity, inner network connectivity/tortuosity and conductivity has a significant impact on activity, selectivity and stability of the electrolysis. Therefore, knowledge of the 3-dimensional structure of the catalyst layer is essential for understanding the influence of chosen ink compositions and the resulting morphology of the catalyst layer on the performance of the electrode.
This work investigates the influence of different copper-to-Nafion ratios on the 3-dimensional morphology of the catalyst layer placed on a gas diffusion electrode. SEM panorama images and mCT measurements were used to characterize the homogeneity of the spray coating as well as the network connectivity and tortuosity of copper, Nafion and pores in the catalyst layer.

Methods
Gas diffusion electrodes (GDE) were spray coated with copper-Nafion inks with a loading of 0.5 mg/cm and a Cu:Nafion-ratio of 10 : 1 and 10 : 6, respectively.
SEM data were acquired on a ZEISS Gemini 300, equipped with the EDS detector UltimMax 65 by Oxford Instruments and the software SmartStitch, Version V01.02.13 by ZEISS for generating large panorama images.
Micro-computed tomography measurements (mCT) were acquired with a ZEISS Xradia Versa 620. X-ray voltage was 40 kV, X-ray current was 75.1 mA and the exposure time was 30 s. The field of view was 763.36 x 763.36 µm and the pixel size was 0.7649 µm. The number of total projections was 1201 with a full 360° tomography. The data evaluation was performed with the Dragonfly software, version 2022.2.0.1409 for Windows.

Results
According to the panorama images, the copper-Nafion ratio has a great influence on the morphology of the catalyst layer. Though the loading over the overall GDE is quite homogeneous for both ratios

(not shown in this abstract), a higher Nafion content results in huge cracks of the catalyst layer. A higher Nafion content also seems to cause more agglomeration of the copper particles (see Figure 2) compared to the sample with minor Nafion. Additionally, the pore network is finer dispersed for smaller Nafion contents as the Nafion tends to form a covering layer on the GDE (except for the cracks). A quantification of the copper, Nafion and pores based on the grey scale of the images results in 26% copper, 65% Nafion and 9% pores for a copper-Nafion ratio of 10:1 and in 21% copper, 71% Nafion and 8% pores for a copper-Nafion ratio of 10:6.
In Figure 3 are 3-dimensional mCT images of the samples, which look quite different to the BSE images concerning the homogenity of the catalyst layers. The sample with less Nafion content seems to have an inhomgeneous thickness of the catalyst coating.

Conclusion
The Nafion content significantly changes the morphology of the catalyst layer. Higher Nafion contents result in cracks of the catalyst layer, agglomeration of copper particles and a minor dispersed pores network.

Poster Group 1

Background incl. aims
Precise correlation in correlative light and electron microscopy (CLEM) is crucial for detailed and accurate studies of cellular structures and functions. Super-resolution techniques, such as stimulated emission depletion (STED) microscopy, hold great promise for high-precision localization in CLEM. However, the intense laser illumination required often leads to rapid photobleaching of fluorescent dyes. This rapid bleaching not only limits the duration of imaging, but also reduces the potential for capturing weak signals, ultimately lowering the effectiveness of super-resolution microscopy in CLEM applications.
We investigate the use of cryoimmersion-light microscopy (cryo-iLM) to face this challenge as cryogenic temperatures can significantly reduce photo bleaching [1].

Methods
To evaluate the photobleaching of fluorescently labeled cells, we used a high numerical aperture (NA) cryo-immersion objective (1.3 NA, 63x). At room temperature, living cells were imaged using water immersion. For cryogenic temperatures, plunge-frozen cells were imaged using the refractive index-matched immersion medium HFE 7200, as described by Faoro et al. [2].
Photobleaching was quantified by measuring the average intensity of wide-field images over time under continuous illumination. To assess STED compatibility, we compared the resolution enhancement to confocal acquisition and evaluated STED-bleaching over a series of images.

Results
Our experiments showed a significantly lower bleaching rate at cryogenic temperatures compared to live cell imaging. This was consistently observed for a variety of fluorescent markers, including organic dyes and fluorescent proteins.
In addition, the improved stability at low temperatures allowed for more robust super-resolution STED imaging. Notably, some dyes that were not compatible with STED at room temperature became suitable for STED at cryogenic conditions. By minimizing bleaching, we achieved clearer and more precise localization of fluorescent signals.

Conclusion
Combining both, low temperatures with the high-NA cryoimmersion objective, significantly reduces photobleaching and enables the visualization of weak signals with greater clarity such as fluorescent proteins. By mitigating the effects of bleaching, cryo-light microscopy improves the feasibility of super-resolution STED imaging.

Poster Group 1

Background incl. aims
Self-propagating High-temperature Synthesis (SHS) is a relatively novel and straightforward method for producing advanced ceramics, composites, and intermetallic compounds [1]. The foundation of SHS lies in the ability of highly exothermic reactions to sustain themselves through a reaction (combustion) wave. SHS reactions have also been observed in Ni-Ti multilayer films [2], possessing great potential as an external heat source in various applications, including joining, ignitors, and intermetallic synthesis on the nanoscale. A novel approach proposes to use nanoparticles to achieve similar self-propagating reactions. This concept is particularly promising due to the ease of application of nanoparticles on various surfaces. Core-shell nanoparticles, especially those with a titanium (Ti) core and a nickel (Ni) shell, are of significant interest. This configuration ensures a stable Ni to Ti ratio while the Ni shell protects the Ti core from oxidation. This study presents basic configurations of Ti and Ni nanoparticles and their composite produced by gas aggregation source (GAS) under different conditions.
Methods
DC magnetron sputtering with two planar magnetrons was used to prepare Ti-Ni core-shell nanoparticles and a mixture of Ni and Ti nanoparticles. The sputtering system consisted of a primary gas aggregation cluster source (GAS) for creating Ti nanoparticles (NPs) and a secondary chamber for coating them with a Ni film, producing Ni nanoparticles, or depositing Ni nanoparticles on Ti ones. Ar gas with 99.996% purity was used as the working gas with a pressure of 35 Pa in the Ni and 11 Pa in the Ti chamber. A current of 400 mA on Ni magnetron and a current varying between 100 and 900 mA on Ti magnetron were used. Further details about the experimental setup are available in the work by Hanus et al. [3].
The nanoparticles were deposited onto a glass substrate. The samples for TEM analysis were prepared by depositing the nanoparticles, suspended in methanol, onto a grid with a SiN or lacey-carbon support film. A Jeol 2200FS transmission electron microscope operated at 200 kV was employed in STEM mode. Chemical mapping was done using energy dispersive spectroscopy (EDS).
Results
Pure Ti nanoparticles were prepared in the aggregation chamber (current of 400 mA). Their size is about 40 nm. Their surface is covered by a 3-5 nm thick TiO2 amorphous film, which probably forms during the exposition of nanoparticles to air. Pure nickel nanoparticles form in the secondary chamber (current of 400 mA). Their size ranges between 8-10 nm. A very thin oxide layer also forms on their surface after longer exposure to atmospheric oxide. However, its thickness is significantly smaller (less than 1 nm).
The composite nanoparticles were formed with a current of 100 mA in the GAS chamber for the Ti particle formation and 400 mA on the Ni coating magnetron. They are composed of a 30-40 nm Ti core encapsulated in a 5-10 nm thick Ni shell.
Conclusion

Titanium and nickel nanoparticles for SHS were successfully synthesized using a DC magnetron sputtering technique, which produced particles with a core-shell structure characterized by a metallic core and an oxidized shell. A thick oxide layer forms immediately on Ti nanoparticles, preventing their reactive properties. The oxide layer on Ni nanoparticles forms after longer exposure to atmospheric air, and its thickness is significantly lower. Composite nanoparticles consisting of Ti-core and Ni-shell could be prepared in the GAS with a simple engineering of the Ni/Ti ratio and used for the SHS synthesis.

3D Characterization of Pore Structures in Shaped Heterogeneous Catalysts Using FIB-SEM Tomography

Dr. Aram Yoon[1], Dr. Jaejin Kim[2], Dr. Xiaodan Chen[1]
[1]Shell Energy Transition Campus Amsterdam, Amsterdam, Netherlands, [2]Shell Technology Center Houston, Houston, USA

Poster Group 1

Background incl. aims
Heterogeneous catalysts are crucial for industrial chemical processes, with their efficiency relying heavily on physical and chemical properties across multiple scales. Scaling up the application of these catalysts necessitates a comprehensive understanding of their structures for multiscale design, particularly for industrial applications where powdered catalysts are typically pressed into shaped forms, like extrudates. These extrudates form porous medium where mass transport limitations predominantly govern the reactions kinetics, making the characterization of pore size and distribution critical.
Methods
Direct measurement of pore structures in shaped catalysts is challenging due to the local inhomogeneities and the large size of extrudates (several millimeters) compared to the nanoscale pores. Traditional transmission electron microscopy is inadequate due to its destructive sample preparation and thin sample requirement. To address these challenges, we employed a combination of focused ion beam and scanning electron microscope (FIB-SEM) tomography to achieve high-resolution imaging of the pore structures within catalyst extrudates. This approach enabled us to capture detailed images of pores ranging in size from 50 to 100 nanometers. Using Avizo software, we reconstructed the 3-dimensional microstructure of the catalysts, providing a comprehensive view of pore volumes and their connectivity.
Results
The application of FIB-SEM tomography, coupled with advanced 3D reconstruction, enabled accurate characterization of pore structures within the catalyst extrudates. Our results revealed intricate details of the pore distribution and connectivity, essential for understanding mass transport properties. The 3 dimensional images facilitated precise estimation of pore volumes, enhancing our ability to model and predict catalyst performance under various operational conditions.
Conclusion
This study highlights the importance of advanced imaging techniques in catalyst characterization. By accurately mapping the 3D pore structure, we gain a deeper understanding of the relationship between pore geometry and catalyst performance. These insights are crucial for optimizing catalyst design to ensure efficient mass transport and improved catalytic efficiency at larger scales.

Cryo-Volume Electron Microscopy characterization of chlorophyll deficient microalgae

Phd Student Malene Olsen[1], PhD Maryna Kobylynska[2,3], Professor Poul Erik Jensen[1], Professor Pippa Hawes[4], Professor Roland Fleck[2,3]
[1]University of Copenhagen, Department of Food Science, Frederiksberg, Denmark, [2]Randall Centre for Cell and Molecular Biophysics, King's College London, London, United Kingdom, [3]Centre for Ultrastructural Imaging, King's College London, , London, United Kingdom, [4]The Francis Crick Institute, London, United Kingdom

Poster Group 1

Microalgae are a novel, valuable food source with multiple benefits including high nutritional value, and potentially with a more sustainable production compared to conventional food protein sources such as soybean, corn and meat. Nevertheless, consumer studies reveal that when applied in food the inclusion levels must be kept low, mainly due to the intense green colour of the algae and taste. By using UV-radiation combined with a visual screening process, we have obtained chlorophyll deficient mutants of the two microalgae species: Chlorella vulgaris and Nannochloropsis oceanica.

Characterization and comparison of the algal mutants and wild types with respect to growth kinetics and biomass composition is ongoing. However, light microscopy indicates that the morphology of the pale mutants is very different from the wild types. Therefore, Focused Ion-Beam Scanning Electron Microscopy (FIBSEM) has been applied to describe these morphological differences and to characterize the algal mutants at the ultrastructural level. The FIBSEM is well suited for site-specific sectioning where the FIB milling exposes a surface that can be visualized either with FIB or SEM to examine the microstructure within each layer and the interfacial structure between layers. By collecting ultrastructural data from a large sample volume and in turn interrogated in silico; novel understandings of the interconnectivity between organelle through an entire cell can be deduced. To date, this has only been successfully applied to chemically processed tissue, with their associated artefacts e.g., significant shrinkage, loss of intracellular soluble content and disruption to membrane structure. Non-chemical fixation using low temperature allows cells and tissues to be studied close to their native biological state. This is a major advantage for the characterization of poorly understood ultrastructural changes such as in the novel microalgae mutants generated in our study. To elucidate and compare the cell morphology of chlorophyll deficient mutants and wild type strains of the single celled microalgae Chlorella vulgaris and Nannochloropsis oceanica we have applied cryo electron tomography by controlled milling of vitrified cells using focussed ion beam milling FIBSEM microscopy at cryogenic temperatures (cryoFIBSEM).

By using a novel cryo vEM (cvEM) approach to generate larger 3D volumes than possible with cryoET through high-resolution sectioning in a cryoFIBSEM, we have been able to observe the microalgae strains close to their native biological state. By successfully overcoming the beam sensitivity of the vitrified samples and avoiding heavy metal contrast, as well as addressing significant challenges in generating sufficient signal-to-noise ratio, we have been able to define the ultrastructural details of the algae. This new approach has revealed significant differences in the ultrastructure between the mutants and the wild types including deformation of the thylakoids and reduced volume of the chloroplast.

Optimized Bright Field STEM Imaging for Detecting Molecules absorbed within Zeolite Pores

Yu Xia[1], Tom Willhammar[1]
[1]Department of Materials and Environmental Chemistry, Stockholm University, Stockholm, Sweden

Poster Group 1

Background incl. aims
Zeolites, characterized by their large and regular pores, are utilized to filter target molecules from mixtures, purify effluent by removing pollutants and in catalysis. Atomic resolution imaging of small molecules in pores will contribute to elucidate host-guest interactions between small molecules and porous structures and understand diverse molecular absorption/desorption behaviors in pores. Scanning transmission electron microscopy (STEM) is a powerful technique to capture interpretable atom-scale images, facilitating localized structural analyses. Recognizing the inherent sensitivity of zeolites and molecules to electron beam exposure, low electron dose imaging techniques, including the differential phase contrast (DPC) employing segmented detectors and 4D-STEM using pixelated detectors, have been developed. Pixelated detectors employed by 4D-STEM offer superior electron collection efficiency with fine resolution and high signal-to-noise ratio (SNR) at probe positions[1]. However, pixelated detectors entail higher costs and longer dwell time compared to segmented counterparts. The integrated DPC (iDPC) technique has shown its power in imaging light elements with low-dose conditions. Recently, a newly developed optimum bright-field (OBF) STEM technique demonstrates enhanced SNR relative to iDPC[23] OBF images are reconstructed by combining the images captured by segmented detectors. Each segmented image is weighted by a frequency filter for the contribution to the Fourier component of the reconstructed OBF image, where the frequency filters are built using phase contrast transfer functions (PCTFs) for the segmented detector[2]. Here, the OBF-STEM technique with a custom-made python package is utilized for the efficient detection of molecules within the pores of ZSM-5 zeolite using a four-segmented detector.
Methods
The theoretical framework of the OBF STEM image can be derived from the single side band (SSB) ptychography[4], where the specimen is weakly electron scattering. The exit wave function M(k ,Q) is given by the convolution of the entrance probe wavefunction ψ(k)·ψ^* (k-Q) on the specimen with the pupil function A(k) A^* (k +Q) , where Q is the spatial frequency of the probe at spaced position r on the specimen in Fourier space. Therefore, the PCTF can be calculated by T^* (k)T(k -Q)-T(k) T^* (k +Q) , where T(k) is the aperture transfer function defined as the multiplication of the aperture function with the probe wave function in reciprocal space. In a segmented detector, the STEM image intensity of the i-th segment I_i (r) is described mathematically as ∫I(k ,r) D_i (k)𝑑k, where D_i (k) is the i-th segmented detector response function in reciprocal space and I(k, r) is the inverse Fourier transform of the diffraction pattern (|M(k,Q)|^2). The OBF STEM image is reconstructed by combining the segmented images weighted by frequency filters in reciprocal space, or combining the convolution of each segmented image with a corresponding point spread function (PSF) in real space[2]. For maximizing the SNR of the reconstructed OBF image, the PCTFs in the segmented detector are optimized by incorporating real-valued functions, such as high/low bandpass filters [2]. In this work, a custom-made python package is developed to calculate the PCTFs and the corresponding real-valued functions for OBF STEM image reconstruction. The specimen of ZSM-5 zeolite absorbed pollutants was imaged with the convergence semi-angle of 21 mrad on an aberration-corrected FEI Titan Cubed Themis Z microscope operated at 300 kV. A four-segmented detector was employed to

capture images using a beam current around 4.7 pA and a dwell time of 2 µs per pixel within a collection angle range of 8-42 mrad, with a camera length of 185 mm.

Results

The ZSM-5 with pollutants in pores was imaged along the [0 1 0] direction under a dose rate of 856 e-/Å². iDPC image (Figure a) and OBF image (Figure b) were reconstructed using the same dataset. Compared with the iDPC image, OBF image demonstrates clearer structural details due to its higher contrast and SNR, evident in line profiles and the cropped image (Figure d) from the same area in iDPC and OBF images. The superior contrast and finer resolution of OBF image enable more distinct observation of pollutants (marked by arrows in the line profiles) within pores than that of the iDPC image.

Conclusion

OBF-STEM images were reconstructed using the custom-made python package. This package implements algorithms to compute the PCTFs and the corresponding real-valued filters for image reconstruction. The reconstructed OBF image demonstrates enhanced contrast and SNR, giving clearer discernment of structural features. Importantly, features within the pores of ZSM-5 were distinctly distinguished in the OBF images compared to those reconstructed iDPC images. These findings imply that the OBF technique, employing a high-speed segmented detector, represents a promising approach for low-dose imaging of molecules encapsulated within the pores of zeolites.

Poster Group 1

It was discovered that the light entering a triangle ultramicrotome glass knife from the bottom exits the knife through its cutting edge, forming an oblique light sheet-like illumination that is suitable for side-illumination of the sample block and 3D imaging. Several challenges were successfully managed, and a working prototype of a novel serial sectioning block-face imaging microscope was constructed. The CELS-3D (Cutting Edge Light Source, Three-Dimensional) is a microscope mounted on a commercial ultramicrotome. The CELS-3D has been characterised and applied for three-dimensional imaging of human liver spheroids with a diameter of approximately 500 micrometres. The structure of nuclei and tight junctions has been successfully reconstructed over the full spheroid volume. The formation of bile sinusoids in the central region of the spheroid was identified, which is crucial for modelling hepatitis viral infection in vitro. In comparison, the confocal microscope was unable to image spheroids to a depth exceeding approximately 50 micrometres and failed to detect the sinusoids.
The CELS-3D can be utilised for the three-dimensional reconstruction of fluorescent biological and/or artificial materials, irrespective of whether they are transparent or not. This encompasses a range of applications, including operation biopsies, experimental organoids/spheroids, artificial cartilage, and bone, among others. The CELS-3D can be effortlessly mounted on the top of any commercially available ultramicrotome, and its operation is straightforward and intuitive. It is anticipated that this technology will find applications in the expanding market for 3D microscopy, which is seeking a compromise between sample size and resolution.

Correlative microscopy of graphene with SEM, Raman spectroscopy and AFM

Dr Lok Yi Lee[1], Juliet Biard[1]
[1]Paragraf Ltd, Somersham, United Kingdom

Poster Group 1

Graphene has been speculated to be a suitable material for producing robust and sensitive Hall sensors [1] and biosensors [2] due to its ultra-high carrier mobility. A key challenge however is producing electronic grade, high mobility graphene at scale. Paragraf has realised this by being the first company in the world to produce graphene using our proprietary and commercially scalable growth method, directly onto target substrates without the need of a transfer process, using standard semiconductor manufacturing tools. [3] We cover all aspects of production, from the growth of graphene to processing into final devices, including Hall sensors and graphene-FETs. We also develop in-depth fundamental structural understanding of our graphene to be able to relate to device performance and electrical properties.

When investigating graphene structural features in detail, we employ a number of microscopy techniques to gain a deeper understanding of the features observed. However, as most microscopy techniques are on the micron scale, it is challenging to locate the same feature reliably using multiple techniques. To address this, we employed a relatively simple and low-cost method from [4] of glueing down a TEM grid to our samples to locate the same 30 µm x 30 µm area across the techniques used. We then performed correlative microscopy on graphene on sapphire substrate to understand how different features appear with different techniques, including scanning electron microscopy (SEM), micron-scale mapping with Raman spectroscopy, and atomic force microscopy (AFM). We were able to identify how wrinkles in the graphene appear in the three techniques, and better understand areas that appear as darker contrast in SEM in-lens (SE1) images.

Poster Group 1

Chaperones assist in the de novo protein folding and prevent protein aggregation. One of the most important chaperone families are the chaperonins (Hsp60s), which are organized as two oligomeric back-two-back rings generating a cavity in each ring where the substrate is placed for its folding. The most complex and important of all chaperonins is the eukaryotic CCT (Chaperonin Containing TCP-1) whose structure and the folding mechanism are key for nanotechnological applications.

The main aim of this project is to build a stable synthetic cylindrical structure capable of encapsulating chemical reagents or small proteins. It has been shown that CCT5 is able to self-oligomerize. When compared to the eukaryotic CCT, poly-CCT5 is easier to purify, can be genetically modified in all subunits and allows a more manageable image processing. These capabilities could enable poly-CCT5 to act as a nanocontainer delivering molecules to specific targets.

Our group used negative staining EM to assess the encapsulation of various nanoparticles inside synthetic poly-CCT5. VENOFER, an iron-sucrose coating NP, produced the best results overall and was chosen for Cryoelectron microscopy (CryoEM) analysis. We generated a 3.3 Å 3D reconstruction of the NP-bound poly- CCT5, with the NP presumably held by CCT5 apical domains. As part of this project, we are now focusing our efforts on the design and the structural characterization of three poly-CCT5 mutants, which rearrange the charge distribution on the cavity, to improve nanoparticle internalization and to prevent undesired interactions.

The apoptosome assembly in situ

Calvin Klein[1], Alicia C Borgeaud[1], Michael R Wozny[2], Thomas Lemmin[1], Wanda Kukulski[1]
[1]University Of Bern, Bern, Switzerland, [2]McGill University, Montreal, Canada

Poster Group 1

Background incl. aims
The apoptosome is a large protein complex crucial in initiating programmed cell death (apoptosis). It forms upon initiating apoptosis and recruits procaspase-9 to activate the caspase cascade, eventually leading to the dismantling of the cell. Although experimental structures of the apoptosome are available, the occurrence of the complex has yet to be shown in situ. In vitro, it is a heptameric assembly of the apoptotic protease-activating factor 1 (Apaf1) and bound cytochrome c [1,2]. Using Cryo-Correlative Light Electron Microscopy (Cryo-CLEM), our lab has found that dense meshworks in the cytosol of apoptotic cells correlate with foci of Apaf1-GFP. Our cell biological data indicate that these foci are functional apoptosome equivalents [3]. Interestingly, these foci disassemble when cells survive apoptotic signals, indicating a potential regulatory function. Based on these findings, we aim to uncover the underlying structure of these dense Apaf1 meshworks within cells.

Methods
To further investigate the Apaf1 dense meshwork, we increased our dataset of electron cryo-tomograms of cryo-FIB milled cells. Additionally, we used a modified sample preparation protocol to unroof cells on cryo-EM grids to obtain tomograms of the dense meshwork in a close-to-native environment without needing prior FIB-milling [4]. We are now implementing a computational pipeline to analyse the amorphous meshwork using Rasterized Subtomogram Extraction (RSE), in which subtomograms from a region of interest are sampled in regular intervals, combined with the latest Relion 5 tomography pipeline for subtomogram classification and averaging.

Results
At present, we acquired a dataset of 12 tomograms of cryo-FIB milled cells and 52 tomograms of unroofed cells showing the Apaf1 dense meshwork. In these tomograms, we can outline the dense meshwork corresponding to the Apaf1-GFP signal of Apaf1 foci. Our cell biological experiments show that the assembly is based on defined molecular interactions, indicating a higher-order structure of the meshwork. However, the dense meshwork has a continuous, cloud-like appearance, in which it is challenging to discern the repeating subunits for subtomogram averaging. We, therefore, implement a systematic approach to extract subvolumes, which we will extensively classify and align in many iterations. Furthermore, our cell biology data indicates that caspase-9 plays a role in the assembly of Apaf1 foci. We therefore consider that caspase-9 might be a structural component of the foci.

Conclusion
By Cryo-CLEM we demonstrated that Apaf1 is associated with high-density amorphous meshworks in cryo-electron tomograms of apoptotic cells. These meshworks are notably different from the currently documented, discrete heptameric apoptosome wheel and thus likely represent an alternative in situ apoptosome assembly structure. Moving forward, we aim to reveal the structure of the meshwork at high resolution. We then want to identify the potential meshwork subunits, construct structural models and understand the biological function of the assembly. In particular, we

want to understand the molecular basis of the transientness of Apaf1 foci and whether it serves to regulate apoptosome function.

Morphology-Driven Photothermal Efficiency in Nanostructured Semiconductors

Dr. Maibelin Rosales[1], Dr. Raynald Gauvin[2], Dr. Andreina García[3], Dr. Senentxu Lanceros-Méndez[1,4]
[1]BCMaterials, Basque Center for Materials, Applications and Nanostructures, Bilbao, Spain, [2]Mining and Materials Engineering Department, McGill University., Montreal, Canada, [3]Advanced Mining Technology Center (AMTC), Universidad de Chile, Santiago, Chile, [4]IKERBASQUE, Basque Foundation for Science, Bilbao, Spain

Poster Group 1

Nowadays, nanostructured semiconductor design represents outstanding model material systems for examining how the precise morphology manipulation at the nanoscale allows to fine-tuning their electronic structures to boost a plasmonic effect. Recent advances in designing metal-oxide semiconductor-based photocatalysts with photo-chemical/-thermal dual effects to photo-oxidize water contaminants and water-splitting reactions to produce hydrogen have garnered significant interest[1].

So far, in semiconductors, this dual functionality has often been achieved by doping or creating heterojunctions with external photothermal agents[2] such as carbon-based materials, conjugated polymers, and noble metal-based nanoparticles[3]. In this work, we have demonstrated that the precise morphological control of SnO_2 nanostructures promotes electronic structure changes in the material that impact its band structure and induce structural defects, such as oxygen vacancies, that enhance the density of free charge carriers enabling a plasmonic behavior tuning[4]. Under irradiation, this effect confers autarchic photo-thermal capability to the nanomaterial by generating hot carriers that produce local heating, which is then transferred to the surroundings. This increased temperature improves the mobility of photogenerated charge carriers of the semiconductor and molecular collisions in the medium, consequently boosting its photocatalytic efficiency[3].

This synergistic effect of photo-chemical and -thermal processes in a single system represents a novel approach to obtain high-performance photocatalysts. Herein, we focus on SnO_2 nanostructures, precisely engineered with varying morphologies such as nanoparticles, nanorods, nanosheets, and nanoflowers, synthesized via hydrothermal methods using structure-directing agents at different temperatures that allow for control of the shape. The microstructure, size, and morphology of these SnO_2 nanostructures were analyzed by a Thermo Fisher Scientific Tecnai F20 field-emission (scanning) transmission electron microscope (FEG-S/TEM) operated at 200 kV and a Hitachi High-Technologies SU-8000 and SU-8230 field emission scanning electron microscope (FE-SEM) operated at low voltage. Demonstrating the precise control of synthesis parameters enabled the achievement of desired morphologies with different structural dimensionalities from zero-dimensional nanoparticles to three-dimensional nanoflowers.

Optical and electronic properties were investigated using diffuse reflectance (DRS) and photoluminescence (PL) spectroscopies. The optical band gap energies (Ebg) were determined using Tauc's plots, and the obtained Ebg values exhibited a nanomaterial shape-dependent response. PL analysis was to assess the nature of structural defects and how they can affect their electronic band structure by tailoring the morphology. The strong emission peaks observed in the PL spectra were linked to surface and structural defects such as tin interstitials, dangling bonds, and oxygen vacancies

(OV), which can introduce localized energy levels within the bandgap, affecting their electronic band structure[4].

Tailoring morphology together with the obtained confinement effect at the nanoscale allowed not only the fine-tuning of the electronic structure of synthesized SnO_2 nanostructures but also control over localized surface plasmon resonance (LSPR), critical for generating high-energy hot carriers and enhancing photothermal conversion[2]. Under blue laser irradiation, the temperature changes in an aqueous medium were evaluated for all nanostructures. Notably, flower-like SnO_2 displayed an increased temperature by up to 14.5°C, attributed to the enhanced local electric field at tips, edges, and corners present in this kind of shape. In parallel, the temperature gradient enhanced the charge carrier transfer, boosting higher reactive oxygen species (ROS) generation, such as hydroxyl radical, which in turn accelerates the photo-oxidation rate[5]. Moreover, under UVA-Vis irradiation, the nanomaterials exhibited remarkable light harvesting and light-to-heat conversion capabilities that significantly enhanced the photocatalytic performance for water pollutant removal and green hydrogen production through a synergistic photo-chemical/thermal effect.

On the other hand, the morphology variation studied through FESEM and HRTEM provided insights into the crystal growth mechanism based on the structural dimensionality of these nanomaterials, ranging from zero- to three-dimension. Furthermore, a potential mechanism as photo-thermo-catalyzers was also proposed. This work and the corresponding findings pave the way for the precise design of nanostructured materials with tailored morphologies for enhanced photocatalytic and photothermal applications, particularly in environmental remediation and sustainable energy production.

Poster Group 1

Nuclear pore complexes (NPCs) bridge across the nuclear envelope and mediate nucleocytoplasmic exchange. Numerous copies of over 30 distinct protein species assemble to form each nuclear pore complex. The NPC's core scaffold is symmetric across the nuclear envelope. Distinct peripheral nucleoporin complexes are attached to the cytoplasmic and nuclear face, where they ensure transport directionality and fulfill compartment-specific roles, such as genome organization. It remains enigmatic how such compositional asymmetry is established on a scaffold architecture that exposes the same interaction surfaces to either side. Here, we combine in situ cryo-electron tomography (cryoET), subtomogram averaging, and template matching with live cell imaging to address this question in both budding yeast and isolated cells from Drosophila melanogaster ovaries. We propose that the cell uses the surrounding cellular milieu as a cue for the correct allocation of components specific to the two faces of the NPC. This would predict the existence of symmetric NPCs when exposed to the same environment on both sides. To test this prediction, we study pores outside the nuclear envelope. Such ectopic NPCs naturally occur, but are either rare, transient, or prevalent in cell types that are not amenable to standard cryoET sample preparation. We use genetically engineered systems to enrich pores in either intranuclear or cytoplasmic double membranes. We show that in contrast to pores at the nuclear envelope, such NPCs are symmetric across the membrane. We furthermore demonstrate that the peripheral nucleoporin configuration depends on the nucleotide state of the small GTPase Ran. Our data indicate that the nuclear transport system is self-regulatory, namely the same molecular mechanism controls both transport and transport channel composition.
Our findings exemplify that not only structural determinants but also the local cellular environment shape the composition and architecture of macromolecular assemblies, highlighting the importance of in situ structural biology.

Background incl. aims

Water pollution is a significant global issue, with various domestic and industrial activities causing a substantial decrease in the availability of clean water [1]. The emission of dyes used in the textile, cosmetics, and food industries is a major contributor to water pollution, accounting for 17 to 20% of global contamination. The production of these dyes requires approximately 150 180 liters of water per kilogram, and approximately 15% of the dyes end up in water-based textile waste [2][3].
Various methods have been explored to address this issue, for the treatment and removal of dyes, with photocatalysis emerging as a particularly effective approach. Photocatalysis enables the high degradation of contaminants under ambient temperature and pressure conditions, using sunlight or ultraviolet light as the irradiation source [4].
MXenes, a novel family of two-dimensional nanomaterials composed of transition metal carbides bonded to organic functional groups, have shown great promise in this regard. Their lamellar structure provides a high surface area, electrical conductivity, and thermal and structural stability, making MXenes ideal for the fabrication and use of nanoparticles in photocatalysis [5]. The aim of this study was to synthesize the Ti_3C_3Tx MXene and, to improve its photocalytic properties by the in-situ deposition of TiO_2 nanoparticles, which was tested by the degradation of methyl orange dye.

Methods

The Ti_3C_3Tx MXene was synthesized by the chemical etching of Al from the precursor Ti_3C_3Tx MAX phase. For this, 0,5 g of MAX phase were added to a premixed solution of 0,5 g LiF and 5 mL 9 M of HCl, and stirred for 24 hours at 50°C. The resulting mixture was washed and centrifuged using deionized water at 12.000 rpm until the pH reached was 6; being later vacuum filtrated, sonicated and dried for 48 hours at 90°C. The further delamination step was performed by sonication in water during 1 h. The MXenes before delamination are multilayer samples (ML) while delaminated MXenes are few layer samples (FL).
The in situ TiO_2 nanoparticles were formed on the surface of the MXene surface by a solvothermal oxidation process dispersing the particles in isopropanol ((CH3)2CHOH) and heating up the solution at 190°C for 24 hours. This procedure was performed in ML and FL samples to compare the effect of the number of layers on the photocatalytic response. The samples obtained from the oxidation process were named ML-TiO_2 d FL-TiO_2. The prepared materials, unoxidized and oxidized samples, were characterized by XRD, Raman spectroscopy, SEM and TEM, while the photocatalytic properties were studied by degradation of methyl orange dye under UV light exposure.

Results

Raman spectroscopy and XRD confirmed the delamination process and the formation of the Ti_3C_2Tx MXene, and the further formation of TiO_2 in the anatase phase. SEM and TEM analysis revealed the formation of 2D lamellar particles and the removal of Al from the initial MAX phase to form the MXene material. Likewise, both microscopy techniques showed the formation of TiO_2 nanoparticles on the surface of the MXene layers from the solvothermal oxidation process. The dye degradation tests showed that the unoxidized ML and FL samples exhibited better dye removal by adsorption under dark conditions, while the oxidized samples exhibited greater photocatalytic degradation under UV light exposure. The anatase nanoparticles formed on the ML-TiO_2 and FL-TiO_2 samples significantly enhanced the photocatalytic activity of the Ti_3C_2Tx MXene, with a better performance for the FL-TiO_2 sample. The tests with various dye concentrations and photocatalyst charge achieved a maximum degradation efficiency of 99.4% for the FL-TiO_2 sample, highlighting the high effectiveness of Ti_3C_2Tx sheets with TiO_2 for removing contaminant dyes.

Conclusion

This study successfully synthesized 2D Ti_3C_2Tx MXenes using chemical etching and exfoliation techniques. The subsequent solvothermal oxidation process facilitated the formation of anatase TiO_2 on the MXene particles. The photocatalytic tests demonstrated that the oxidation process of the Ti_3C_2Tx MXene enhanced the photocatalytic properties over the adsorption process of the unoxidized MXene, and that the TiO_2-coated samples exhibited superior photocatalytic degradation of Methyl Orange under UV light. The optimal degradation performance, achieving a maximum efficiency of 99.4% for the delaminated FL-TiO_2 sample, which highligts the potential of the Ti_3C_2Tx MXenes with TiO_2 for effective removal of contaminant dyes, making them a promising solution for water pollution treatment.

DELiVR: An end-to-end deep-learning pipeline for cleared-brain cell annotation

Moritz Negwer[1], Doris Kaltenecker[2], Rami Al-Maskari[2], Ali Ertürk[2]
[1]Radboudumc Nijmegen, Donders Institute for Brain, Behavious and Cognitionn, Nijmegen, Netherlands, [2]Institute for Tissue Engineering and Regenerative Medicine, Helmholtz Munich, Neuherberg, Germany

Poster Group 1

Background:
Automated detection of specific cells in three-dimensional datasets such as whole-brain light-sheet image stacks is challenging. Deep learning is a promising method for light-sheet image analysis, but only is as good as the training data for this specific dataset.

Methods:
We realized that virtual reality (VR) is an ideal approach to generate custom deep-learning training data. We found that VR-generated training data leads to better model performance, but more importantly is also generated much faster. We built DELiVR, a broadly applicable processing pipeline to segment arbitrarily labelled cells in light-sheet image stacks of cleared mouse brains.
We have open-sourced the entire pipeline, docker containers, FIJI plugin, and training data at https://discotechnologies.org/DELiVR/ .

Results:
Here, we present DELiVR, a virtual reality-trained deep-learning pipeline for detecting c-Fos+ cells as markers for neuronal activity in cleared mouse brains. Virtual reality annotation substantially accelerated training data generation, enabling DELiVR to outperform state-of-the-art cell-segmenting approaches. Our pipeline is available in a user-friendly Docker container that runs with a standalone Fiji plugin. DELiVR features a comprehensive toolkit for data visualization and can be customized to other cell types of interest, as we did here for microglia somata, using Fiji for dataset-specific training. We applied DELiVR to investigate cancer-related brain activity, unveiling an activation pattern that distinguishes weight-stable cancer from cancers associated with weight loss.

Conclusion:
Overall, DELiVR is a robust deep-learning tool that does not require advanced coding skills to analyze whole-brain imaging data in health and disease.

Fabrication and charaterization of plasmonic nanopillars on a thin membrane for TEM investigation

Maria Serra González[1], Matthias Keil[1], Rucha Deshpande[1], Rafael Taboryski[1], Shima Kadkhodazadeh[1]
[1]DTU Nanolab, Kongens Lyngby, Denmark

Poster Group 1

Plasmonic resonances are characterized by a highly localized and enhanced electromagnetic field around structures the size of the excitation wave, also known as “hot-spots". This phenomenon has been exploited in recent years in fields such as sensing, imaging or catalysis. The hot-spots enhance the signal in Raman spectroscopy [1], increase sensitivity for label-free protein detection [2], or generate localized heat for catalysis [3]. In these studies, plasmonic effects are usually quantified through these secondary effects or simulations rather than the direct measurement of the electromagnetic field in the hot-spots. In this work, we present the fabrication of a plasmonic sample consisting of a nanopillar array on a thin membrane suitable for a TEM study, which will allow probing the surface plasmons (SPs) with an electron beam. Excitation of the SPs will be possible with the mounting of a white LED in the chip, and thus the electron beam will be deflected and measurable in the vicinity of the hot-spots.

For the sample fabrication, we employed a combination of resolution enhancement techniques on a DUV stepper tool namely off-axis illumination, cross- triple exposure and the addition of assist feature lines on the design [4]. We achieved a hexagonal array of nanopillars with 150 nm diameters and 350 nm pitch. Deep Reactive Ion Etching (DRIE) was employed for the silicon oxide pillars’ etch and UV lithography was used to pattern and align the openings for the membranes with an accuracy of 2 um. A KOH bath etched the back of the silicon wafer to achieve 20 nm thick membranes. Finally, a 19 nm of aluminum coating ensured the plasmonic effects. Optical characterization on a micro-spectrophotometer of the fabricated chips confirmed plasmonic resonances on the visible range, Figure 1 b). The reflectance shows a resonance dip at 500 nm wavelength that differs significantly to the reflectance in the unpatterned area of the same membrane. This proofs that the addition of nanostructures increases the absorption of light in the form of localized surface plasmons.

Additionally, the sample was mounted on a TEM grid by means of a lift-out and welding process. Using a xenon ion beam, the nanopillar membrane was released from the substrate and mounted on a TEM grid and to a TEM electrical chip welding it with tungsten, Figure 1 a). A preliminary simulation of the fabricated nanopillar presented plasmonics resonances for visible wavelengths. An example is shown in Figure 2 a) where the EM-field distribution is highly localized in the top of the pillar quadruplicating the intensity of the excitation beam of 430 nm wavelength. The spectral shape of the simulated reflectance in Figure 2 b) is a good match to the reflectance measured in Figure 1 b). The measured dip at 500 nm shifts to the simulated dip at 650 nm, still within the visible range. Thus, the model describes the physics of the structure well.

TEM-based study of the effect of precursor in thermal polymerization synthesis of graphitic carbon nitride

Dr. Rosaria Brescia[1], Paolo Negro[2], Prof. Federico Cesano[2], Prof. Domenica Scarano[2]
[1]Electron Microscopy Facility, Istituto Italiano di Tecnologia, Genoa, Italy, [2]Chemistry Department of Excellence and NIS (Nanomaterial for Industry and Sustainability) Interdepartmental Centre, University of Torino & INSTM-UdR, Turin, Italy

Poster Group 1

In the last years, graphitic carbon nitride (g-C_3N_4) emerged as an attractive alternative to carbon materials, especially for photocatalysis. Several synthesis strategies were shown to lead to a plethora of partially polymerized allotropes, while the fully polymerized form of g-C_3N_4 is hardly obtained. The 3D structure of g-C_3N_4 obtained by thermal polymerization of N-rich precursors is usually well described as consisting of tri-s-triazine building blocks arranged in layers bound by Van der Waals forces, more or less hydrogenated [1,2]. Among possible precursors, melamine (M) and urea (U) have been tested in thermal polymerization methods [3]. The mixture of these two precursors can lead to a tunable combination of high reaction yield and high specific surface area. This contribution provides a study at nanometer scale of the material obtained using M and U precursors and mixtures of them, which is key for understanding the variations in catalytic functionalities.
The material investigated has been synthesized via thermal polymerization in air at 550°C starting from powder precursors, using pure melamine (sample M100), pure urea (sample U100) and mixtures of them (U/M (mass)= 80/20 and 50/50, resulting in samples U80 and U50, respectively) [4]. The obtained powders, after grinding in a mortar, have been suspended in ethanol, sonicated and drop-cast onto holey-carbon-coated TEM grids. BF-TEM and SAED analyses (using a SA aperture of 5.8 µm) were carried out by a Tecnai F20. For HRTEM analyses, an image-Cs-corrected JEM-2200FS with a direct electron detection camera (Gatan K2 Summit) was used, which allowed to obtain large field-of-view images at minimized electron-dose-rate thus beam-induced damage, expected for this material [5]. HRTEM images were obtained at an electron dose rate of about 30 e-/(Å²·s) and a total dose of about 330 e-/Å².
Similar to what reported earlier, morphological analysis shows that, while M100 material consists of thicker and bulkier flakes, U100 is characterized by crinkled, thinner and porous flakes (BF-TEM in panels a, e). SAED analysis shows polycrystalline flakes in both samples, but a higher crystallinity characterizes M100, which exhibits a higher number of sharp diffraction rings compared to U100 (panels b, f). For both samples, SAED patterns match with an orthorhombic phase, hydrogenated ($C_{24}N_{30}(NH_2)_6$, ICSD 194747) reported for g-C_3N_4 obtained by thermal polycondensation of melamine [1]. The bulkier flakes in M100 are formed by nanometer-size crystalline domains, which give rise to sharp diffraction rings corresponding to the (hk0) planes of the structure, generated by the in-plane stacking arrangement of tri-s-triazine units. The dominant diffraction feature in SAED patterns for U100 is instead the (002), corresponding to the distance between stacked graphitic planes, while (hk0)-related features are much less visible: this stands for a much weaker in-plane order and higher defectivity in the material. FFT analyses of HRTEM images, obtained from smaller areas, show a hexagonal-symmetry pattern for M100, with rings that however show an in-plane-rotation of the crystallites forming the flake (panels c, d). HRTEM analysis of U100 confirms the totally random orientation of crystallites and the presence of (002) planes due to rolled-up flakes (panels g, h). Increasing electron doses show faster amorphization and final degradation in U100, due to the knock-on of hydrogen atoms, probably present at a higher content due to incomplete polymerization

of the urea precursor [5]. From the comparison between SAED and HRTEM results, the comparably well-defined (hk0) peaks for M100 signify long-range order within the extended layers. Intermediate compositions lead to intermediate characteristics in the nanometer-scale structure, as expected. In summary, overall the material obtained by thermal polymerization of U/M powders is characterized by a lack of long-range order. However, significant differences occur between the outcomes of different U/M precursor ratios, which can be explained in terms of nanostructure organization of crystalline domains. This tunable structure allows to control the material properties with the aim of optimizing their employ in application.

Poster Group 1

Background incl. aims
Biological materials are of spectacular beauty and source of inspiration for principles of material design and synthesis. They are composed of a remarkable small number of simple building blocks which are often organized, at different length scales, in patches of periodic or quasi periodic units. Prominent examples are the cases of trabeculae in bone or skeletal elements of echinoderms, color-bearing photonics crystals structures in arthropods and pore systems in cuticular materials or bone. The structural features (3D texture) and orientation of the periodic/quasiperiodic units largely dictate the properties of the materials to which they belong. Yet, segmenting and classifying these regions in large 3D datasets --a prerequisite for a complete understanding of the material's properties-- is incredibly challenging. In fact, while it is relatively simple to obtain a binarized volume of the component these structures are made of (e.g. trabeculae, pores or channels etc...), it is not trivial to segment different regions with similar 3D organization and orientation or, even more so, recognize and classify those regions that exhibit the same texture but that are differently oriented with respect to each other.
Methods
To address this, we propose a pipeline that, with minimal supervision and without user bias, extracts, classifies and learns, in reciprocal space, 3D textural features from tomographic datasets. The learned features can then be used to segment out, in the real space, regions which differ by their structural regularity and spatial periodicity. Also, the proposed pipeline allows to easily identify regions of the dataset that are equivalent by rotation and quantitatively compare textural properties of different datasets.
Results
Using this pipeline, we were able to segment large tomographic datasets (in the order of 10^{10} voxels) of several different biological materials with minimal memory and storage imprint and user supervision. As an example, the graphic shows how the pipeline allows an unbiased and automatic segmentation of textural features in a sea urchin test plate (µCT dataset $4 \cdot 10^9$ voxels, top), lacuno-canalicular network in bone ($1.8 \cdot 10^9$ voxels, laser scanning confocal microscopy, bottom left) and a photonic crystal in weevils scales (FIB/SEM dataset $1.5 \cdot 10^9$ voxels, bottom right).
A segmentation of about 10^9 voxels dataset can be run in a few hours on a desktop PC with a small GPU (8GB of RAM) and 32 GB RAM.
Conclusion
The pipeline presented in this work allows the segmentation of large volumetric datasets that exhibit quasi-periodic features and is particularly useful in those cases where the aim of the imaging is to establish relationships between the structure and the function of the investigated.

In-Situ Microstructure-Mechanical Property Mapping of Multi-Component Materials Using PI 89 Auto SEM PicoIndenter

Sanjit Bhowmick[1], Kevin Schmalbach[1], Justin Cheng[2], Eric Hintsala[1], Douglas Stauffer[1], Nathan Mara[2]
[1]Bruker, Minneapolis, United States, [2]Department of Chemical Engineering and Materials Science, University of Minnesota, Minneapolis, United States

Poster Group 1

Background
Next-generation structural materials are designed to achieve superior performance by combining different elements and phases, each contributing distinct properties such as strength, toughness, or corrosion resistance. However, the often complex distribution of these multiple phases leads to challenges in characterizing the variations in mechanical properties across different regions of the material. Understanding these spatial variations is crucial for further refinement and optimization of the chemistry and microstructure of these complex alloys. Precise knowledge of how each phase and its distribution affect the overall mechanical behavior allows researchers and engineers to fine-tune the material for specific applications, ensuring optimal performance and reliability.

Methods
One major challenge for the characterization of these materials is the alignment of separately measured mechanical property and microstructure maps. Bruker's PI 89 Auto introduces advanced automation to the Hysitron PI 89 SEM PicoIndenter to address this challenge. This tool automates the positioning of the Rotation and Tilt Stage (R/T stage) for indentation after SEM imaging and EBSD/EDS mapping. The integration of TriboScan Auto software allows high-throughput testing with precision and control, seamlessly transitioniong between nanoindentation, SEM imaging, and EBSD/EDS analysis. From an EDS/EBSD map, the PI89 auto enables the co-localized acquisition of quantitative in-situ mechanical data at user-defined regions of interest. This significantly enhances the efficiency and accuracy of correlative structure-property analysis, facilitating advancements in material science and engineering. In this study, two heterogeneous alloys, a two-component steel and an accumulative roll bonded copper-niobium (ARB Cu/Nb) nanolaminate, are selected. The steel sample demonstrates significant variations in properties resulting from differences in chemistry and microstructure introduced during the synthesis process. This steel is fabricated by laser cladding 410 stainless steel onto a 4140 steel substrate, a technique that produces distinct microstructural zones identifiable through chemistry maps from Energy Dispersive Spectroscopy (EDS) and grain orientation maps from Electron Backscatter Diffraction (EBSD). These zones include: (1) the base 4140 steel substrate; (2) the heat-affected zone; and (3) the high chromium (Cr) 410 steel cladding.

Results
Figure 1 illustrates the three microstructural zones and their mechanical properties, which are assessed through a lateral nanoindentation hardness profile. Notably, the heat-affected zone is considerably harder than both the base substrate and the cladding. This increased hardness is attributed to the microstructural alterations induced by the laser cladding process, which include grain refinement and potential phase transformations due to the severe local heating. Elevated hardness in heat affected zones is commonly observed in many structural metals, but the facilitated correlation of chemistry and structural data makes it quick to identify these regions and measured their local properties with high spatial resolution.

The accumulative roll bonded copper-niobium (ARB Cu/Nb) alloy exhibits differences in mechanical properties across its component phases. This alloy is synthesized through a process involving repeated stacking, roll-bonding, and cutting of pure copper and niobium sheets. This method results in a lamellar microstructure characterized by alternating layers of copper and niobium. An array of Berkovich nanoindentations placed across several layers of the ARB Cu/Nb material allows for precise mapping of the mechanical properties of individual phases, as illustrated in Figure 2. By aligning a chemical map from Energy Dispersive Spectroscopy (EDS) with a nanoindentation hardness map, the mechanical heterogeneity of the respective component phases is correlated. This analysis reveals that the niobium phase is stiffer than the copper phase as expected. The increased hardness of the copper relative to the niobium phase is not necessarily intuitive, and can be attributed to the distinct grain sizes within each phase. Specifically, the copper phase exhibits a smaller grain size compared to the niobium phase. This disparity arises from the greater propensity for dynamic recrystallization in copper during the accumulative roll bonding process. Dynamic recrystallization, which involves the formation of new, strain-free grains during deformation, is more pronounced in copper due to its lower melting point and higher diffusivity compared to niobium.

Conclusions

This work highlights the utility of the PI 89 Auto in correlating local mechanical behavior with differences in grain structure and chemistry. By providing seamless integration of nanoindentation with SEM imaging and EBSD/EDS analysis, the PI 89 Auto enables high-resolution, high-throughput characterization of complex materials like ARB Cu/Nb and laser-clad steel. This capability is crucial for advancing our understanding of the relationships between microstructure and mechanical properties, thereby facilitating the development and optimization of advanced structural materials.

Electron Energy-Loss Spectroscopy of Liquids

Sofie Tidemand-Lichtenberg[1], Shima Kadkhodazadeh[1], Kristian Speranza Mølhave[1]
[1]Technical University of Denmark, Kgs. Lyngby, Denmark

Poster Group 1

Background incl. aims
Liquid phase transmission electron microscopy (LPTEM) makes it possible to study reactions and dynamics in liquids at atomic resolution, with application in biology, battery studies, catalysis etc. This makes it a powerful tool for understanding the underlying mechanisms of liquid phase processes and interactions with other liquids or solids.
Electron energy loss spectroscopy (EELS) enables elemental analysis of materials through energy measurements in the transmission electron microscope (TEM). From EELS measurements it is possible to extract not only the elemental composition, but also obtain chemical bond knowledge of the electronic structures from the energy-loss near-edge structure (ELNES).
Combining LPTEM with EELS makes it possible to examine the elemental composition of liquids as well as their electronic structure and thereby chemical bonding structure through the ELNES. Additionally, it will enable the analysis of the beam induced changes in sample chemistry in the liquids and can be a valuable tool to understand radiolysis of liquids.
The aim of this study is firstly to measure, analyze and understand the molecular structure of a range of different liquids through their EELS spectra with associated ELNES structures, and assess if there are prominent radiolytic effects of the beam on liquid.
Methods
Nanochannel LPTEM chips of silicon nitride, supplied by InsightChips, were used to encapsulate the water. The nanochannels allow flow and thereby exchange of liquids while inserted in the TEM and makes it possible to have thin layers of liquids, thereby enhancing the resolution of the EELS spectrum compared to other silicon nitride based LPTEM systems. Graphene based LPTEM methods do not allow flow and hence cannot be used to establish a baseline measurement where there is a need for continuous fresh supply of the liquid to avoid radiolytic effects.
To obtain a sufficiently high resolution to resolve the ELNES structure of the water a Spectra Ultra S/TEM with a monochromator was used in for the measurements in both scanning transmission electron microscopy (STEM) and TEM mode. When the beam was focused on one of the channels it was possible to generate bubbles through radiolysis, which was then analyzed using the EELS system on the microscope. This allows us a better understanding of the liquid – electron beam interaction. The bubbles are temporary and dissolve in minutes if not continuously irradiated.
Results
From the oxygen edge on the core-loss spectrum it is possible to extract information about the structure of the water. Additionally, it is possible to determine the molecular composition of the radiolytic gases generated from the interaction between the liquid and the electron beam. Finally, it has been possible to evaluate the structure of other liquids such as ethanol and hexane.
Conclusion
From the experimental measurements of liquids, we present an approach for determination of the structures of different liquids. Additionally, the aim was to obtain knowledge of the radiolytic processes that occur in liquids when exposed to a high dose electron beam.

Structural biology analyzes of photoreceptor outer segment: a closer look at PDE6

Dr Vineeta Kaushik[1], MSc Luca Gessa[1], Dr Sławomir Tomczewski[1,2], MSc Łukasz Olejnik[1], MSc Nelam Kumar[1], Dr Humberto Fernandes[1,2]
[1]International Centre for Translational Eye Research, Warsaw, Poland, [2]Institute of Physical Chemistry, Polish Academy of Sciences, Warsaw, Poland

Poster Group 1

Background incl. aims
Sight is perhaps the most spectacular human sense. The front of the eye allows light to pass through and channels it to the photoreceptor layer on the retina. There it triggers biochemical reactions that ultimately are converted to electrical signals that are sent and processed in the brain to generate images. Many components are required to create a vision, and it took millions of years of evolution to arrive at such a phenomenal organ. The conversion of photons to electrical pulse relies on the phototransduction cascade that involves many proteins at the outer segments of the cells and on its stacking of discs. There is a long-standing observation that in addition to the phototransduction activation, light stimulus also evokes morphological changes in the photoreceptors, still, the molecular determinates of this phenomenon have remained evasive. Recent developments in the Optical Coherence Tomography (OCT) field (including Optoretinography (ORG)) allow direct imaging of photoreceptors, and offer a new biomarker with the measurement of morphological changes detected upon light stimulus. At the same time, there is now evidence that a phosphodiesterase enzyme, namely Phosphodiesterase 6 (PDE6), that is at the core of the phototransduction signal pathway and is attached to the disc in the photoreceptor's outer segments, may bridge consecutive discs. Its structure has been determined in slightly different conformations that render the different protein lengths, thus opening the possibility that PDE6 is the molecular driver of the morphological changes observed. Our goal is to test if PDE6 is the molecular driver behind the observed morphological changes and a ORG biomarker.
Methods
To test our hypothesis, we isolated rod PDE6 and full outer segments (ROS) and employed Cryo-Electron Tomography (cryoET) and Cryo-Soft X-ray Tomography (cryoSXT) to test our theory in the cellular environment. The resolutions archived are modest compared to the Cryo-Electron Microscopy (cryoEM) structures already determined for PDE6, but still adequate to measure ROS disc spacing under different conditions and add to the “big picture” of the observed morphological changes. Importantly, the measurements are done with PDE6 in its natural environment and in the presence of relevant membranes. Additionally, we are also imaging fixed ROS, isolated under different conditions with Transmission Electron Microscopy (TEM).
Results
We have established the conditions to isolate and deposit ROS in cryo-grids, freeze the samples, prepare lamellas and collect tomograms. The tomograms are then processed so that information on the ROS disc spacing, under different conditions, is collected and analyzed. Such knowledge may have implications for therapeutics diagnostics and functional imaging of photoreceptor physiology.
Initial TEM images were obtained, and larger sample sets are being prepared.
Conclusion
We are at the initial sets of this project, but we have overcome already some technical difficulties, and expect now to collect larger data sets to test our hypothesis. At the same time, we are looking

for other possible microscopic techniques that may add information to the observed morphological phenomenon.

Advancements in Quantifying Neuroinflammation: Leveraging AI-Based Microscopy for Enhanced In Vivo Analysis in pharmaceutical studies

Dr Emilie Tresse-Gommeaux[1], Franziska Wichern[1], Lotte Frederiksen[1], Marie Barkai[1], Dr Morten Skott Thomsen Lindskov[1]
[1]Lundbeck, Valby, Denmark

Poster Group 1

Background
In the field of pharmaceutical research, accurately quantifying imaging data is essential. This precision is crucial for assessing neuroinflammation, a key factor in numerous neurological disorders. However, powered in vivo studies, especially for pharmacokinetics (PK) and pharmacodynamics (PD) evaluations, require utilizing large cohorts of animals. Additionally, recent technological advancements have significantly increased the capacity for multiplexing, allowing for more comprehensive data collection. This increase in data complexity poses new challenges for analysis.

Methods and Results
In our current studies investigating neuroinflammation, to manage and analyze the extensive data generated, we employ AI-based microscopy analysis. This innovative approach enables automated evaluation of drug efficiency in vivo, providing a robust and scalable solution for high-throughput studies. Our findings demonstrate the potential of AI-driven methodologies to streamline the analysis process, thereby enhancing the accuracy and efficiency of neuroinflammation assessments.

Conclusions
By integrating these advanced technologies, we pave the way for more in-depth research and faster, more precise therapeutic developments. The implications of our work extend beyond neuroinflammation, offering a framework for the application of AI in various bioimaging research areas. This approach not only improves the reliability of data interpretation but also significantly reduces the time and resources required for comprehensive analysis, ultimately accelerating the drug development pipeline and improving outcomes for patients.

Revealing the Microstructure of Binary Solvent Hydrogels: a Novel Cryo-SEM Approach

Mr. Aria Khalili[1,2], Dr. Mohammad Amirul Islam[2], Xinyu Wang[1,2], Dr. Darren Makeiff[2], Dr. Mohtada Sadrzadeh[1], Dr. Kenneth D. Harris[1,2], Dr. Jae-Young Cho[1,2]
[1]Department of Mechanical Engineering, University of Alberta, Edmonton, Canada, [2]Quantum and Nanotechnologies Research Center, National Research Council Canada, Edmonton, Canada

Poster Group 1

Hydrogels' biocompatibility and resemblance to biological tissues result in diverse applications in tissue engineering, drug delivery, agriculture, and bioelectronics. Binary solvent gels, such as those in aqueous dimethyl sulfoxide (DMSO) are more stable and interact more favorably with hydrophobic compounds. The internal structure of these binary solvent hydrogels remains poorly understood due to the lack of sample preparation techniques specific to the materials systems. In this study, a benzimidazolone (BZI) derivative supramolecular hydrogel is synthesized in both single and binary solvent systems. The single solvent hydrogel was prepared in water while the binary solvent hydrogel was obtained from 75 wt.% water and 25 wt.% DMSO solvent. We provide a novel preparation method for characterizing binary solvent hydrogels using cryogenic scanning electron microscopy (cryo-SEM). The preparation conditions for the binary solvent hydrogel were obtained by introducing a soaking treatment in deionized water (DIW) and tuning the appropriate sublimation temperature and duration while ensuring specimen integrity. We demonstrate that our new cryo-SEM characterization method can successfully remove residual solvent to expose the structural details of binary solvent hydrogels which was little known previously. The method will be harnessed in the future to comprehend the microstructural evolution of the binary solvent BZI hydrogel when it is loaded/unloaded with hydrophobic drugs. This newly developed method helps to understand the other binary solvent hydrogel structures, and the structure with organic solvents in their system using cryo-SEM characterization.

Charting the molecular landscape across layers of vitrified mammalian hippocampus using electron cryotomographyaa

Mr Jake Smith[1], Dr Calina Glynn[2], Dr Matthew Case[2], Miss Rebecca Csöndör[2], Miss Maria Sanita[2], Dr Thomas Glen[2], Dr Michael Grange[1,2]
[1]Division of Structural Biology, University of Oxford, Oxford, United Kingdom, [2]Rosalind Franklin Institute, Didcot, United Kingdom

Poster Group 1

Background incl. aims
Our understanding of neurological function and disease relies on knowledge of both the cellular architecture of brain tissue and the molecular organisation within neurons and glia. Electron cryotomography (cryo-ET) is a powerful technique for investigating the structure and distribution of biological macromolecules in their native, cellular environment. Traditional sample preparation for cryo-ET of tissues involving chemical fixation and microtomy leads to artefacts that can obscure high-resolution detail, impeding biological interpretation on the molecular scale. Alternatively, tissues can be studied in their native, hydrated state by preparing vitreous samples with high-pressure freezing (HPF), combined with nanofabrication approaches such as focused ion beam (FIB) milling.
The advent of plasma sourced focused ion beam (PFIB) instruments offers enhanced milling speeds afforded by the greater beam coherence at high currents that plasma sources provide [1]. This has the potential to greatly improve the throughput of sample preparation for thick tissue samples. Similarly, recent advancements in cryogenic lift-out of high-pressure frozen samples on grids have shown the ability to excise large sections of material from HPF samples, and has enabled the analysis of more complex biological models such as C.Elegans embryos and organoids by cryo-ET [2,3]. Applied to mammalian tissues, the approach promises to unlock the molecular characterisation of brain organisation. Here we outline a robust technical workflow for fabricating brain tissue lamellae using PFIB. We leverage serial lift-outs to access new sampling geometries from HPF samples spanning the mouse hippocampus CA1 stratum radiatum.
Methods
The brain of a 184 day old female C57BL6 mouse was divided into hemispheres and sectioned to 100 µm using a vibratome on ice where 2 mm biopsies of hippocampus were taken for incubation in cryoprotectant. Hoescht 33342 nuclear stain was added prior to vitrification in copper-coated gold carriers using the EM ICE HPF (Leica). The sample was loaded into the Helios Hydra G5 PFIB (TFS), where fluorescence mapping was performed using an integrated light microscope (Delmic Meteor) within the microscope chamber. A 350 µm region of CA1sr was identified and adjacent trenches were milled with 200 nA Xe plasma. Undercuts were performed at 4 nA to relieve the sample from the bulk of the material. A cryogenically cooled tungsten manipulator (TFS) adapted with a copper block attachment was then used to lift out the sample, and serial sections were deposited on a 400 x 100 mesh copper support grid (Agar Scientific). Automated lamellae thinning was performed using Xe for Rough (4nA), Medium (1nA) and Fine (0.1nA) milling followed by manual polishing with argon (60-20pA). Tilt series were acquired using a Titan Krios G4 with an energy filtered Falcon 4i detector (TFS). Tilt series were preprocessed in Warp and reconstructed with WBP in AreTomo before visualisation in IMOD.
Results
A novel milling approach was developed to isolate sections spanning mouse hippocampal layers for serial lift-out from HPF carriers. Firstly, the location of the pyramidal cell layer was identified using a

correlated light and electron microscopy (CLEM) approach. The distribution of fluorescently labelled nuclei allowed for the cell body layer of the CA1 to be identified and guided the lift-out of targets spanning from the CA1 stratum oriens to the CA1 stratum lacunosum. The use of the xenon plasma to shape the sample allowed deep trenches adjacent and above the region to be milled in less than 30 minutes. This utilised beam currents ranging from 60-200 nA, with resulting lamellae showing no visible damage artefacts. The orientation of the milling enabled undercuts to be made using a 90º relative stage rotation so that the tissue could be excised. Subsequently, we could deposit up to 42 serial sections that sample across a 350-400 µm region containing multiple layers of the CA1. Sections were thinned to TEM transparency with >90% success, where 246 tilt series were collected in the CA1 stratum radiatum (CA1sr).
From these data, the cellular organisation and content across the mammalian CA1sr could be characterised. These include multiple different cell types, such as glia with patches of ribosomes in cell bodies (n=12/251) and neuronal projections (n=79/246). Cellular features observed include microtubules (n=221/246), actin (n=75/246) and endoplasmic reticulum (ER) (n=38/246). Manipulation of the geometry of the lift out by isolating a section of tissue within the plane of the sample provided access to a previously unobserved view of the CA1 apical dendrite cytoskeletal network in 14% (n=35/246) of tomograms. This perspective revealed networks of cytoskeletal elements, ER, and mitochondria. Furthermore, 9% of tomograms in this dataset contained a confirmed synapse (n=22/246), with a further 11% (n=27/246) showing putative synapses. The quality of the tomograms reconstructed from this tissue sample is sufficient to identify canonical synaptic features including cleft proteins, post-synaptic density, active zone organisation and synaptic vesicle endocytosis.
Conclusion
This work presents a routine approach for generating lamellae for cryo-ET of multiple layers of mammalian hippocampus from a single lift out using plasma FIB. The developed pipeline incorporates a cryo-CLEM aspect to guide the lift-out of targets spanning 350-400 µm across the CA1 region, generating over 40 deposited sections of high-pressure frozen brain biopsy in a single 24-hour microscope session. Semi-automation of lamellae thinning using a hybrid Xe/Ar plasma approach produces sufficiently thin lamellae to characterise cellular organisation and content across the mammalian CA1sr. By lifting out a section of tissue in the plane of the sample, previously inaccessible views of the CA1pyr apical dendrite cytoskeletal network could be imaged in vitrified samples. The spatial relationship between sequential lamellae, which sample every 5-10 µm of the CA1sr, demonstrates the feasibility of acquiring cellular cryo-ET data with enhanced biological context using our approach. The workflow we present here has the potential to be adapted for different cryogenically preserved model systems and tissues, opening up possibilities for observing biomolecules within their most native environment. Our approach paves the way for more comprehensive, contextually rich structural studies of brain tissue at the molecular level.

Poster Group 1

Anti-cancer drug treatment has been a standard approach for managing aggressive human pancreatic cancer. Effective, label-free monitoring of cell death is crucial for assessing drug efficacy and elucidating the mechanism of apoptosis. In this study, we utilized stimulated Raman scattering (SRS) microscopy to evaluate individual pancreatic cancer cells treated with a newly synthesized hydroxyl group-introduced chalcone derivative and the commercially available gemcitabine. SRS microscopy, by detecting inelastic vibration scattering of biomolecules, provided high-resolution imaging data revealing morphological and compositional alterations during apoptotic cell death. SRS imaging identified distinctive apoptotic features, including cellular shrinkage and membrane blebbing, without the need for staining. Notably, treatment with hydroxyl group-introduced chalcone derivative induced more pronounced structural and biomolecular changes, such as increased lipid droplets and decreased protein levels, compared to gemcitabine during apoptotic cell death.

Evaluation of pH-sensitive drug delivery systems for lung cancer therapy via multiplex fluorescence microscopy

Dr. Sanghee Nah[1], Ruda Lee[2], Jung Hoon Choi[3]
[1]Seoul Center, Korea Basic Science Institute, Seoul, Republic of Korea, [2]International Research Organization for Advanced Science and Technology, Kumamoto University, Kumamoto, Japan, [3]Department of Anatomy & Institute of Veterinary Science, College of Veterinary Medicine, Kangwon National University, Chuncheon, Republic of Korea

Poster Group 1

Non-small cell lung cancer (NSCLC) is characterized by the presence of tumor-associated macrophages that can polarize into a tumor-promoting phenotype, along with elevated levels of folate receptor beta (FRβ). Additionally, calpain-2 (CAPN2) is widely expressed in NSCLC and contributes to tumor progression. To enhance anticancer treatment efficacy and minimize side effects, developing innovative drug delivery systems with precise targeting and controlled release is essential. Here, we employed multiplex fluorescence microscopy to demonstrate that pH-sensitive, FRβ-targeted liposome-based nanoparticle drug delivery systems facilitate precise targeting and acid-responsive release in NSCLC. Our findings reveal that folate-mediated targeting of FRβ in tumor-promoting macrophages and NSCLC cells significantly suppresses tumor growth, while the stimulus-responsive release mechanism reduces drug-related toxicity. Furthermore, multiplex fluorescence imaging reveals that the combined use of docetaxel (an anticancer agent) and doxycycline (an anti-CAPN2 agent) with FRβ-targeted pH-sensitive liposomes exhibits a synergistic effect in suppressing tumor progression.

Observation of phase transformation of Sn by transmission electron microscopy

Mr. Yamato Kirii[1], Mr. Tetsuya Kubota[1], Mr. Sotatsu Yanagimoto[1], Mr. Takumi Sannomiya[1]
[1]Tokyo Institute of Technology, Yokohama, Japan

Poster Group 1

Background
Tin (Sn) experiences phase transformation from metallic β phase to semiconductor α phase at 13 °C, and to liquid phase at 232 °C [1]. During the phase transformation from β phase to α phase, the metallic luster is lost [2], and the structure becomes prone to collapse, which is known as tin pests. In recent years, lead-free solder has attracted attention where Sn is often used as a substitute for lead (Pb) in the electronic products. Since the electronic elements become miniaturized down to nanoscales, understanding of the behavior of Sn at nanoscales is important. In this study, we investigated the phase transformations of Sn nanoparticles at low temperatures using transmission electron microscopy (TEM) and also carried out the optical measurement at high temperatures.
Methods
On a TEM grid with a SiN membrane, Sn of 99.9% was deposited with a target thickness of 14 nm for a flat configuration. The Sn-deposited sample was annealed at a temperature of 300 °C for 3 hours to form particles. The prepared sample was measured in TEM after being cooled down to -177 °C using liquid nitrogen. At -177 °C, the sample was held for one hour to allow for a complete phase transformation, and the TEM images and diffraction patterns were acquired. The temperature was then raised to room temperature (20 °C) by the heater and the TEM image and diffraction pattern were acquired.
For the optical measurement, we first deposited Sn nanoparticles of different sizes on borosilicate glass at film thicknesses of 1.5 nm, 3 nm, and 6 nm. The samples for the optical measurement were annealed under the same conditions as before to convert the films into nanoparticles. The particle sizes for each sample were measured to be 21.8 nm, 30.6 nm, and 83.0 nm, respectively. The samples were then coated with a 13.3 nm thick layer of AlN to prevent oxidation. The transmission spectra of the Sn nanoparticles of different sizes were measured while changing the temperature up to the phase transition point.
Results
The obtained TEM images at -177 °C and room temperature are shown in Fig.1(a), and (b), respectively. Although volume change is expected by the phase transformation to the α phase, no clear change in the shape of the nanoparticles was observed in the bright field TEM images. The diffraction patterns at -177 °C and room temperature are shown in Fig.2(a) and (b). The sharp Debye rings are clearly observed in Fig. 2(a) at -177 °C, while the Debye rings at room temperature are broad and vague as shown in Fig. 2(b). This indicates the crystallinity change (from large crystalline to smaller one) during the phase transformation although no clear shape change in the nanoparticles was observed in the bright field TEM image. The low-temperature crystal structure was identified to be the diamond structure, while the crystal structure at the room temperature was unable to be determined.
For the optical measurement at high temperature, the transmission spectrum for the nanoparticle with means diameter of 30.6 nm is shown in Fig. 3. It can be observed that the transmission intensity and the wavelength of the resonance peak change drastically at the phase transition from β phase to liquid. Moreover, the resonance wavelength shifts to the shorter wavelength at the liquid phase

together with the decrease in the transmission intensity, and the peak width. The transmission spectra of the samples with other sizes showed similar results.

Conclusions

We have successfully observed the phase transformation of Sn nanoparticles from the β phase to the α phase from the diffraction patterns obtained using TEM. The diffraction pattern at low temperature showed only α-phase rings, indicating a complete transformation of Sn nanoparticles into the α-phase. In the optical measurement at high temperature, we successfully observed the solid-to-liquid phase transition of the Sn nanoparticles in the transmission spectra.

Pulse counting in the SEM

Dr Jonathan Peters[1], Dr Lewys Jones[1]
[1]truboTEM Ltd., Dublin, Ireland

Poster Group 1

Single electron pulse counting has revolutionised low-dose TEM and STEM imaging by providing zero background noise, quantitative information, and fast detector response times. This allows the uses of lower doses with faster image acquisition times whilst maintaining image fidelity and signal-to-noise ratio. Whilst this technology is common in the context of (S)TEM, the benefits of electron pulse detection are not obvious in the context of SEM and similar techniques such as Helium ion microscopy. Beam-related modification of samples can still occur (for example in battery anode materials), particularly for insulating samples where a low dose-rate may allow charging effects to dissipate. Scanning at high speeds can achieve this but can run into problems with slow detector response times, particularly scintillator-based technologies such as Everhart–Thornley detectors. Pulse counting can mitigate this, though the effect on image contrast is not as simple as the case of (S)TEM. For example, in secondary electron imaging, each signal pulse on the detector may represent multiple electrons, with the number (and therefore intensity) determined by the secondary electron yield from the sample. In this work, we present and discuss preliminary data using the turboTEM Pulse counter combined with SEM detectors to show the benefits and potential use cases for SEM imaging, from mitigating noise for low signals, increasing detector speed, and exploring the possibilities of new imaging modes.

Poster Group 1

Background incl. aims
Quantifying electrostatic potentials in semiconductors at high spatial resolution is essential for understanding and optimizing the performance of semiconductor devices. Various electron beam-based microscopy techniques are employed to achieve this goal. Among these techniques, electron holography in a transmission electron microscope (TEM) has proven particularly effective for demonstrating the interface potential in p-n junctions and heterostructures. This technique provides highest energy precision at nm scale resolution, while minimizing electron beam induced damage to the sample. However, previous studies have revealed intriguing results. In particularly, the electron optical phase contrast observed across p-n junctions is always smaller than anticipated, whereas the phase contrast across a n-n+ doping step is larger than expected. This work aims to elucidate the physical origin of the phase contrast measured by electron holography of doping structures, seeking to reconcile these discrepancies and enhance our understanding of the underlying mechanisms.
Methods
We use an n-n+ doping step in GaN with Si concentrations of 8×10^{17} and 3.5×10^{18} cm^{-3} as our As model system. lamellas were prepared using focused ion beam (FIB) milling. The FIB-prepared lamellas are investigated by off-axis electron holography in a TEM (FEI Titan G2 60–300 HOLO, FEI instrument) operated at 300 kV. The lamella is kept at edge-on orientation and tilted away from the [10-10] zone axis to suppress the dynamical diffraction.

Results
An example of a phase map derived from a hologram acquired across GaN doping step is displayed in Fig. 1a. The investigated lamella exhibits a crystalline thickness of 257 ± 6 nm and a damaged layer on the surface due to FIB processing. [1] The corresponding phase change profile is plotted in Fig. 1b, showing that the difference in the phase contrast across the doping step is 0.40 ± 0.02 rad. Lamellas with crystalline thicknesses ranging from 188 to 380 nm were measured, indicating an almost thickness-independent phase contrast across the doping junction. For quantitative interpretation of the measured phase change profiles, self-consistent electrostatic potential calculations are carried out, taking the presence of a surface Fermi-level pinning of the TEM lamellas into consideration. By fitting experimental data with self-consistent electrostatic potential calculations, we revealed a surface Fermi-level pinning of 0.7 eV above the valence band in III-nitride lamella. From the calculation, we find the predominant contribution to the phase contrast is shown to arise from the doping-dependent screening length of the FIB-induced surface Fermi-level pinning occurring in the defect-rich crystalline inner shell (below the outer amorphous shell). This near surface depletion region remains unchanged for lamellas with different thicknesses, resulting in an almost constant electron optical phase contrast vs. thickness. The contribution of the built-in potential is almost negligible since its value is too small for modulation doping and only relevant for large built-in

potentials at e.g. p-n junctions. Thus, the weak built-in potential of GaN doping steps adds only a small thickness dependence to the phase contrast. [2]

Conclusion

The electron optical phase contrast probed by electron holography at n-n+ GaN doping steps is found to exhibit a giant enhancement, in sharp contrast to the always smaller than expected phase contrast reported for p-n junctions. We unravel the physical origin of the giant enhancement by combining off-axis electron holography data with self-consistent electrostatic potential calculations. The predominant contribution to the phase contrast is shown to arise from the doping dependent screening length of the surface Fermi-level pinning, induced by FIB-implanted carbon point defects below the outer amorphous shell. The contribution of the built-in potential is negligible for modulation doping and only relevant for large built-in potentials at e.g. p-n junctions. This work provides a quantitative approach to so-called dead layers at TEM lamellas.

Graphic

Fig. 1. (a) Phase map across an n-n+ GaN doping step. The n-GaN layer exhibits a darker contrast. (b) Phase change profile extracted from the phase map averaged over a width of 500 nm. The n-n+ interface is positioned at 0 nm. The phase contrast across the doping step Δφ junction is 0.4 rad.

Localization of SHP-1 in Natural Killer Cells Across Education

Sophia Hald[1], PhD Thuy Thanh Luu[1,2], Petter Höglund[1]
[1]Center for Hematology and Regenerative Medicine (HERM), Department of Medicine Huddinge, Karolinska Institutet, Stockholm, Sweden, [2]CH Deparment of Medicine, University Hospital Basel, Basel, Switzerland

Poster Group 1

Natural killer cells learn to differentiate self from non-self cells through a process called education, wherein inhibitory receptors on natural killer cells interact with self-MHC class I molecules on healthy cells, leading to the acquisition of functional competence. Inhibitory receptors transmit signals via the recruitment of Src homology region 2 domain-containing phosphatase-1 (SHP-1), which downregulates activating signals, suggesting a role of SHP-1 in NK cell education.
Our recent super-resolution imaging studies have demonstrated a link between SHP-1 expression, localization, and morphology in activating synapses. Educated natural killer cells exhibited reduced SHP-1 expression and localized less to activating synapses compared to uneducated natural killer cells, indicating that SHP-1 may regulate the NK cell education process.
Interestingly, we also observed that the educating receptor Ly49A associates more extensively with SHP-1 in resting natural killer cells of uneducated cells compared to educated cells, suggesting a role for Ly49A in regulating SHP-1 involvement with activation synapses.
To further elucidate the role of SHP-1 in natural killer cell education we aim to develop novel techniques of investigating the natural killer cell synapses in real time. We will utilize high-resolution live cell imaging and super resolution techniques on primary cells and in vitro systems. In these studies, we will investigate SHP-1 correlations, localization, and dynamics, using continuously developed and refined analysis scripts to optimize and automate the data analysis process.
These investigations aim to provide a deeper understanding of SHP-1 regulation in natural killer cells and may lead to new therapeutic strategies for natural killer cell-related diseases.

Poster Group 1

Background:
Ligamentum flavum (LF) significantly contributes the development of lumbar spinal stenosis, which is a serious disease in the aging population. The aim of this study is to characterize the mechanical properties of native human ligamentum flavum and correlate them with histopathological changes.
Methods:
Mechanical property gradients across the cranial, medial, and caudal regions of LF were mapped and compared with corresponding histological sections. Coincidence analysis of mechanical property maps with pathological alterations in LF microstructure was conducted to assess the influence of these changes on micromechanical properties.
Results:
Results demonstrated significant heterogeneity in LF mechanical properties, with local variations correlating with specific histopathological features. Pathological changes, such as chondroid metaplasia and loss of elastic fibers, were found to impact the distribution of micromechanical properties.
Conclusion:
These findings highlight the importance of considering LF heterogeneity in its mechanical characterization and provide insights into the complex behavior of LF under pathological conditions.

Annular EDS in Transmission and TKD Combined for Chemical and Crystallographic Nano-Analysis in SEM

Dr. Purvesh Soni[1], Dr. Anna Mogilatenko[2,3], Dr. Meiken Falke[1]
[1]Bruker Nano GmbH, Berlin, Germany, [2]Ferdinand-Braun-Institut gGmbH, Leibniz-Institut für Höchstfrequenztechnik , Berlin, Germany, [3]Institute of Physics, Humboldt-University of Berlin, Berlin, Germany

Poster Group 1

Background and aims
The behavior of artificial or naturally occurring functional nanostructures can only be understood and / or tuned to our needs, if their chemical composition and geometric arrangement are fully understood. Correlative microscopy allows fast and specific explanation of macroscopic behavior based on nanoscale properties. We demonstrate the combination of large collection angle energy-dispersive X-ray spectroscopy (EDS) and transmission Kikuchi diffraction (TKD) [1] in SEM for studying the element composition and crystallographic properties of various materials prepared as electron transparent specimens. We show, that using the combination of these techniques in SEM can either deliver sufficient quantitative data on the nanoscale without the need for high-end STEM analysis or help to carefully prepare for and minimize the latter.

Methods
For the experiments we used an annular EDS detector [2] placed horizontally between the specimen and the SEM pole piece, thus providing a high solid angle of around 1 sr for X-ray collection. This geometry allows high count rates in case of low X-ray yield from thin lamellae, light element containing samples and in case of fast scanning needed for beam sensitive large specimens. The annular arrangement of the silicon drift detector quadrants parallel to the specimen surface around a small aperture for passing the electron beam furthermore enables a high take-off angle, minimizing absorption and enabling the spectroscopic analysis of rough topography or bent specimens. This geometry was combined with an electron detector directly underneath the specimen for on-axis Kikuchi diffraction pattern acquisition. Thus, element distribution and specimen thickness were delivered by quantitative EDS applying the Cliff-Lorimer and the EDS Zeta-factor methods [3], and crystallographic grain phase, size and orientation were accessible via TKD. For standard-based EDS, the specimen thickness was measured directly using grain size and specimen tilt.

Results
Some of the results are shown. The top part of the figure demonstrates the combination of crystallographic and chemical layer analyses of a Cu(In,Ga)Se_2 (CIGS) solar cell structure detail prepared as electron transparent lamella. Four crystallographic phases with large and small crystallites and different crystallite distributions could be identified over a wide specimen region using TKD. The respective IPF-Z colorings for each phase are shown combined to illustrate this. Knowing the crystal structure of the different functional layers and with that, their density, helps refining the accuracy of quantitative EDS to a few atomic percent. The CdS buffer layer and Ga-grading profile was quantified based on the Cliff-Lorimer method using a broadened line scan and the composition of a well-known CIGS region of the specimen as standard.
The lower part of the figure shows a similar combination of analyses for a copper connect. The specimen thickness was determined by tilt to be between 60nm and 80nm. The larger Cu plug

crystallites are in the same size range as the specimen thickness. This allows to conclude, that the overlap of Cu and Si in the spectroscopic signal is caused by the connect being slightly tapered, and that sample thickness does not cause further overlaps in that region. The quality of the Cu connect is important for the device performance. Crystallites of a few nm in diameter were identified in the Cu connect and Cu film as well, which is of interest, since crystallite size and grain boundary distribution can influence device behavior under extreme conditions.

Conclusion
Our data show, that the element composition and crystallography of device layers and interconnects can be studied quantitatively in SEM with the spatial resolution of a few nanometers and few atomic percent accuracy. The combination of annular EDS and TKD in SEM is a powerful tool and complements high-end STEM analysis. It should be applied not only to semiconductor structures. Further examples from materials and certainly life science would be valuable indeed to explore its potential.

High throughput automated SEM imaging and feature identification using AI/ML models

Mr. Aloshious Lambai[1], Mr. Zeb Akhtar[1], Dr. Araujo Cesar[1], Dr. Supriya Nandy[1], Dr. Elina Huttunen-Saarivirta[1], Dr. Marko Mäkipää[1]
[1]VTT Technical Research Centre of Finland Ltd, , Finland

Poster Group 1

Background
Accelerated materials development requires integrating automation with Artificial intelligence (AI)/Machine learning (ML) based workflows along selection of material composition, production, characterization, and testing [1]. Each stage possesses unique possibility of incorporating automation and AI/ML models, supporting efficient experimental activities and ultimately computational modelling, and reducing time and cost. Materials Acceleration Platforms (MAPs) [2] address these possibilities. MAPs concept involves developing the methods for predicting optimal alloy compositions, the automation of manufacturing processes, and the implementation of advanced materials characterization techniques. Among these, the field of high-throughput characterization remains the least developed.

This work focuses on developing protocols for the automated imaging and defect detection in High-entropy alloys (HEA), through automated SEM imaging and AI/ML based models. The developed protocols are then extended to automated fatigue fracture surface analysis of 316L stainless steels and the detection of features such as facets, dimples, and striations.

Methods
Automated imaging was performed with a Zeiss Ultra plus SEM at an accelerating voltage of 15 kV. This developed facility allows imaging of random fields of HEA samples at the desired magnification using in-house developed code and SmartSEM macro functions. The collected images were segmented to identify defects and background information using a DeepLab-v3+ encoder-decoder architecture for semantic segmentation. The encoder extracts information from the input image through convolutional layers, while the decoder refines the segmentation results, thus capturing fine details and improving the localization of object edges. A dataset of 160 images (1024 x 768 pixels each) with annotated masks was utilized with 70%, 15%, and 15%, respectively, as training, validation, and test sets.

The developed SEM automation and AI/ML protocols in HEAs were subsequently applied to the fatigue fracture surfaces of fatigue of 316L stainless steels samples. Rather than inputting random fields in the case HEAs, user-defined feature selection from overview images and comprehensive fracture surface mapping of 316L stainless steels were utilized. Figure 1 illustrates the method employed for automated fracture surface imaging. Additionally, the ML algorithm developed for void detection are being refined to identify fatigue fracture surface features.

Results
With this guided automatic image acquisition, over 1000 images were captured at a rate of ~60 images per hour using SEM from multiple samples within 24 hours without human intervention. The AI/ML model predictions on the collecte data set demonstrated highly accurate segmentation of

defects in images, with only minor deviations in a few instances, achieving scores of 0.994 for IoU (intersection over union) and 0.003 for dice loss, respectively. The predicted masks, generated within seconds, provide detailed information about the size, shape, and location of defects in the SEM images, thereby aiding in the analysis and decision-making process for alloy optimization and characterization.

Conclusion and outlook
Integrating automation and AI/ML models facilitates rapid material development by streamlining the traditionally tedious workflows required for optimizing material properties. We developed techniques for high-entropy alloys (HEAs) and extended them to fracture surface analysis through automated SEM image acquisition and feature identification using AI/ML models. This approach minimizes human intervention, accelerates analysis, and significantly reduces the costs and time associated with these activities.

Effect of thin 2D support layers on the catalytic properties of catalysts

Jeongwook Bae[1], Joohyun Lim[1]
[1]Department of chemistry, Kangwon National University, Chuncheon, Republic of korea

Poster Group 1

Background incl. aims
Electrochemical catalysts composed of metals used as active materials and supports for dispersion of active materials have advantages on both activity and stability. Carbon nanomaterials are widely used as conductive supporting materials. The coverage of support materials, even by a very thin layer of graphene, has been regarded as harmful for electrochemical reactions due to the physical blockage of active sites. However, recent research reported that the catalytic performance could be optimized depending on whether the active metal surface is covered with a monolayer of graphene, which alters the adsorption and desorption energies of reactants1 Considering diverse structures from the composites of metal nanoparticles and 2D support materials, controlling their structures and investigating structure-property relationships are important for developing novel catalysts. In this work, we used Pt nanoparticles as an active catalyst, and 2D MnO2 as support to prepare Pt-exposed and Pt-covered models for structure-relationship study.
Methods
Pt nanoparticles were synthesized using polyvinylpyrrolidone as a surfactant and ethylene glycol as a reductant. 2D MnO2 nanosheets were synthesized through oxidation of Mn2+ by H2O2 in the presence of tetramethylammonium hydroxide. To obtain Pt/MnO2 composites, the electrostatic self-assembly strategy was conducted. By changing the self-assembly process, two composite models were prepared. One is Pt nanoparticles covered with 2D MnO2 nanosheets (Pt-covered), and the other is Pt nanoparticles placed on the surface of 2D MnO2 nanosheets (Pt-exposed). The local structures and relative ratio between Pt and MnO2 were analyzed using transmission electron microscopy (TEM), X-ray diffraction (XRD), and inductively coupled plasma optical emission spectroscopy (ICP-OES), respectively.
Results
Two models had a similar Pt to MnO2 ratio. The Pt-covered model showed more dispersed Pt nanoparticles in the composites with less thickness of the 2D MnO2 layer assembly. The Pt-covered model revealed a lower electron transfer number for the oxygen reduction reaction compared to the Pt-exposed model, highlighting the possibility of controlling the catalytic pathway by changing the local structure of the composites.
Conclusion
In this study, we synthesized two model structures of Pt nanoparticles and 2D MnO2. Through ORR measurement, we observed that the catalytic activity varied depending on the structural differences. This indicates that the selectivity of catalytic reactions can be adjusted by controlling the catalyst structure. The detailed structure-relationship of the two models will be discussed.

1. Background incl. aims
Electrocatalytic water splitting is an environmentally sustainable method to produce clean hydrogen but generally demands expensive high-purity water. Thus, direct seawater electrolysis can be attractive, yet it has serious challenges, such as inorganic precipitation and chlorine corrosion, which reduce electrocatalytic activity. Seawater acidification using a bipolar membrane (BPM) has been proposed as a promising approach to mitigate these problems.[1] Meanwhile, Pt is the most active electrocatalyst for the hydrogen evolution reaction (HER), but its high cost limits its use. Therefore, two-dimensional MoS2 has emerged as a potential non-precious metal catalyst. Hybrid electrocatalysts, specifically Pt nanoparticles anchored on MoS2 nanosheets, have also been studied to achieve the required HER activity. However, it has not yet been studied under seawater conditions. Here, we investigate MoS2 nanosheets as a catalytic support in Pt/MoS2/carbon cloth (Pt/MoS2/CC) cathode, focusing on the structure and HER performance under a BPM-based seawater electrolysis system, compared with Pt/CC and MoS2/CC.
2. Methods
2.1. Synthesis of Pt/MoS2/CC
Pt/MoS2/CC was synthesized via the hydrothermal method followed by the sintering under N2 gas.
2.2. Physical and chemical characterization
Field-emission scanning electron microscopy (FE-SEM) was used to examine the morphology of the samples. Field-emission transmission electron microscopy (FE-TEM) was conducted to analyze the morphology and crystal structure of the samples. Energy-dispersive X-ray spectroscopy (EDS) was performed to check the chemical composition of the samples in SEM and TEM. X-ray diffraction (XRD) analysis was applied to determine the crystal structure of the samples. X-ray photoelectron spectroscopy (XPS) was employed to investigate the bond between Pt nanoparticles and MoS2 nanosheets with Pt and Mo oxidation states.
2.3. Electrochemical characterization
Electrochemical measurements were performed using a potentiostat. Linear sweep voltammetry (LSV) was conducted on a three-electrode system in acidic conditions. Chronopotentiometry (CP) was conducted on the BPM-based seawater electrolyzer in simulated seawater.
3. Results
SEM images of Pt/MoS2/CC showed that carbon cloth was entirely covered with dense MoS2 nanosheets, and Pt nanoparticles were attached to MoS2 nanosheets. In addition, Pt nanoparticles were not uniform. XRD patterns confirmed that the crystal structure of MoS2 was maintained after the sintering at 400/450 °C. During HER under a BPM-based seawater electrolysis system, Pt/MoS2/CC cathode showed lower overpotential and higher stability than Pt/CC.
4. Conclusion
Based on the result, MoS2 nanosheets are anticipated to enhance the anchoring strength of Pt nanoparticles, provide additional active sites, and compel the formation of inorganic precipitates, thereby contributing to stable catalytic activity. More details about the structural interaction

between MoS2 nanosheets and Pt nanoparticles, as well as the electrode characteristics of MoS2 in seawater, will be discussed.

Filtration technologies are of the highest interest to human civilisation since they decrease air pollution and can expand access to drinking water. In the case of application in the food industry, bacteria and microorganisms' growth are the additional factors that influence the lifetime of membranes. Appropriate materials can be deposited on the membrane surface to limit these phenomena. However, such coatings shouldn't affect the filtration parameters of the membranes. During the work, different types of nanocrystalline ceramics coatings (CuO, AgO, ZnO and Cu+ZnO, Ag+ZnO, Ag+AgO, AgO+CuO) were deposited using two magnetron sputtering techniques: DC MS (Direct Current) and HPIMS (High Power Impulse). The influence of deposition parameters on coating thickness, surface morphology, microstructure and chemical composition was analysed. The distribution of the deposited material on the membrane surface, the interface between the coating and substrate, and antibacterial properties were analysed. The investigation evidenced that the obtained coatings were characterised by homogeneous, nanocrystalline structures, but they had different microstructures and morphology. For example, CuO coatings exhibit columnar or needle-like structures, while nano-grains in AgO coatings have more equalized shapes. Moreover, in multicomponent coatings (AgO+CuO), changes in the cathode (copper or silver) power result in differences in coating microstructure. The use of two sources leads additionally to the composite structure (matrix and fine particles) of the coating. The performed investigation also revealed that the application of the HPIMS technique allows the deposit of coatings of more homogeneous and less porous microstructure with smaller grain size compared to the DC MS technique. Coatings exhibits good antibacterial properties.

Background: Metabolic Syndrome (MS) includes a series of metabolic disorders such as abdominal obesity, insulin resistance, impaired fasting glucose, hypertension, and dyslipidemia, with insulin resistance being a dominant factor in these conditions (1. MS is associated with obesity resulting from a high-fat and high-sugar diet combined with a sedentary lifestyle and is increasing as a global public health issue. Infertility affects 15% of couples worldwide, with male factors playing a role in 50% of cases (2). Paternal obesity leads to reduced sperm count, increased sperm DNA damage, and long-term epigenetic changes (3). Vitamin D3 plays a role in the regulation of reproductive processes in addition to maintaining calcium and phosphorus homeostasis. Vitamin D deficiency can impair testicular development and spermatogenesis by inhibiting testicular germ cell proliferation (4). We aimed to explore the impact of metabolic syndrome on male infertility and analyze the influence of vitamin D supplementation on testicular damage, cell proliferation, and apoptosis induced by a high-fat and high-fructose diet.
Methods: To create a metabolic syndrome model, we utilized a specialized diet comprising 17% fat and 17% fructose, along with another diet consisting of 20% fructose water over a period of 15 weeks. The study involved twenty-four male Sprague-Dawley rats. Based on dietary variations and vitamin D administration, we established four groups: Healthy Control (SC), Metabolic Syndrome (MS), MS+Vitamin D (MSD), and Healthy Control+Vitamin D (HCV) groups. The Vitamin D-treated groups received oral vitamin D supplementation at a rate of 170 IU/week for 12 weeks. At the end of the 15-week period, the animals were euthanized. Testicular tissue samples were fixed in 10% buffered neutral formalin and embedded in paraffin for further analysis. Throughout the experiment, daily food intake, water consumption, weight changes, as well as fasting blood glucose levels were monitored. Immunohistochemistry techniques involving primary antibodies against aromatase, StAR, 8-OHdG, Vitamin D receptor (VDR), PCNA, and activated caspase-3 proteins were performed. Serum testosterone levels were measured using ELISA method, and TUNEL method was used to determine apoptotic cells.
Results: Statistical analysis revealed that animals in the MS group exhibited significantly higher daily caloric intake, were heavier, and had elevated fasting blood glucose levels compared to other groups. VitaminD administration led to decreased blood glucose levels inthe MSD group compared tothe MS group possibly due to its metabolic regulatory effect. Morphological examination indicated irregular seminiferous tubules with reduced diameters in the MS group compared to other groups, resulting from germ cell loss and a thickening of the basement membrane. Moreover, the number of spermatid cells within these tubules as well as the number of spermatozoa within the lumen were

significantly diminished when contrasted with other groups. Testicular morphology showed improvement in the MSD group compared to the MS group. Expressions of aromatase, 8-OHdG, activated caspase-3, and TUNEL positivity were markedly increased with in the MS group; conversely StAR, VDR, and PCNA expressions along with serum testosterone levels was substantially decreased. Conclusion: It is suggested that high fat and fructose-induced metabolic syndrome contributes to male infertility by disrupting testicular structure however, vitamin D administration can ameliorate this damage.

Global BioImage Analysts' society: CZI funded initiative and future association

Dr Simon F. Nørrelykke[1]
[1]Department of Systems Biology, Harvard Medical School, Boston, USA

Poster Group 1

GloBIAS is a non-profit association to be officially constituted by 2025. GloBIAS aims to develop, discuss and establish the role of BioImage Analysts worldwide by expanding the NEUBIAS activities globally in the same spirit and disciplines, to provide the community with a sustainable base (educationally and financially) through a society and welcome a larger number of scientists involved in bioimage analysis.

3D Spatial Transcriptomics: A MERFISH Platform for High-Resolution Molecular Imaging

Postdoc Sofie Bendixen[1], PhD Jakob Tornby[1], Scientific Staff Morten Ebbesen[1], PhD Rikke Tholstrup[1], PhD Katharina Kaiser, Professor Jonathan Brewer[1]
[1]Department of Biochemistry and Molecular Biology, University of Southern Denmark, Odense, Denmark

Poster Group 1

Spatial transcriptomics (SP) is a rapidly growing technology in the field of genomics that gives insights into the cellular organization and their molecular interactions within complex tissues. High-resolution imaging-based SP techniques allow us to visualize and quantify numerous RNA species within individual cells even in subcellular compartments.
We have developed an in-house automatic imaging-based platform that utilizes computational algorithms to localize individual transcripts in 3D. This platform is built on the MERFISH (Multiplexed Error-Robust Fluorescence In Situ Hybridization) technology that combines the principles of fluorescence in situ hybridization (FISH) with multiplexed barcoding strategies. Our platform has been built to encompass a wide range of samples, including cell cultures and tissues. In line, we have implemented tissue clearing in our protocol to reduce background autofluorescence in various tissues - improving our signal-to-noise and spot detection.
Current tools for processing the imaging data from a MERFISH experiment are deficient when processing these large 3D data sets. Thus, we have developed a barcode decoding tool utilizing iterative clustering, which has been incorporated into a larger pipeline consisting of open-source packages. This pipeline is written in Python and is highly focused on utilizing the GPU, parallelization, and machine learning. To validate the pipeline, a simulator of 3D MERFISH data has been developed, which can be tuned to different levels of noise and bit-errors.
By combination of error-robust encoding and super-resolution microscopy, MERFISH overcomes the limitations of traditional FISH techniques, providing enhanced accuracy and sensitivity in detecting and quantifying RNA molecules. Furthermore, the versatility and adaptability of MERFISH make it a valuable tool for unraveling the intricate molecular landscape of cells and tissues, with implications in numerous fields ranging from developmental biology and neuroscience to cancer research and beyond.

Poster Group 2

Ni coarsening during operating conditions in Ni/YSZ solid oxide cells is the dominant degradation mechanism of these devices1. In this study, we showcase Scanning 3DXRD (S3DXRD) and high-energy X-ray fluorescence tomography (XRF) to map the 3D volume of a solid oxide under ex-situ heat treatment with an unprecedented spatial resolution of 100 nm. Scanning 3DXRD is highly advantageous compared to conventional tomography as it adds crystallographic information to the spatial maps. This helped us to pinpoint the areas where we observed Ni particle aggregation coarsening which is detrimental to these devices. We observe correlations between Ni grain growth quantified using crystallographic information and Ni coarsening observed through the XRF maps. These results advance our understanding of Ni coarsening mechanisms in a SOC device and can help us solve the challenge of making them more stable under operating conditions.
