point-like diffraction patterns as a 2D array, with one pattern taken at each point on a 2D array grid of tilts. Figure 1a is the average electron diffraction pattern over all tilts, where the intensities are quasi-kinematic due to the averaging of the intensities. Figure 1b shows the expected structure of the Zeolite at the [100] orientation. Figure 1c is the recovered LARBED Patterns for individual selected disks from the incident beam to the (0,2,6) family of reflections. The bright lines perpendicular to the g-vector direction are generally where the Bragg excitation is satisfied. Note the exact zone axis displays the most complex interactions with highly varying intensity in nearly all beams. This is indicative of multiple scattering effects between many beams as they are all in or near excited conditions. This represents, to our knowledge, the first example of this type of pattern on a large unit-cell, dose-sensitive crystal.

The details within the disk excitation lines also show the effects of small crystalline differences. For a perfect Ia-3d cubic crystal we expect each family of reflections to maintain expected mirror and rotational symmetries(4mm1R). In this case, there are several excitation lines with variations in the families of reflections. These deviations will also be present when performing microED and will subsequently affect the intensity integration. These types of deviations are not accounted for by multiple scattering alone.

Conclusions

Our results show unexpected intensity variation relevant to electron diffraction intensity integration. The splitting of excitation lines is the result of dynamic effects from small defects, orientation, or thickness differences in the sampled region of the crystal. These effects are apparent in LARBED patterns and can potentially be utilized to supplement microED data in the future. Careful selection of the intensities from LARBED patterns have the potential to aid statistical analysis of solved crystal structures.

Imaging Toxoplasma gondii tachyzoite infection: tracking a single protein effector by X-ray fluorescence microscopy

Dr Caroline Bissardon[1], Dr. Alexandre Boudgour[2], Victor Armijo[1], Dr Peter Cloetens[3], Gergely Papp[1], Dr Mohammed-Ali Hakimi[2], Dr Matthew W. Bowler[1]
[1]EMBL-European Molecular Biology Laboratory, Grenoble, France, [2]Institute for Advanced Biosciences (IAB), Team Host-Pathogen Interactions and Immunity to Infection, INSERM U1209, CNRS UMR5309, University Grenoble Alpes, Grenoble, France, [3]European Synchrotron Radiation Facility, Grenoble, France

Background incl. aims

Toxoplasma gondii is an intracellular parasite that infects over half the world's population and is the causative agent of toxoplasmosis – a condition extremely dangerous for developing foetuses and those with a weakened immune system. However, most people are unaware of infection as the organism tightly controls its host's immune response using a range of secreted effector proteins. A common strategy for intracellular pathogens is to take control of host signalling networks in order to re-wire the response to its own requirements (parasitism). There is increasing evidence that T. gondii uses a repertoire of products stored in a large heterogeneous family of secretory dense granules (DG) as effectors to subvert key functions of the host cell, primarily by taking over host cell gene transcription during infection [1,2]. However, the molecular mechanisms, and crucially, transport of these proteins, both out of the parasite vacuole and from host cytoplasm to nucleus, are unknown. We study the mechanisms, dynamics and transport of proteins delivered by T. gondii in human cells following invasion using a new metal-tag for XRF combined with phase contrast imaging and structural biology.

Methods

1. HFF primary cells (HFF-1 (ATCC® SCRC-1041TM)) cultured on Si3N4 membrane (Silson) in DMEM medium supplemented with 10% heat inactivated FBS (Invitrogen) [3]
2. Cells infected with Toxoplasma: Type I RH strain endogenously tagged at the GRA16 locus (RH ku80 GRA16-His12-HA(Hyaluronan)-Flag)
3. Samples cryofixed with EG at 24h exposure. Pressure wave generation spread the liquid and remove the excess, ethane jet vitrification on both support sides [5] and stored in LN2
4. Samples analysed (PC/XRFM)

Results

T. gondii uses a repertoire of products stored in a large heterogeneous family of secretory dense granules (DG) as effectors to subvert key functions of the host cell [1,2]. GRA16 was the first DG stored protein (GRA protein) shown to be exported to the host nucleus4 and binds USP7 (HAUSP) and PP2A-B55 via unknown mechanisms [4]. Once in the nucleus it controls p53 levels to determine cell fate by somehow modulating the activity of USP7 to deubiquitinate p53. Exported DG proteins are intrinsically disordered and cannot be exported if they contain a folded region. This has limited the study of these proteins by fluorescence labelling. We have labelled GRA16 with a short metal binding motif (12 histidines collating Ni2+) that will not interfere with export and will be labelled in vivo. A proof-of-concept experiment demonstrated that the tagged protein can be visualised by XRF (Fig.1).

Conclusion

By directly mapping these proteins in their native environment at high resolution, we hope to gain insight into how, when and where these proteins emerge from the parasite and enter the host cell for the first time. We reveal the location and timing of GRA16 and is also relevant to other parasite diseases such as malaria, Chagas disease and sleeping sickness. The concept of labelling these proteins with metals and imaging at high resolution has been successful and opens a large range of applications in the study of these and other proteins. We plan to complement these experiments with correlative techniques including sub-cellular mapping of the samples by light microscopy (staining using MitoTracker, CytoPainter…) before X-ray fluorescence as well as X-ray tomography. The knowledge gained would provide much needed information on how these parasites adapt the host cell to become a supportive environment that could be used for potential therapeutic applications.

Fully Integrated Pixelated 4D-STEM Detector for Scanning Electron Microscopes

Pavel Stejskal[1], Rastislav Motúz[2], Michal Horák[3], Tomáš Šikola[4]
[1]AdvaScope, Brno, Czech Republic, [2]TESCAN Group, Brno, Czech Republic, [3]Brno University of Technology, CEITEC, Brno, Czech Republic, [4]Brno University of Technology, Institute of Physical Engineering, Brno, Czech Republic

Poster Group 2

Four dimensional scanning transmission electron microscopy (4D STEM) refers to a technique where the electron beam scans across a 2 dimensional array on the sample while a detector positioned below the sample records a 2 dimensional pattern for each point in the array, thus creating a 4 dimensional dataset. 4D STEM is a common technique in TEM and is used for virtual imaging, orientation and strain mapping, and differential phase contrast. This work focuses on developments in detector design, centred on miniaturization and low energy sensitivity, which enable a 4D STEM detector to be used in scanning electron microscopy(SEM).
Presented is a 4D STEM solution based on a Timepix 3 hybrid pixelated detector. This detector consists of a matrix of 256 x 256 smart digital pixels (pixel pitch 55 µm), each containing advanced electronics for signal processing including digital registers. The digitisation is performed immediately for each detected electron recording complex information (position, energy and time) which suppresses unwanted signals and therefore selects only relevant events. This principle significantly improves image quality, reduces noise and increases the resolution and contrast in the acquired images. For 4D STEM applications the main advantages of this approach is the so-called data-driven readout, where every single detected event is streamed directly out of the chip, thus allowing dwell times of hundreds of nanoseconds, effectively removing the traditional bottleneck arising from the requirement to store a full pattern for each point in the array.
Figure 1 shows a map of 1536 x 1024 pixels of a stainless steel specimen, acquired in only 80 s. The full dataset with individual diffractograms along with the subsequent virtual diffraction image is shown. In this example, the high contrast arises from the noisless operation of the detector paired with the low energy sensitivity and the virtually unlimited dynamic range.
With a full integration of the detector into a microscope vacuum chamber the complete workflow from lamella preparation to 4D STEM imaging can now be realised. This approach significantly improve the performance capabilities achievable within SEM.

Advanced electron microscopy of trimetallic core-shell Pt/Au_xCu_{1-x} nanoparticles

Just Jonasse[1], Ms Marta Perxés i Perich[1], Ms Savannah Turner[1], Dr Jessi van der Hoeven[1]
[1]Materials Chemistry and Catalysis, Debye Institute for Nanomaterials Science, Utrecht University, Utrecht, Netherlands

Poster Group 2

Background:
Noble metal catalysts are widely used in heterogeneous catalysis due to their superior catalytic performance. By coating an inexpensive nanoparticle core with a noble metal, a core-shell catalyst is obtained, which can exhibit an increased catalytic activity[1], whilst limiting the use of expensive noble metals[2]. The increased activity of the core-shell catalyst compared to their monometallic counterpart can be caused by two distinct phenomena; i) lattice strain in the shell material induced by the lattice mismatch between the core and shell metal, and ii) electronic interactions of the core with the shell material[3]. In many cases, these effects are difficult to disentangle and a suitable model system to solely investigate the influence of shell lattice strain on catalytic activity is missing. In this work, we achieve such a system through the synthesis of trimetallic Pt-shell Au_xCu_{1-x}-core nanoparticles and investigate its structure using electron diffraction and high-resolution scanning transmission electron microscopy, yielding insight into the composition and crystal structure of this trimetallic system.

Methods:
Three transmission electron microscopy (TEM) techniques were applied to investigate the trimetallic Pt-shell Au_xCu_{1-x}-core system: selected area electron diffraction (SAED), high resolution STEM (HR-STEM) and elemental mapping (STEM-EDX). Pt/Au_xCu_{1-x} nanoparticles were dropcast onto Carbon Type-B, 200 mesh Hex, Molybdenum grids from Ted Pella, and then cleaned to limit carbon contamination using a literature procedure[4]. STEM-EDX maps and SAED patterns were acquired with a Talos200X microscope operated at 200 kV. I) SAED patterns were acquired for 1000-2000 Pt/Au_xCu_{1-x}nanoparticles with a selected area aperture size of 200 µm, a camera length of 520 mm and a screen current of 0.045 nA. II) STEM in combination with energy dispersive X-ray (EDX) mapping was used in a 512x512 px region with a pixel size of 0.512 nm/px, a dwell time of 5.00 µs/px and a screen current of 0.750 nA. III) HR-STEM images were acquired with an aberration-corrected Spectra300 microscope operated at 300 kV at a camera length of 145 mm and a screen current of 0.150 nA for a 2048x2048 px region and a pixel size of 27.29 pm/px.

Results:
In this work, we show the synthesis and characterization of Pt/Au_xCu_{1-x} nanoparticles (Figure 1a). Our nanoparticles were monodisperse in size with an average diameter of 12-15 ± 2.0-3.0 nm and a composition that could be varied from x = 0.81 to x = 0.23. Using SAED, STEM-EDX and HR-STEM, we show that it was possible to control the structural and compositional properties of these nanoparticles, without compromising size and shape control. A typical SAED pattern of many Pt/$Au_{0.59}Cu_{0.41}$ nanoparticles is shown in Figure 1b and allowed for the determination of the FCC lattice parameter, which was varied as a function of copper content. Combining this with HR-STEM imaging (Figure 1c), and STEM-EDX maps and linescans (as shown in figure 1d & 1e), the epitaxial overgrowth of the Pt-shell over the Au_xCu_{1-x}-core was directly related to the core composition and structure.

Conclusions:
In this study, the structure, composition and morphology of trimetallic Pt/Au_xCu_{1-x} nanoparticles, with x varying from x = 0.81 to x = 0.23, was elucidated. Advanced electron microscopy techniques revealed monodisperse core-shell nanoparticles with an epitaxially grown Pt shell and an average FCC lattice parameter that could be controllably varied as a function of copper content.

PS-03 (3), Lecture Theater 2, august 30, 2024, 14:00 - 16:00

Background incl. aims
Group III-Sb semiconductor nanowires are an important material system with potential uses in applications such as quantum electronics, optoelectronics, and sensing. This is due to their excellent electrical properties, including high carrier mobility and narrow band gap. However, current device development is slowed down by the difficulty to control the growth of Sb-based nanowires, as compared to the more common III-As materials. To a large extent this is caused by the complex growth conditions of antimonides, as elemental antimony exhibits low vapour pressure and surfactant effect.[1,2] In order to understand the limits and possibilities of the III-Sb nanowire system, a thorough investigation of the growth behaviour is therefore needed. Since atomic scale dynamics and liquid catalyst composition are parameters that are not readily accessible during conventional nanowire growth, in-situ investigations are crucial to develop a comprehensive understanding of the nanowire growth.
Methods
Herein we utilize a Hitachi HF-3300S environmental transmission electron microscope (ETEM) to grow and analyze Au-seeded GaAs and GaSb containing nanowire heterostructures in-situ as demonstrated in Figure 1 (a). This allows us to acquire high frame rate videos of nanowires using a Gatan OneView IS camera in addition to acquiring X-ray energy dispersive spectroscopy (XEDS) compositional data using an Oxford Instruments SDD X-MaxN 80T system. In order to conduct the in-situ growth studies Norcada MEMS chips with ex-situ aerosol deposited Au particles were used.[3] To perform the growth of GaSb nanowires trimethylgallium (TMGa) and trimethlyantimony (TMSb) were used as precursors.
Results
When conducting in-situ XEDS measurements during the growth of Au-seeded GaSb segments we have shown that the Ga concentration in the particle is in the range of 66 – 94 at.%, while the Sb concentration is in the range of 3-4 at.% depending on the used V/III ratio between precursors. The particle composition had a significant impact on the particle volume, which in turn affected the nanowire diameter as shown in Figure 1 (b-c). We observed that steady-state axial growth of GaSb nanowires with diameters in the range of 50-100 nm can be achieved (for the lowest and highest Ga concentration, respectively).[4] Varying the vapor phase composition and particle composition had a further effect on the growth dynamics. We examined the growth process by extracting incubation and step-flow process times from the nanowire growth videos at different V/III ratios. These processes describe the time it takes for a new layer to nucleate and subsequently the time it takes the layer to cover the liquid-solid interface, respectively. Our experimental observations and Monte-Carlo modelling of the growth revealed both processes to be predominantly affected by Sb atom abundance (in vapor and liquid phase). Lastly, we examined GaSb-GaAs heterostructure formation dynamics. Here we were able to show qualitative analysis of the kinking mechanism often found in these and similar high lattice mismatch heterostructures. Furthermore, we were able to demonstrate

that the growth of these highly lattice mismatched heterostructures can be attained via ternary GaAsxSb1-x segments.

Conclusions

In this study we offer a thorough in-situ analysis of the Au-seeded GaSb nanowires. Firstly, we demonstrate how the precursor flows affect the seed particle composition, which in turn affects the seed particle volume subsequently leading to dramatic changes in nanowire morphology. Furthermore, we examine in close detail the layer-by-layer growth dynamics revealing how precursor flows affect the step-flow and incubation processes revealing the growth to be mainly Sb limited. Lastly, we demonstrate how GaSb-GaAs heterostructures can be attained without nanowire kinking which offer insight into high lattice mismatch nanowire heterostructure growth strategies.

IM-08, Lecture Theater 2, august 28, 2024, 10:30 - 12:30

Background incl. aims
Vanadium dioxide (VO_2) exhibits a remarkable phase transition at around 68°C, accompanied by significant changes in its electronic and structural properties. This transition holds great promise for the development of advanced electronic switches, optical detectors, logic and memory storage and nonlinear circuit components [1,2]. However, the ultrafast dynamics of this transition are not fully understood, limiting its practical application. The temporal evolution of the structural phase and the question whether thermal or nonthermal effects dominate remains a controversial, debated topic to date [3], in particular, whether VO_2 transitions directly from the monoclinic phase (M1 - $P2_1/c$) to the rutile (R - $P4_2/mnm$) phase, or whether an intermediate monoclinic phase (M2 - C2/m) exists under certain conditions in a transient state. This potential intermediate phase which typically occurs under applied strain was proposed by X-ray spectroscopy and later disproved by ultrafast electron diffraction (UED). Our experimental approach which allows for a complete determination of the phase will shine light on this most recent debate.

Methods
Here, to investigate the spatio-temporal evolution of the phase transition we use an ultrafast transmission electron microscope (UTEM) which combines the nanometer spatial resolution of the TEM with the temporal resolution of femtosecond pulsed lasers. Our approach relies on the combination of an optical pump pulse for exciting the sample and a photoemitted electron probe pulse to detect structural dynamics in our sample. The UTEM allows us to probe the atomic structure on a sub-micron area with femtosecond resolution, thus extending the capabilities offered by UED [4] and X-ray techniques. Using this pump-probe technique, a change of the delay of the laser excitation with respect to the electron probe allows us to capture time-resolved diffraction movies in a stroboscopic approach. Given the similar diffraction patterns of the different structural phases of VO_2, the phases taken along well-defined zone axes can easily be confused. This is especially true with the conditions relevant for ultrafast electron microscopy, where one is further limited by low electron count rates (SNR), low spatial coherence and resolution. We overcome these difficulties by extending ultrafast electron diffraction, for the very first time, to ultrafast three-dimensional electron diffraction (3D ED [5]), where at each time delay the diffraction pattern of the sample is collected at multiple angles oriented off zone axes. This tilt series of diffraction patterns can then be combined and analyzed to build a complete 3D model of the atomic crystal structure without prior knowledge of the material. This approach allows us to clearly distinguish the different structural phases in VO_2 at moderate SNR and without the need of atomic structure simulations for comparison.

Results
We characterized the ground state of a single-crystalline VO_2 lamella made via focused ion-beam milling in a conventional TEM and confirmed its excellent crystalline quality by electron diffraction. Defocused imaging revealed bending and stress contrast in the lamella (see Graphic). Static 3D ED of VO_2 as a function of temperature (between room temperature and 100° C) showed the structural transition from the M1 to the R phase, without any evidence of a stress-induced M2 phase (see Graphic). These results were consistent, regardless of the electron probe size and position on the lamella.
The ultrafast 3D ED results are distinctly different from the static results. We unambiguously observe a transition pathway between the two monoclinic phases (see Graphic), from M1 to M1+M2, on a timescale of 500 fs. This can be indicative of several scenarios: (i) either the nature of the ultrafast photo-induced phase transition is different compared to the thermal phase transition, or (ii) the M2 phase is a metastable, transient state (and thus cannot be resolved in a static measurement), or (iii) the photo-excitation leads to excitation of intense acoustic modes which induce notable stress in the material, placing VO_2 on a transition trajectory to a different structure. Our results were reproducible, and the sample did not show any sign of photoinduced damage. Importantly, the laser repetition rate of 12 kHz was kept such that the system could return to its ground state between sequential pump laser pulses.

Conclusions
In summary, we have for the first time demonstrated the feasibility of 3D ED in the ultrafast regime. The results allowed us to unequivocally determine the crystal structure of VO_2 in the time-resolved regime. Surprisingly, and in contradiction to existing literature, we unequivocally detect the presence of a monoclinic M2 transition state in our well-defined, single-crystalline sample. The M2 phase persists over several picoseconds. We plan to extend our study by collecting more data sets at longer temporal delays and with the intention to gain further insights into the underlying mechanisms governing the transition. Of special interest is how photoexcited acoustic modes or different lamella geometries affect the transient stress and ultimately the transition pathway. We believe that ultrafast 3D ED will become indispensable for transient structural determination in the near future. In contrast to three-dimensional X-ray or neutron diffraction, our approach is more readily available, does not require large-scale facilities, and offers better spatial resolution, thus facilitating the exploration of micro/nano-crystals and individual domains.

Effect of preparation and oxygen evolution catalysis on CoNiFe oxide electrocatalysts revealed by STEM-EELS

Dr. Nils Rockstroh[1], Ms. Trang Pham[1], Mr. Carsten Kreyenschulte[1], Ms. Annette-Enrica Surkus[1], Mr. Robert Francke[1]
[1]Leibniz Institute for Catalysis e.V. (LIKAT), Rostock, Germany

Poster Group 1

Background incl. aims
Hydrogen is considered as a competent and green energy carrier that can be obtained by water electrolysis [1]. However, this process is mainly limited by the water oxidation half reaction, the OER (oxygen evolution reaction). Therefore, substantial efforts for this reaction focus on the development of catalysts that are comprised of abundant metals, and which simultaneously fulfil the requirements of high current densities, low overpotential, high mass activity and excellent stability. Here, such a system is presented using CoNiFe oxide in alkaline oxygen evolution. The effect of the synthesis procedure as well as the influence of the catalytic conditions on the material are investigated by STEM coupled with EELS and EDX.

Methods
The catalysts were investigated by a probe corrected JEOL JEM-ARM200F (Schottky emitter) equipped with a Gatan Enfinium ER EELS and a JEOL JED-2300 EDX spectrometer having a silicon drift detector (dry SD60GV). A rather high beam current was applied to keep the acquisition time low. The FWHM of the zero-loss peak (ZLP) was about 1.2 eV and the DualEELS mode was applied. The spectra were recalibrated at each pixel by the position of the ZLP.

Results
CoNiFe (2:2:1)/M, synthesized under an oxygen-deficient atmosphere (1 vol% air in Ar), shows the best catalytic performance. Synthesis of CoNiFe (2:2:1) under a reductive atmosphere (CoNiFe (2:2:1)/H; 5% H2 in Ar) or oxygen-rich conditions (CoNiFe (2:2:1)/A; air) leads to less active catalysts. While CoNiFe (2:2:1)/M and CoNiFe (2:2:1)/A show a quite uniform distribution of the incorporated metals, CoNiFe (2:2:1)/H shows enrichment of metallic Ni containing nanoparticles on the bulk. More pronounced differences can be observed in the EEL spectra, in particular at the O K edge. Whilst CoNiFe (2:2:1)/A shows a pronounced pre-edge feature at about 528 eV, it is only barely noticeable and slightly shifted to higher energy losses in CoNiFe (2:2:1)/H and CoNiFe (2:2:1)/M. Additionally, CoNiFe (2:2:1)/M exhibits a feature at about 545 eV, which was not present in the other materials. This behaviour is also observed in the spectral regions (L edges) of Co, Ni, and Fe. All M L edge features of CoNiFe (2:2:1)/A ressemble that of oxidized metals M [2-4]. In contrast, CoNiFe (2:2:1)/H and CoNiFe (2:2:1)/M show both, reduced and oxidized states of the contained metals. In CoNiFe (2:2:1)/H, metallic Ni was observed, with Co and Fe remaining oxidic. In addition to metallic Ni, CoNiFe (2:2:1)/M exhibits also partially reduced Co. The incomplete reduction of the metal centers in CoNiFe (2:2:1)/M and CoNiFe (2:2:1)/H is also reflected by the presence of an oxygen signal.
The most active catalyst CoNiFe (2:2:1)/M was also investigated after electrolysis in the absence of nafion. The observed decrease of the ECSA (electrochemically active surface area) was also reflected by a denser appearance of the particles and a decreased size of the crystallites constituting these particles (see graphic). The composition of the material has also changed considerably with a non-uniform distribution of the constituting elements. Some regions lack almost completely Ni and

exhibit a reduced contents of iron, leading to a cobalt enriched material. The EEL spectra at the O K edge ressemble those of the fresh catalyst, while the L edges of Co and Fe point towards the presence of these metals in their oxidized forms.

Conclusion
STEM-EELS is a powerful method to investigate changes of electrocatalysts at the nm scale. The different preparation procedures of CoNiFe (2:2:1) yield materials with differently oxidized metals which can be observed by EELS. While CoNiFe (2:2:1)/A exhibits completely oxidized metals, metallic Ni is present in CoNiFe (2:2:1)/H and non-oxidic Ni and Co are present in CoNiFe (2:2:1)/M. After electrolysis in the presence of CoNiFe (2:2:1)/M the signal shape at the O K edge is retained, however, the material is lacking some Ni. STEM-EELS is thus able to detect changes at a very low concentration of the analyte that may escape the eye of bulk analysis methods.

L-TEM characterization of controlled skyrmion nucleation in synthetic antiferromagnetic multilayers

Sara Villa[1], Dr Christopher Barker[2], Dr Kayla Fallon[1], Mr Colin Kirkbride[1], Dr Trevor Almeida[1], Prof. Cristopher Marrows[3], Prof. Stephen McVitie[1]
[1]School of Physics and Astronomy, University of Glasgow, Glasgow, United Kingdom, [2]National Physics Laboratory (NPL), Teddington, United Kingdom, [3]School of Physics and Astronomy, University of Leeds, Leeds, United Kingdom

Poster Group 1

Background incl. aims
Skyrmions are circular magnetic textures whose topologically protected nature makes them great candidates for the development of novel information storage devices which are both power efficient and non-volatile [1]. Effective control of the skyrmion nucleation process is required for the development of such devices. Previous research has demonstrated how a focused ion beam (FIB) microscope can be used to engineer skyrmion nucleation sites in ferromagnetic multilayers by creating artificial point-life defects [2]. Such defects induce intermixing at the interfaces between the layers, which results in local modifications of the magnetic properties in this kind of samples where the strength of exchange interactions is highly correlated with the sharpness of the interfaces.
The present work builds on this research by applying this technique to a synthetic antiferromagnetic (SAF) multilayer sample. SAF multilayers are characterized by the presence of the RKKY interaction, which creates antiferromagnetic coupling between individual ferromagnetic layers. SAF skyrmions, which have been found to arise in such systems under specific field regimes, are characterised by minimal dipolar fields and are not susceptible to the skyrmion Hall effect. These properties make them more stable and better suited for spintronic applications than ferromagnetic skyrmions [3].
Methods
In this project, an array of point-like defects was irradiated on a SAF multilayer using the 10 nm probe (FWHM) of a Ga+ FIB. Defects were induced by a range of Ga+ ion doses, spanning from 10^{13} ions/cm² to 10^{18} ions/cm². The magnetic behaviour of the sample within the irradiated region was observed under Lorentz transmission electron microscopy (L-TEM) in the Fresnel mode, which allows for the direct visualization of magnetic textures. This led to the in-situ observation of the skyrmion nucleation and pinning behaviour in the presence of an external magnetic field. The magnetic behaviour of the sample outside of the skyrmion phase was also recorded.
Results
Nucleation and pinning of skyrmions were observed at the location of the defects. This behaviour was observed in the ferromagnetic regime of both sides of the hysteresis loop (Fig.1). We note that, in the non-irradiated state, skyrmion nucleation is only observed when starting from a saturated state, and only after the field had passed through zero.
Conclusion
The behaviour recorded in the irradiated areas of this SAF system differs from the behaviour recorded prior to irradiation. The field regime at which we observe skyrmion nucleation and pinning at the location of the artificial defects indicates that these skyrmions are likely to be ferromagnetic in nature in this initial study. The effects of FIB irradiation on the SAF phase of the sample are currently under investigation.

Poster Group 2

Background incl. aims

Coherent phase modulation of the free-space electron wavefunction has the potential to dramatically extend the applications of electron microscopy by enabling, e.g., enhanced image contrast in Cryo-Electron Microscopy [1], Single Pixel Imaging [2] and quantum information processing [3]. Measuring the phase degree of freedom is challenging because conventional approaches to electron detection are sensitive to deposited energy. Pump-probe ultrafast electron microscopy allows for the implementation of phase retrieval algorithms by comparing pre and post-excitation images, using the pre-excitation image to define a reference phase. Here we demonstrate phase retrieval performed on a probe beam passing through a fast moving, dilute free electron gas.

Methods

Our specimen in pump probe experiments is shown in Fig. 1 a. and consists of a nanometer thin gold film suspended on a standard 3 mm gold TEM grid. We illuminate the specimen with point projection optics (i.e., Lorentz microscopy) and collect the scattered beam at long diffraction camera length, so that the electron intensity on the detector mixes momentum and real-space information, a critical experimental detail for enabling phase reconstruction. We pump the specimen with 1030 nm, 290 fs laser pulses, emitting a low energy cloud of electrons in the path of the probe beam. We record changes in the detected probe caused by the electron cloud as a function of pump-probe delay. The specimen geometry is invariant in one of the two directions transverse to the probe beam trajectory and we improve signal to noise by averaging along the invariant direction, as indicated in Fig. 1 a.

Results

Figure 1. b. shows the modulation of the transmitted beam intensity as a function of position on the sample and delay time. Relying on charge conservation, a deflection angle is computed from the local change in beam intensity as a function of delay as shown in Fig. 2, and from this deflection angle the phase-change of the electron beam is calculated. Figure 3. shows the phase shift as a function of delay time and position using a 2π periodic colormap.

Conclusion

We have demonstrated how the combination of pump-probe specimen modulation with point projection electron optics (Lorentz microscopy) enables phase retrieval. In subsequent experiments,

phase retrieval has allowed us to go further and extract key experimental observables from our data, e.g., the charge density of the specimen gas.

This work is part of the SMART-electron Project that has received funding from the European Union's Horizon 2020 Research and Innovation Programme under Grant Agreement No. 964591.

Hard X-ray nano-imaging of Toxoplasma gondii tachyzoites & merozoites

Dr Caroline Bissardon[1], Dr Alexandre Boudgour[2], Victor Armijo[1], Dr Peter Cloetens[3], Gergely Papp[1], Dr. Mohammed-Ali Hakimi[2], Dr Matthew W. Bowler[1]
[1]EMBL-European Molecular Biology Laboratory, Grenoble, France, [2]Institute for Advanced Biosciences (IAB), Team Host-Pathogen Interactions and Immunity to Infection, INSERM U1209, CNRS UMR5309, University Grenoble Alpes, Grenoble, France, [3]European Synchrotron Radiation Facility, Grenoble, France

Background incl. aims

High resolution imaging of biological samples is currently undergoing several revolutions. Light microscopy can obtain details at subcellular scales in organs and whole organisms and cryo-electron tomography is approaching atomic resolution of macromolecules in situ. Hard X-ray nano-imaging is an emerging technique allowing high resolution phase contrast imaging combined with X-ray fluorescence microscopy of biological samples. Phase contrast tomographic imaging of biological samples using X-rays fills several spatial and temporal gaps in the imaging tool box and when correlated with other techniques it will provide breakthrough results in understanding cellular processes. Tomograms can be collected providing 3D reconstructions, at resolutions of 50 nm, that can be combined with the distribution of elements within the sample. We have been applying this technique to the study of toxoplasma tachyzoites and pre-sexual merozoites in human cells. This study is already providing important information on the physical interaction between these developmental stages (Figure 1C) and their effects on the host cell but also on the effects on metabolism, for example iron distribution in the cell.

Methods

1. HFF primary cells (HFF-1 (ATCC® SCRC-1041TM)) cultured on Si3N4 membrane (Silson#) in DMEM medium supplemented with 10% heat inactivated FBS (Invitrogen) [1]
2. Cells infected with Toxoplasma: Type I RH strain endogenously tagged at SEC14 or GRA1 locus.
3. Samples cryofixed with EasyGrid at 24h exposure. Pressure wave generation spread the liquid and remove the excess, ethane jet vitrification on both support sides and stored in LN2[2].
4. Samples analysed (PC/XRFM)

Results

Several types of imaging are extremely powerful techniques in the study of these processes: one of them is XRF & PC imaging. Phase contrast tomographic imaging of biological samples using X-rays fills several spatial and temporal gaps in the imaging tool box and when correlated with other techniques it will provide breakthrough results in understanding cellular processes. Tomograms can be collected providing 3D reconstructions, at resolutions of 50 nm, that can be combined with the distribution of elements within the sample. With this technique at cryogenic temperature, we can obtain crucial information on the morphology and the divalent cations distributions within the samples in near-native conditions. It is important to provide an overview of the different elements and then proteins that can be implicated in the metabolism and development of the disease. We then managed to obtain information that is providing new insights in parasite research. This study is already providing important information on the physical interaction between Toxoplasma tachyzoites and pre-sexual merozoites [3] and their effects on the host cell but also on the effects on metabolism, for example iron distribution in the cell. We also studied mutants revealing interesting features regarding the

calcium and other ion distributions within the cells and the parasite itself (Fig 1). In order to find some insights of the bio-metabolic mechanisms of the different stages of TG infection [4], we studied the ionic distribution of all the elements present intrinsically within the infected cells and parasite itself. While potassium K expressed the well-preservation of the samples – parasite, other elements – iron Fe & calcium Ca – present some very interesting & intriguing distributions. They seemed to be concentrated in the dense granules, and this phenomenon appeared to be overexpressed in the case of TG mutants.

Conclusion
Thanks to reproducible and automated sample preparation, the study of the cells infected by TG parasites through diverse techniques especially the XRFM. EG offers the in-depth vitrification of the samples with a very good ice quality (no crystalline ice present in the sample) and a vitrification that is homogenous on the whole cell height which allows a high-quality data collection. The preliminary results are extremely promising. Fe- & Ca-ionic distributions with the parasites and the cells reveal a change in the metabolic processes in TG mutants.

Poster Group 2

Background incl. aims
Bacterial contamination of biomedical surfaces is a serious threat that can lead to nosocomial infections, with a prevalence reported up to 10 %.1 Treatment of such infections is complicated by emerging antimicrobial resistance.2 Potential solution lies in the development of novel antibacterial surfaces that prevent the initial bacterial adhesion. In this sense, magnetron sputtered ZnO thin films are attracting attention as the properties, including biological, of the thin films can be regulated by changing the sputtering conditions. In addition, doping ZnO with elements from group I and IB (e.g. Ag and Cu) can influence the structural and morphological properties of the thin films. However, a major disadvantage for the biomedical application of this material is the lack of porosity.3 The aim of this research was to evaluate the differences between Ag and Cu doping of ZnO and to determine whether changes in surface morphology due to the coating with calcium phosphate can influence the biological responses of the material.
Methods
Ag- and Cu-doped ZnO thin films were prepared by magnetron sputtering, followed by biomimetic deposition of calcium phosphate to potentially improve bioactivity. Characterization focused on microscopy techniques including scanning electron microscopy (SEM), helium ion microscopy (HIM) and atomic force microscopy (AFM) to investigate microstructural changes. Additional characterization of structure and composition included grazing incidence small-angle X-ray scattering (GISAXS), energy dispersive spectroscopy (SEM/EDX), and X-ray diffraction (XRD). Wettability and surface free energy were assessed, and ion release was measured using inductively coupled plasma mass spectrometry (ICP-MS). Biological characterization included cell viability assays with MG-63 cells and biofilm formation assays with Staphylococcus aureus and Pseudomonas aeruginosa.
Results
Microscopic analysis revealed that the thin films have irregular granular structures in all cases, with Ag or Cu doping influencing the size and shape of grains. Increased Ag or Cu content had opposite effects on the grain size of the nanostructured thin film. Further SEM/EDX and XRD analyzes indicated that Ag or Cu were incorporated into the ZnO crystal structure. Calcium phosphates were successfully deposited as individual crystals or aggregates. The deposition of calcium phosphates slightly improved cell viability, with the effect being greater for Ag-doped ZnO. The addition of calcium phosphates also showed better prevention of biofilm formation.
Conclusion

Ag- and Cu-doped ZnO thin films with calcium phosphates were investigated as antibacterial surfaces for biomedical applications. The doping allowed control over the morphology of the nanoparticles, while the deposition of calcium phosphates showed the potential to improve cell viability and inhibit biofilm formation. These results are promising for the development of effective coatings to prevent nosocomial infections and for a variety of other antimicrobial applications.

Influence of titanium surface modifications on formation of composite calcium phosphates / silver nanoparticles coatings

Suzana Inkret[1], Dr. Ina Erceg[1,2], Prof. Dr. Silke Christiansen[2,3], Dr. Maja Dutour Sikirić[1]
[1]Department of Physical Chemistry, Ruđer Bošković Institute, Zagreb, Croatia, [2]Fraunhofer Institute for Ceramic Technologies and Systems IKTS, Forchheim, Germany, [3]Innovation Institute for Nanotechnology and Correlative Microscopy – INAM, Forchheim, Germany

Poster Group 2

Background incl. aims
Due to their chemical and mechanical stability, as well as biocompatibility titanium and its alloys are among most frequently used materials for hard tissue implant materials [1]. However, they are biologically inert, a problem which is usually surpassed by coating them with bioactive calcium phosphates, which results in improved adhesion of coating material and cells [2]. As major problem in orthopaedic surgery are implant associated infections, the coatings should in addition have antimicrobial properties. One way of achieving this is incorporation of antimicrobial components in calcium phosphate coatings. In this sense, silver nanoparticles attract attention due to the fact that silver exhibits a broad spectrum of antimicrobial activity and is unlikely to cause bacterial resistance [3].
Methods
The titanium surface was chemically modified using two different methods using strong acids, namely hydrochloric acid previously described by Lu et.al. [4] and using a mixture of hydrochloric and sulfuric acid previously described by Wang et.al. [5]. After modification of the titanium surface, composites of silver nanoparticles and calcium phosphates were coated by wet chemistry method. The influence of the different surface modifications on the formation of the composites was investigated by scanning electron microscopy (SEM), energy dispersive X-ray spectroscopy (EDS), Raman spectroscopy and atomic force microscopy (AFM).
Results
The modification of titanium surfaces changes surface properties such as roughness and wettability, as shown by AFM and contact angle measurements. Composites of calcium phosphates and silver nanoparticles formed on treated, but also on untreated titanium surfaces. SEM and EDS measurements showed that the morphology and uniformity of the coatings change depending on the surface modification.
Conclusion
Surface modification of titanium is an important step in a process for coating titanium with functional materials such as composites of calcium phosphates and silver nanoparticles, as it modifies surface properties and thus influences the deposition of coatings. The results obtained can contribute to the development of an ideal procedure for the preparation of antimicrobial coatings on titanium surfaces.

IM-04 (2), Lecture Theater 1, august 27, 2024, 14:00 - 16:00

Background
Having been utilized in scanning electron microscopes, secondary electron emission is considered a well-established nano-scale probe for mapping the surface morphology of materials. It has also been demonstrated that secondary electrons (SE) emitted from materials can provide additional information on the local work function, bulk density of state (DOS), surface potential, charging/discharging characteristics, and elemental/chemical properties of bulk materials. The nano-scale lateral resolution and surface sensitivity of low-voltage scanning microscopes give them a unique advantage for the investigation of surfaces. However, the surface contamination caused by exposure to electron beams has always been a limiting factor for this purpose. Since the yield of SE emission is higher than that of Auger emission, the secondary electron emission spectromicroscopy (SEES) performed in an ultra-high vacuum chamber using a scanning Auger microscope (SAM) can be a very powerful tool for surface characterization, especially in the case of ultra-thin materials. Moreover, the concurrent SEES and Auger spectromicroscopy can also provide useful information on the analysis of light elements and hold promise for enabling nanoscale hyperspectral electron spectromicroscopy studies of 2D materials.
Method
We adapt our scanning auger microscope (SAM), equipped with a cylindrical mirror analyzer (CMA) and operated in an ultra-high vacuum, to SEES by tilting the sample holder and applying a negative bias to the sample. We also measured DOS/SEES signals on different materials at low voltages of 500 and 1000 eV.
Results
The SEES results showed that the SAM can perform SEES on different materials when the sample is tilted and negatively biased. The experimental SEES results on metals are in agreement with the Chung and Everhart theory. Moreover, quantum-state contrast on different materials, including ultra-thin films, can be mapped using the SEES acquisition approach. However, the DOS information can be extracted partially, due to a degree of distortion in the signal.
Conclusion
From the results, one can conclude that the SAM can be a proper platform for SEES. However, a lens should be commissioned to pre-accelerate the SEs properly before the entrance to the CMA, mitigating the field distortion around the sample holder. Moreover, the technique can promise the quantum-state mapping of 2D materials due to the limited degree of beam-induced surface contamination.

Impact of Electron Beam Irradiation on Carbon Black Oxidation

David Wahlqvist[1], Dr Mattias Mases[2], Dr Daniel Jacobsson[1], Dr Henrik Wiinikka[3], Dr Martin Ek[1]
[1]Center for Analysis and Synthesis, Lund University, Lund, Sweden, [2]Division of Materials Science, Luleå University of Technology, Luleå, Sweden, [3]RISE Energy Technology Center, Piteå, Sweden

Poster Group 2

Background
The use of environmental transmission electron microscopy (ETEM) in oxidation studies of nanocarbons, such as carbon black (CB), has revealed new, and confirmed previously suggested, oxidation mechanisms [1]. However, connecting ETEM studies to technical processes (occurring at very different conditions) is not necessarily straightforward. Primarily, the influence of the electron beam can present a large issue that is not easily resolved. For nanocarbon oxidation, there is a clear increase in oxidation rate depending on the dose rate, however, there are few studies reporting any quantification of this effect [2].
To better understand the origin of the beam-enhanced oxidation rate, we note that CB reacts with oxygen gas only at active sites, imperfections in the graphitic shell. These active sites are inherent to CB but can also be generated through interactions with the electron beam through 3 distinct mechanisms. Firstly, ionized oxygen species can react directly with the graphitic shell of CB, these species can be produced through ionization interactions with either primary electrons (PE) or secondary electrons (SE). Additionally, active sites can be generated through atomic displacements in CB by PE. These three mechanisms; ionization of O2 by PE [3], ionization of O2 by SE [4], and atomic displacements by PE; have different underlying mechanisms and respond differently to variation of reaction and imaging conditions.
Methods
In our study, we have observed the oxidation of CB at varying electron dose rates and electron energies in two ETEM setups. Data were collected using electron energy loss (EEL) spectroscopy time-series for determination of an average oxidation rate over agglomerates, as calculated from the time-dependent decrease in the C-K signal. This data were complemented with data high-resolution time resolved image series to investigate the local effect on individual particles and to validate the EEL spectroscopy results.
Results
Our experiments show that in situ beam-enhanced CB oxidation is localized to the irradiated area, that the oxidation rate is not significantly affected by changes to the electron energy, and that the in situ beam enhancement is non-linear in nature. Additionally, the reaction only occurs in the presence of an oxidizing gas, i.e. not in inert gases like N2. These findings contradict that ionization by PE is the driving force behind the increase in oxidation rate in TEM, as the ionized species are expected to spread out over an area larger than the illuminated, and the rate at which ionized oxygen species is expected to approximately double as the electron energy is reduced from 300 keV to 100 keV. Similarly, oxygen ionization by SE, is also expected to increase when the electron energy is decreased, however, this mechanism may have a minor impact if the CB sample is located on a support, in which case an excess of SEs is generated. Rather, the results are consistent with atomic displacement as the main driving force; given that the electron energy required to knock an atom out of its lattice position is exceeded, the probability of displacement does not change to a large extent over the relevant electron energy scale. Additionally, atomic displacements can only occur where the electron beam has been located, and no damage is observed outside of the irradiated area.

Conclusion
We have shown that CB oxidation is mainly affected by elastic high-energy electron-sample interactions, with a smaller contribution from inelastic electron-gas processes from secondary electrons emitted from the sample and sample support. While this process suggests that there are no safe conditions, the beam effect can be made vanishingly small compared to the intrinsic oxidation. We show how EELS can link processes seen at individual particles to whole agglomerates. This further illustrates the importance of comparing results obtained in the ETEM with results obtained via other methods such as TGA or its like.

Atomically sharp domain walls in antiferromagnetic thin films

Filip Krizek[1], Jan Zubáč[1], Zdeněk Kašpar[1], Kamil Olejník[1], Vít Novák[1], Tomáš Jungwirth[1]
[1]Institute of Physics of the Czech Academy of Sciences, Prague, Czech Republic

Poster Group 1

High-quality thin films of antiferromagnetic tetragonal CuMnAs, grown by molecular beam epitaxy, have recently found application in spintronic devices. These devices leverage various intriguing magnetic phenomena, such as Néel vector reorientation via spin-orbit coupling, or thermal quenching into high-resistivity states, to achieve novel functionalities.
In this study, we conducted scanning transmission electron microscopy (STEM) measurements to investigate the magnetic structure of epitaxial CuMnAs thin films on the atomic scale. Our aim was to explore the origin of sharp transitions observed by DPC-STEM technique and relate them to the presence of an abrupt change in the antiferromagnetic order .
Complementary results obtained by 4D-STEM strongly suggest the existence of atomically sharp antiferromagnetic domain walls in epitaxial CuMnAs thin films, at least on the qualitative level. The existence of such features not only contributes to a deeper understanding of the physical mechanisms underlying the intriguing functionalities of CuMnAs devices but also sheds light on the intricate interplay between crystalline and magnetic structures in antiferromagnets.
Our more recent findings suggest that some of the intriguing phenomena previously observed exclusively in CuMnAs may have a more universal origin and can be observed in other materials. We will highlight a family of materials which, while grown in the form of thin films, have nearly the same crystallographic structure as CuMnAs but exhibit distinct ferromagnetic and antiferromagnetic magnetic orders. This naturally epitaxial material platform holds great promise for the design of high-quality magnetic heterostructures, but can also serve for further development of advanced STEM techniques.

PS-09, Lecture Theater 2, august 26, 2024, 14:00 - 16:00

Perovskite-structure transition metal oxide epitaxial thin films exhibit a variety of functionalities that make them highly promising for the development of novel electronic devices, including non-volatile memories, sensors, and flexible electronics. In recent years, interest has arisen in transforming these thin films into perovskite membranes, that can be detached, transferred and layered similarly to architectures established for 2D materials. Compared to epitaxial heterostructures, this offers potential benefits of, for instance, no structural mismatch strain effects, possibilities to create texture (wrinkles), versatile stacking and, ultimately, scaling down to the 2D limit [1]. Recently, such membrane structures have been studied with Cs-corrected scanning transmission electron microscopy (STEM) using a plan-view geometry [2]. In contrast, here we focus on cross-section studies, where atomic structural quality and flatness/roughness can be precisely assessed. By combining with electron energy-loss spectroscopy (EELS), we further apply this approach with a goal of probing the bonding of membranes transferred to single-crystal substrates, and how this evolves with thermal annealing.
For the measurements, 30 nm-thick $SrTiO_3$ membranes are grown on a 16 nm-thick $Sr_3Al_2O_6$ sacrificial layer on a (001) $SrTiO_3$ substrate using pulsed laser deposition. After dissolving the $Sr_3Al_2O_6$ layer in deionized water, the resulting $SrTiO_3$ membrane is transferred onto a Nb-doped $SrTiO_3$ (001) carrier substrate. This membrane heterostructure is either left “as is”, or is subjected to a thermal annealing at one of a series of temperatures. Focused ion beam milling is then used to prepare a cross-section lamella. These samples are studied in STEM mode using a double-corrected FEI/Thermo Fisher Scientific Titan Themis 60-300, operated at 200 or 300 kV, with STEM-EELS maps recorded in counting mode using a Gatan GIF Continuum ERS equipped with a K3 detector.
By imaging membranes in cross-section from both before and after the steps of $Sr_3Al_2O_6$ dissolution and transfer, it is found that the quality of the $Sr_3Al_2O_6$ sacrificial layer is crucial for final membrane quality, with a flat and uniform $Sr_3Al_2O_6$ layer being necessary for obtaining a flat $SrTiO_3$ film having a high quality of epitaxial growth. The figure shows an example cross-section high angle annular dark-field (HAADF) STEM image of a $SrTiO_3$ membrane transferred to the Nb:$SrTiO_3$ carrier substrate. Because of the twist of the membrane to the carrier substrate, while the cation columns are resolved in the substrate, the membrane depicts only atomic planes. This is, however, still sufficient to study the atomic nature plane-by-plane using Cs-corrected STEM-EELS mapping. Membrane and substrate are separated by a ~2 nm interface gap.
From a STEM-EELS map, the left-hand panels of the figure show EEL spectra of the Ti L-edge and O K-edge, integrated from three different regions: the carrier substrate, the membrane, and also the 2 nm interface gap. It can be seen that there are no significant differences between the membrane and carrier substrate, where the Ti L_3, L_2 peaks show the signature t2g and eg splitting for Ti^{4+}, and the O K-edges share the same fine structure [3]. To the right of the HAADF image, a line-profile is shown of

the Ti L-edge signal extracted across the heterostructure. Surprisingly, the intensity does not decay to zero within the interface gap. Looking at the corresponding EEL spectrum, the lack of splitting in the Ti L_3, L_2 peaks structure indicates that, in the interface gap, Ti exists in a reduced form [4]. This may be due to the free surface of the membrane and substrate having dangling Ti bonds that are observed in projection.
In summary, we are applying atomic-resolution STEM in a cross-section geometry to study the chemical bonding of transition metal oxide membranes transferred to carrier substrates. By thermally annealing these heterostructures, we expect to create different bonding states between the membrane and the substrate, that will be measured using STEM-EELS.

Poster Group 1

Background incl. aims

Aberration-corrected scanning transmission electron microscopy (AC-STEM) has evolved into a powerful method for atomic-level visualization and chemical analysis of materials, thanks to equipment improvements and the incorporation of electron-matter interactions into reconstruction algorithms. Particularly, 4D-STEM has become an impressive technique, combining 2D position- and 2D momentum-resolved measurements, capable of high-precision imaging and extensive materials characterization, with the aid of fast direct electron detectors and computational imaging methods. One notable method is Multi-slice Ptychography, which allows for obtaining not only a highly resolved transverse image but also an axial one; however, the axial resolution is currently limited by a few nanometers, preventing its use for de novo atomic structure determination.
To overcome this limit, tilt-series 4D-STEM data collection and tomography reconstruction have been used for 3D atomic resolution phase contrast imaging [1], however the reconstructed volume has so far been limited by the projection approximation.
Here we present and experimentally demonstrate an approach to discern individual atoms in a substantial volume, three times larger than the traditional depth of field, while retaining atomic resolution in three dimensions.

Methods

We applied a two-step multi-slice electron ptychographic tomography method, where 4D-STEM scans are conducted with overlapping probes at various tilt angles using a fast-framing direct electron detector in an AC-STEM. Thirty-six 4D-STEM datasets were captured from a Co3O4 nanocube. The diffraction images were obtained using a the 4Dcamera, capturing full diffraction patterns at each position. The reconstruction used multi-slice ptychography on the captured images, which accounted for the wave propagation through the sample and onto the detector. Five slices along the depth were reconstructed, slightly oversampling the 5nm depth of field due to the 13nm size of the cube (see Fig. 1).
The initial ptychography reconstructions underwent denoising and contrast adjustments to highlight the nanoparticle over the substrate, followed by an alignment process for accurate 3D reconstruction. A developed two-step optimization algorithm refined the alignment through iterations of reconstruction and alignment adjustments of down-sampled volume. The final reconstruction at full resolution utilized the obtained alignment and Gaussian blurring to maintain fidelity within the Nyquist limit, resulting in clear visualization of the nanocube's inner structure and lattice.

Results

Due to its strong contrast, the amorphous carbon substrate introduces more noise into the reconstructed volume compared to prior ADF-STEM tomography reconstructions of metal nanoparticles. This substrate scattering challenges direct tracing of Co atomic peaks. Instead, the experimental Co lattice is aligned with the Co_3O_4 crystal model by fitting Bragg peak positions in Fourier space and optimizing volume translations in real space, revealing the expected positions of Co and O atoms. This method is preferable to previous peak-by-peak tracing due to contrast variations from the substrate. The results display good agreement between the fitted atomic model and the reconstructed volume.
Higher-symmetry zone axes allow for clearer differentiation of Co atoms, while lower-symmetry axes don't resolve Co atoms less than 2 Å apart due to substrate contrast. Three-dimensional resolution is measured using the 3D power spectrum; the resolution along the axes was estimated, showing sufficient clarity to distinguish neighboring Co atoms in the structure. However, to resolve Co and O atoms effectively, our simulations indicated that a 3D resolution of 1 Å is necessary owing to the weaker signal from O atoms.

Conclusion
We have achieved unprecedented 3D phase-contrast imaging in electron microscopy, attaining an axial resolution of 2.04 Å and transverse resolution of 0.7 Å within a volume surpassing the depth of field limit by a factor >3x. Our method, sequential multi-slice ptychographic tomography, removes the depth-of-field limits of existing techniques and suggests the possibility of reconstructing crystalline oxide samples up to 70 nm thick. Although the resolution was not sufficient to discern oxygen atoms within the Co_3O_4 lattice or to cope with the high background from amorphous substrates, we anticipate that future improvements in algorithms, experimental design, and detector efficiency will address these challenges. Adopting crystalline substrates for the interim may aid in resolving weakly scattering atoms at atomic resolution. Moreover, incorporating explicit atomistic models in ptychographic tomography can better account for effects like thermal diffuse scattering, further enhancing resolution. Importantly, ptychographic electron tomography shows promise due to its amenability to experimental automation at atomic resolution by trading in experimental complexity of ADF-STEM tomography against data size and compute, positioning it as a forerunner for large-scale, high-resolution, 3D imaging within the realm of 4D-STEM.

Poster Group 2

Complementary Field-Effect Transistors (CFETs) represent a significant innovation in semiconductor technology currently drawing a lot of interest as they can be a potential solution for extending Moore's law by allowing considerably higher density compared to conventional CMOS. The novelty of these devices lies in the possibility to integrate different polarity transistors within a single structure, stacking nmos on top of pmos or vice-versa. That allows substantial density scaling benefits with enhanced performance and reduced power consumption. [1] CFETs represent an evolutionary step from the nanosheet transistors (NSFETs) which consist of several vertically stacked lateral nanosheets per device and where pmos and nmos devices are positioned next to each other on the same horizontal plane in the wafer instead of vertically atop one another as in CFETs. In both architectures, unlike finFET-based CMOS, in order to reduce their parasitics, inner spacers are introduced in-between the vertically stacked NS and prior to the source/drain (S/D) epitaxial growth, a flow addition which will also impact the S/D epi process. [2]

Strain engineering is a crucial technique for enhancing the mobility of conventional semiconductor devices. In general, channel strain, induced by the S/D in both conventional and novel CMOS, depends on the epitaxial layer composition used for the S/D (with SiGe typically used for pmos), its geometry and defectivity. Understanding the strain distribution within these structures is important for optimizing device characteristics. Previous studies on NSFET devices [2] demonstrated that the presence of inner spacers impacts S/D growth and, by consequence, the strain distribution induced in the channels. In this work, we evaluate and compare the channel strain distribution in aggressively scaled (CFET-NS) relative to more relaxed (NSFET) gate pitches, employing nanobeam electron diffraction (NBD) and Bessel diffraction [4] to discern the most apt technique for studying strain in these novel architectures.

TEM samples are prepared by focused ion beam lift-out technique. Strain analysis is performed by NBD and Bessel in a double corrected Titan3 G2 60-300 transmission electron microscope operating at 200kV. CFET and NSFET samples consist of fin-shaped structures of Si/SiGe layers. The sacrificial SiGe layers, destined later for etching to release the NS, are also recessed post-S/D recess to accommodate inner spacer deposition. CFET samples feature a single pmos Si channel sandwiched between SiGe50 S/D at the bottom and one nmos Si channel at the top, while the NSFET sample consists of a dual Si-channel pmos. Notable, the main difference between NSFET and CFET devices in this study lies in the gate pitch dimensions, with NSFET at 100nm and CFET at 50nm.

Strain profiles along the Si channels (indicated by blue arrows in Figure 1a and b) in double Si-channel NSFET (Figure 1a) and single Si-channel CFET (Figure 1b) devices, processed until after epitaxial SiGe S/D growth, are depicted in Fig1c and Fig.1d, respectively. Both single-level NSFETs and bottom NS of CFET exhibit tensile channel strains, a significant departure from traditional finFETs characterized by compressive strain. [3] This tensile strain originates from the lattice mismatch of the SiGe/Si

multilayer stack in the fins, which persists after fin patterning. The introduction of inner spacers further amplifies tensile strain in the channels. Inner spacers lead to separate SiGe epitaxial growth from the bottom and lateral fronts, resulting in defects or air gaps at the interface where the three growing fronts converge. In addition, CFET exhibits lower strain compared to NSFET likely due to their smaller S/D and gate pitch than in NSFETs. TCAD simulations could offer additional insight into local strain behavior in these devices. Furthermore, we perform a comparison between the NBD and Bessel techniques for assessing strain in CFET devices. As shown in Figure 1d, while the NBD technique reveals minimal or no strain, the Bessel method (dotted curves) enables measurable strain detection. As previously observed [5], the Bessel technique demonstrates superior sensitivity compared to NBD, becoming the preferred technique for strain evaluation in such innovative architecture devices.

IM-03 (1), Plenary, august 28, 2024, 10:30 - 12:30

Introduction and motivation
Multi-junction solar cells that are based on MOVPE-grown III-V compound semiconductor layers achieve the highest solar cell efficiencies, as they absorb light from a large part of the solar spectrum. Tunnel junctions provide electrical interconnections to the device sub cells, while yielding high current capabilities and high optical transparency. As the tunnelling probability decreases exponentially with increasing depletion width, high dopant concentrations are required to achieve the narrowest junctions. Structural and electrical analysis with high spatial resolution is essential to provide feedback to optimize the growth process. Electrostatic potentials at p-n junctions can be measured quantitatively with nm spatial resolution using off-axis electron holography (EH).
Methods
Here, we combine EH with in situ electrical biasing and optimized TEM sample preparation to study electrically-contacted p-AlGaAs/n-GaInP tunnel hetero-junctions grown in upright and inverted configuration. First electron-transparent specimens of different thicknesses were studied to assess the influence on the measured electrostatic potentials of the presence of electrically-inactive specimen surface layers introduced during focused ion beam (FIB) milling. The crystalline thickness of each specimen was measured using convergent beam electron diffraction (CBED) in a scanning TEM (STEM) (Fig. 1B). The TEM specimens were prepared using dedicated chips for an electrical biasing TEM holder (Protochips Aduro 500). Reliable contacting was achieved by developing two different FIB milling procedures. First, conventional FIB milling was used to extract a region of interest, while preserving a pre-deposited Ohmic top contact (Fig. 1A). Tungsten was then deposited in the FIB workstation onto the bottom of the sample to provide a second electrical contact. The second approach involved the use of plasma FIB milling to extract slices of the wafer that contained the original top and bottom metal contacts. Electron hologram stacks were recorded from both junction configurations to improve the sensitivity and spatial resolution of the results. Measurements of depletion width were recorded as a function of both specimen thickness and applied external bias.
Results
Phase images (proportional to projected electrostatic potential) were reconstructed from the holograms as a function of applied electrical bias. Figure 1C shows a phase image recorded at zero bias and a corresponding line profile of the phase across the junction.
The inverted and upright junction configuration exhibit similar depletion widths measured at zero bias. Analysis under external bias is necessary to reveal differences in tunnelling performances occurring in the current regimes of operation under light. Our results demonstrate the importance of optimizing specimen preparation when performing in situ electrical biasing experiments. In particular, to create Ohmic electrical contacts, as opposed to the Schottky contacts that are normally formed using FIB metal deposition. By using an optimized specimen preparation approach, we could

compare the electrostatic potential distribution across upright and inverted p-AlGaAs/n-GaInP junctions reliably.

Conclusions

This study demonstrates the progress that has been achieved in realizing successful in situ characterization of dopant potential distributions in III-V tunnel hetero-junctions in real solar cell devices.

IM-13 (1), Lecture Theater 5, august 27, 2024, 10:30 - 12:30

Background
In this work we aim to investigate SARS-CoV-2 entry mechanisms using cutting edge cryo-methodologies to obtain structural insights in the mechanism of infection. SARS-CoV-2 is the causative agent for the recent Covid pandemic and as such has been the centre of both scientific and public attention over the past few years. While this has resulted in numerous publications over a very short amount of time, much is still unknown, also about the entry pathway. For the virus to enter it needs 2 steps, first the viral Spike protein needs to bind to a host cell surface receptor, the most common being ACE-2, although others have been reported to facilitate SARS-CoV-2 entry. Two possible pathways have been identified: direct viral fusion at the cell membrane or viral endocytosis and fusion once internalised. This depends on the presence of host-cell proteases (most commonly TMPRSS2) at the cell surface, as the viral spike protein needs to be cleaved before fusion can commence.
Precisely identifying sites of binding and/or fusion is difficult when doing an infection experiment. Here we aim to use correlative and multimodal imaging in cryogenic conditions to study the viral entry within the very first hour, at a time that the cell-population is basically unaware of an ongoing infection and not releasing stress-effectors. For this we are using cells that can only be infected through the endocytic pathway and a fluorescently labelled virus, which we want to track in a correlative manner. High-resolution fluorescence data is essential to localize the areas of interest and the recent purchase of the cryo-stellaris 8 confocal microscope (Leica) allows us to collect this type of data. After initial mapping and localization of areas of interest, we aim to study the samples using either cryo soft X-ray tomography (cryo-SXT), and/or cryo electron tomography (cryo-ET). Both methods have the advantage of providing 3D information of biological samples preserved as close as possible to their native state. Cryo-SXT is a transmission based, medium-resolution (30 nm half pitch) but high throughput synchrotron technique that relies on the absorption of the X-ray light by the sample. It is a powerful technique to study the cellular ultrastructure of thick samples (<10 micron) and can even be used for quantification by comparing the absorption coefficients of different structures. Cryo-ET is a transmission-based technique that does require very thin samples (<300nm) but can provide nanometre resolution data in return. Using this technique, molecular interactions can be visualized and using sub-tomogram averaging, protein structures can be resolved in situ.
Methods
Mammalian cells are cultured on classical TEM Quantifoil grids and infected with SARS-CoV-2 at an MOI of 10. To synchronize the start of the infection, the virus and cells are kept at 4 degrees Celsius, as at this temperature no fusion takes place, and after 30 minutes the cells are moved back to the incubator at 37 °C. The grids are then fixed by plunge-freezing at various timepoints during the first hour of infection. Next, cryo-fluorescence is used to localize sites of interest. The same sample can then be used either for cryo-SXT acquisitions, or for cryo-ET of cell peripheries and of cryo-FIB milled

lamellae. Collected tilt series have to be aligned and reconstructed to obtain the final 3D tomograms which can be used for the correlation, segmentation and analysis.
Results
By registering the fluorescent map obtained at the confocal microscope with the low magnification TEM map of the grid, we were able to locate areas of interest. Lamellae preparation was required only for the later timepoints as in this timeframe the internalised virus is located in thicker areas of the cells (>300 nm). We visualized the virus at the cell surface and inside vesicles, bound to surface proteins or in the process of fusion. Using cryo-SXT we were able to confirm some of the phenotypes that we observed by cryo-ET, and it allowed us to put it into perspective of a larger area of the cell. It was possible to compare cellular morphologies, and the changes thereof over the course of the first hour of infection.
Conclusion
Visualizing different stages of infection within their native environment can greatly improve the understanding of their underlying cellular processes. Here we use 3 complementary modalities that allow us to look at the SARS-CoV-2 infection process with complementary imaging methods at low (cryo-confocal), medium (cryo-SXT) and high (cryo-ET) resolution. While this approach is very time-consuming, it gives a more complete multiscale overview of the complex mechanism of virus-host interaction.

PS-06, Lecture Theater 1, august 29, 2024, 10:30 - 12:30

Background incl. aims
Bio-resorbable magnesium implants are promising candidates for the treatment of bone fractures due to their mechanical properties, their immunological response during healing, and the reduced need to perform a second surgery for implant removal. Some studies show how the placement of bio-resorbable implants alters the bone nanostructure, which changes from the preferred orientation along the bone shaft to a wrapping around the implant surface [1].
There are, however, no accounts in the literature on how physical exercise applied immediately after implantation might influence the bone nanostructure and the healing process around magnesium implants. This question is of great importance for understanding the impact of mechanical stimuli during healing and could be of relevance for post-surgical recovery treatments.
Methods
We designed an animal study on two groups of rats, one group underwent physical exercise immediately after implantation and the other one was sedentary. The bone with the implant was explanted after 2 and 6 weeks and the explants were studied.
For the aims of the study, we used two complementary synchrotron 3D imaging techniques, i.e. small-angle scattering tensor tomography (SASTT) and phase-contrast high-resolution computed tomography (PCµCT). Each one of the samples was measured with both techniques and the results were correlated with each other.
Results
We have investigated the role physical exercise plays in bone healing around Mg implants in a short-term study. With SASTT we studied the orientations of the bone nanostructure in 3D [2]. We have observed how the degree of orientation of hydroxyapatite, the thickness of the mineral particles, and the nanostructural orientations in bone change when physical exercise is applied. With PCµCT we characterized the osteocytes' network (considered responsible for mechanotransduction) by imaging the lacunae in 3D. We performed a shape and orientation analysis of the osteocytes to study the effect that physical exercise has on this network, and we correlated the results of both techniques.
Conclusion
Our study proved that physical exercise favors remodeling and bone healing around bio-degradable implants and alters the orientation of the bone structures at different length scales. These results are highly relevant for understanding degradable implants' behavior and are expected to be of clinical significance in the treatment of bone fractures.

Grain evolution during annealing of a semisolid Al-Cu alloy studied with lab-based diffraction contrast tomography

Jun Sun[1], Jette Oddershede[1], Florian Bachmann[1], Jules Dake[2], Erik Lauridsen[1]
[1]Xnovo Technology ApS, Køge, Denmark, [2]Ulm University, Ulm, Germany

PS-02 (2), Lecture Theater 5, august 28, 2024, 14:00 - 16:00

Background incl. aims
3D experimental data of simultaneously high temporal and spatial resolution is key to validation of computational modelling of materials phenomena. In this study, we exploit lab-based diffraction contrast tomography (DCT) [1], to capture the evolution of grain structure over a series of interrupted annealing treatments of a semisolid Al-Cu alloy [2,3]. The time resolved response measured on the present Al-Cu model system provides insights into the rearrangement, densification and coarsening of powder compacts at late-stage sintering. The wealth of the experimental data lends itself particularly well to investigations of both grain size and orientation (rotation) evolution.

Methods
The semisolid Al-Cu alloy specimen was subjected to ten sequential isothermal heat treatments, each 15 min at 630°C, and we used lab-based DCT to non-destructively track the microstructural evolution of individual grains through the corresponding eleven temporal states of interrupted annealing. The lab environment setting allows us to reconstruct the results and analyze changes to the microstructure before subsequent treatment of the sample. Furthermore, we take advantage of the recently developed DCT advanced acquisition schemes [4] to cover a large sample volume of 10 mm^3.

Results
During the experiment, we observe both grain coarsening (from 1934 grains with a mean grain size of 194 µm at the initial state to 934 grains with a mean grain size of 247 µm after ten annealing steps) and grain rotations. A statistical study of the evolving grain structure reveals that the disappearing grains are generally among the smaller ones at the beginning of the experiment. In addition, the rotations of individual grains are typically small fluctuations irrespective of grain size, but when an abruptly large rotation is observed, it is more likely to occur for a smaller grain at the last annealing step(s) before the grain vanishes. Finally, the experimental data indicates that Σ3 twin boundaries are especially stable, and that grains sharing such a boundary will rotate together in their local environment to keep the boundary intact.

Conclusion
Our investigations show that the crystallography of grain contacts undoubtably plays a pivotal role in the microstructural evolution of semisolid systems during heat treatment and should be included in predictive simulations of coarsening. To help incorporate our experimental observations into the next generation of models, the eleven grain maps have been made publicly available to the scientific community via the Materials Data Facility [5].

Detection of weak ELNES signals using dose-fractionated spectrum imaging combined with direct detection

Andrew Thron[1], Liam Spillane[1], Saleh Gorji[2], Ray Twesten[1]
[1]Gatan Inc., Pleasanton , USA, [2]Gatan GmbH, Unterschleissheim, Germany

Poster Group 2

Background:
Recent studies showed that mixed Fe-Co oxide nanoparticles could replace more expensive Ir oxide and Ru oxide for the oxygen evolution reaction for water electrolysis [1]. Acquiring spectra at a high resolution is especially advantageous for understanding how the valence state of Fe and Co changes across the nanoparticles and potentially influences their catalytic behavior. EELS combined with STEM has proven effective at studying chemical changes at the sub-nm level [2]. Previous studies systematically characterized how the Fe L2,3 edge changes with changes in local symmetry based on the phase of Fe oxide [3]. The L2,3 edges of the first-row transition metals probe the unoccupied 3d states, which are sensitive to spin-orbit coupling, linking local symmetry changes to oxidation state. However, the transition metal K-edges probe unoccupied 4p states and are more sensitive to nearest neighbor distances, bonding angles, and the onset of the K edge undergoes measurable shifts with changes in oxidation state. Characterizing the Fe K edge at the sub-nm scale could add more profound insight into changes in structure and chemistry.
The cross-section of the transition metal K edges is ~3 orders of magnitude smaller than the corresponding L2,3 edge. This requires increased acquisition times and the likelihood that radiolysis and sample drift will compromise the measurement. It was shown in polymer blends that the performance of the microscope does not limit the resolution of an EELS spectrum image. Instead, the resolution is limited by a critical dose above which the polymer structure changes [4]. Gatan recently implemented new software and hardware tools that acquire and analyze weaker signals without compromising the sample. Using direct detection cameras for EELS on the GIF Continuum increases the detection efficiency needed to collect weaker, higher-energy K-edges, mitigating radiolysis by reducing acquisition times [5]. Upgrades to DigiScan 3 enable continuous in-line drift correction, where features in the simultaneously acquired ADF image are used to monitor drift, reducing latency during the drift measurement. Coupled with the fast, sub-millisecond frame rate of these direct detection cameras, accurate and frequent drift correction is critical in ensuring no spatial blurring of the spectrum image during long acquisition times. Finally, the in-situ spectrum imaging in DigitalMicrograph allows tracking and monitoring of the experiment over time and the total dose to be fractionated over multiple, individually saved passes. This enables integration or removal of passes after acquisition, enabling the enhancement of the SNR or removal of passes that may be compromised by sample damage or contamination.
In this study, we demonstrate why it is critical to combine the sensitivity and speed of direct detection with the ability to fractionate the dose over several passes using in-situ spectrum imaging when acquiring weaker ionization edges. We show how these tools can be utilized to study the spatial resolution limits based on the dose threshold of Fe oxide and mixed Fe-Co oxide nanoparticles. Ultimately, we explore how the material's interaction with the electron beam limits the resolution of the measurement and how this compares to analogous techniques such as scanning XAS.
Methods:

A JEOL F200 with a cold-FEG with a post-column Gatan Continuum Spectrometer was used to acquire EELS spectrum images (SI) at 200 kV. The spectrometer is fitted with single electron counting (K3, Gatan) and hybrid pixel thresholding (Stela, Gatan/Dectris) cameras, and were used to collect SI datasets targeting the Fe K edge (7112 eV). DigitalMicrograph's Elemental Quantification tool and concurrent standards were used to study the reduction of the Fe oxide particles as a function of applied dose. The linear-least squares tool in DigitalMicrograph was used to measure the shift in the Fe K-edge across the nanoparticles by fitting Gaussian functions to the pre-peak and main peak after the edge onset.

Results :

An EELS spectrum image acquired from a cluster of Fe¬2O3 nanoparticles is shown in the ADF image in Figure 1a. The spectrum image was acquired using multi-pass spectrum imaging. A step size of 5 nm and a pixel dwell time of 330 µs was used to minimize the total dose per pass while being able to resolve individual particles in the SI. The short pixel dwell time combined with inline drift correction enabled frequent and accurate drift correction to minimize drift artifacts during the measurement. In Figure 1b, an elemental map was created from the integrated intensity of the Fe K-edge, and the smaller particles can be resolved in the cluster. The Fe K-edge ELNES extracted from the Fe¬2O3 particles is plotted in Figure 1c, along with the fitted Gaussian functions of the pre-peak and the main peak of the K-edge. Shifts in the pre-peak and the main peak were measured by mapping the position of the fitted Gaussian in Figure 1e and 1f, respectively. The pre-peak originates from a weak 1s to 3d quadrupole transition. As a result, the SNR is lower than the main peak, producing a larger variability in the fit in Figure 1e. The main peaks in the Fe K ELNES originate from a stronger 1s to 4p dipole transition, resulting in a signal that is an order of magnitude larger than the pre-peak. A shift in the main peak is observed in Figure 1f, from 7130 eV in the smaller particles to 7132 eV in the larger particles. To confirm this trend, further measurements are needed from well-separated particles.

Conclusion:

Detailed analysis of the weaker Fe K-edge is possible across individual particles. However, further experiments are needed to determine why the main peak of the Fe K edge shifts with changes in particle size. In-situ experiments fractionating the dose over several individually acquired passes are needed to confirm that the shift in the main peak is caused by radiolysis. We will apply this workflow to a mixed Fe-Co oxide system to study how the oxidation state changes with the concentration of Fe and Co, by examining changes to the ELNES of the Fe and Co K-edges. Finally, we aim to study how radiolysis limits the spatial resolution of weaker ionization edges.

Arctis WebUI redefines lamella preparation for cryo-electron tomography workflow

Veronika Vrbovská[1], Radovan Spurný[1], Radim Kříž[1], Radek Tichý[1], Pavel Tomášek[1], Ladislav Chvíla[1], Michaela Müllerová[1], Anna Kasáková[1], John Mitchels[1], Miloš Hovorka[1]
[1]Thermo Fisher Scientific, Brno, Czech Republic

Poster Group 2

Background
Cryo-electron tomography has emerged as a valuable technique for visualizing proteins and protein complexes in their natural cellular environment. To achieve high-resolution imaging, the preparation of thin cryo-lamellae containing the region of interest is a critical step. However, the usual methods for lamella preparation are often time-consuming and require the use of several applications, presenting challenges for inexperienced users in the cryo-tomo workflow.

Methods
The Arctis cryo-Plasma Focused Ion Beam system plays a pivotal role in the automated production of cryo-lamellae from cells. The system is supported by the Arctis WebUI, with a web-based user interface that streamlines the creation of cryo-lamellae with minimal user inputs. WebUI is a unified platform where users can map and navigate through the sample using electron, ion, or optical tilesets. Additionally, the integration of a fluorescent light microscope enables in-situ targeting of specific cellular structures. Prepared lamellae are transferred to a Transmission Electron Microscope for cryo-electron tomography. The Thermo Fisher Scientific Selectris Imaging Filter is utilized to significantly enhance contrast during data acquisition through zero-loss filtering. Data collection is facilitated by Tomography 5 software, enabling unattended data acquisition, seamlessly connected with Tomo Live software, allowing automatic on-the-fly data reconstruction.

Results
We will provide a comprehensive overview of the application workflows for lamella preparation facilitated by the Arctis WebUI. The key advancement is the use of the fully automated optical tileset, which allows the selection of cells directly based on their fluorescently labelled features that are not visible through standard electron or ion imaging. With the combination of the 3D targeting solution, users gain valuable insights into the cellular content and can precisely identify target areas for lamella preparation. The automatic determination of ROI depth in the optical stack significantly accelerates and simplifies the 3D targeting process, eliminating the requirement for manual browsing through the entire optical stack. Once the lamellae are milled, they are transferred to a cryo-Transmission Electron Microscope through the common sample loading interface and utilized for cryo-electron tomography data collection.

Conclusion
With the capability to seamlessly process multiple (up to 12) grids with cells, Arctis WebUI streamlines the preparation of cryo-lamellae for tomography, enhancing efficiency and productivity in the field of cryo-electron microscopy. The integration of optical tileset and 3D targeting enables more precise lamella placement, guarantees data collection from specific sites in cryo-TEM, and ensures the presence of accurate structures in the resulting tomography data. These workflows significantly reduce the need for extensive user input, allowing researchers to concentrate on solving

biological problems while the WebUI automates the sample preparation process for cryo-tomography.

IM-03 (3), Plenary, august 29, 2024, 10:30 - 12:30

X-ray/Extreme ultraviolet (EUV) coherent diffraction imaging (CDI) is an efficient technique for the characterization of nano-structures. Unlike conventional microscopy, CDI does not rely on complex high-quality X-ray/EUV optics. However, in order to obtain a reconstructed image of the object, generally, a large amount of diffraction data is required. To reach the necessary level of oversampling, ptychography is often utilized. It is a form of CDI in which a focused light beam is scanned over the sample, obtaining a unique diffraction pattern at each scan position. This allows to reach the necessary amount of over-sampled data. The technique enables reconstruction of both amplitude and phase distributions, much like holography, via advanced iterative phase retrieval algorithms. Utilizing information about both absorption and phase shift in every pixel of the object's image yields chemical sensitivity. In addition, the relative transparency of many materials in the EUV/soft x-ray range allows buried structures and interfaces to be imaged that would otherwise be opaque in electron or probe-based microscopies.
Given the high spatial resolution that can be achieved with ptychographic CDI, we recently proposed [1] its exploitation to image atom probe samples. Atom probe tomography (APT) is highly complementary to transmission electron microscopy (TEM), as it enables nano-scale compositional analysis on 3D objects, which has triggered lots of attention in the semiconductor industry [4]. For APT analysis, the sample is shaped into a nano-sized object that resembles a tomography pin [2] but with much tighter aspect ratio and dimensions, i.e. the tip's endpoint has a radius of less than 100 nm, the length can be several hundreds to thousands of nanometer while the thickness of the sample changes along its z-axis with typical tapper angles around 5˚ to 10˚.
While APT is capable of atom-level resolution, the fidelity, and the resolution in APT is sample dependent. The reason is, in an atom probe microscope, the sample itself acts as the ion optics and thereby its shape and properties define the magnification during analysis.
Knowledge of the tip's actual shape, and the ability to monitor it during APT measurement is expected to provide substantial improvement in resolution and fidelity of APT reconstructions.
So far, most high-resolution EUV/X-ray ptychographic images were taken from thin film samples with imprints or holes, showing spatial resolution below 10 nm [3]. In this work we show the results of ptychographic imaging of APT tips with two distinct sources: soft x-ray produced by a synchrotron radiation at 800 eV (1.5 nm), and tabletop EUV light at 92 eV (13.5 nm). The shape of a typical APT tip significantly differs from both a typical thin planar sample for which the ptychography resolution is studied, and the more arbitrary 3D samples like grains or cells. The APT tip represents a conical needle with radius from 150 nm down to ~50 nm, where both the internal and surface structure of the top few hundred nm is of interest [4]. This leads to several challenges, on the one hand, the typically deployed planar approximation of the object is no longer valid, which leads to a decrease of resolution in the lower, and thus thicker part of the tip. On the other hand, the apex of the tip is very small both in lateral and axial dimensions. This leads to a miniscule change in the absorption and the

phase shift resulting in low contrast and, consequently, also lower resolution, and higher requirements for the detector's dynamic range.
We demonstrate capabilities for quantitative analysis of chemical composition, shape determination and resolving of embedded structures. The imaging test was performed with two types of tips: Si fin and Mo/Si Multilayer, as the first one represents a 3D low-contrast structure and the second – a high-contrast layered structure. The fin-type tips analysis allows to study and demonstrate 3D imaging while the characterization of high-contrast layer structure allows analysis of the dependency of ptychography resolution on the thickness of the sample.
Using 800 eV light produced by a synchrotron together with a CDI setup with a 0.07 detection NA, on the example of the first needle we here demonstrate the ability to image buried interfaces with sub-30 nm resolution, while simultaneously determine the exterior geometry with 11 nm resolution as shown in Fig. 1 a,b.
Using the tabletop EUV source with 0.5 detection NA, we determine the exterior geometry of the second APT needle with 15 nm resolution, see Fig.1d. For comparison scanning electron microscope images of the two needles are presented in Fig. 1c, e, respectively. Please note that since the angle between the impinging SEM beam and the tip axis is 52 degrees, the SEM images are vertically elongated by 27% The EUV imaging clearly suffers from rather low signal-to-noise ratio due to large focal spot size (~20 µm) and sub-optimal EUV flux at our current setup compared to the synchrotron source. Nevertheless, we were able to resolve the needle exterior geometry in the colour-phase brightness-amplitude image (Fig 1.d) which perfectly matches SEM image (Fig 1.e).
Our first experimental results prove the feasibility of ptychographic imaging of APT tips using both synchrotron soft x-ray and tabletop EUV light sources. Ultimately, this might be a potential path forward to establish relevant information to feed into APT data reconstruction schemes to improve the spatial accuracy of reconstructed atom probe data [5].

PS-03 (1), Lecture Theater 2, august 29, 2024, 14:00 - 16:00

Background incl. aims
Narrow GaAs nanowires (radius in the range of 10 nm) can undergo extreme elastic stretching when overgrown by much thicker, highly mismatched In(Al,Ga)As shells. Subsequently, GaAs in such core/shell heterostructures has demonstrated up to 40% bandgap reduction [1] and 30-50% boost in electron mobility [2]. Compared to planar epilayers, such nanowires offer superior flexibility by facilitating elastic relief along the side facets and strain partitioning between the core and the shell. This effectively reduces the strain energy and expands the coherency limits. However, plastic relaxation ensues once the lattice mismatch surpasses a critical threshold. This critical limit is determined by the intricate 3D strain distribution within the nanowires and the plastic relaxation mechanisms involved. In this contribution, we determine experimentally the critical misfit of such core/shell GaAs/In(Al,Ga)As nanowires featuring narrow cores and thick shells, using (scanning) transmission electron microscopy ((S)TEM) methods. Additionally, we utilize high-resolution (S)TEM (HR(S)TEM) combined with theoretical calculations, to obtain the 3D strain fields. Finally, we employ topological analysis with HR(S)TEM to identify the operating plastic relaxation mechanisms.
Methods
The [111]-oriented GaAs/Inx(Al,Ga)1-xAs core/shell nanowires were epitaxially grown on Si(111) substrates in the self-catalysed vapour-liquid-solid mode by molecular beam epitaxy. The shell composition was varied systematically from x = 0.2 to 1, while the core radius and shell thickness were fixed at 10 nm and 80 nm, respectively. (S)TEM and HR(S)TEM observations, as well as energy dispersive X-ray spectroscopy, were performed in a 300 kV probe-corrected ThermoFisher Scientific Titan Themis 60/300 microscope and a 200 kV JEOL JEM F200 CFEG microscope. Samples were prepared along <1-10> and <11-2> zone axes by ion-thinning, as well as along [111] with cross-sections prepared by ultramicrotomy. The 3D strain fields were directly determined from the HR(S)TEM observations, using geometrical phase analysis (GPA). The experimentally-extracted strain fields were compared to theoretical ones obtained by finite element analysis, performed using thermal expansivity to model the lattice mismatch, and with atomistic energetical calculations, employing the Tersoff interatomic potential [3]. Plastic relaxation mechanisms were investigated by employing diffraction contrast TEM and HR(S)TEM observations.
Results
Experimental observations showed the axial strains to be uniformly distributed. In contrast, the elastic relaxation along the free facets, combined with the hexagonal geometry of the core, resulted in opposite radial and tangential strain gradients in the core and shell as determined by GPA on (111) cross-sections of the nanowires. Even the plastically-relaxed nanowires retained radial and tangential elastic relaxation. These results were consistent with the theoretical continuum and atomistic

calculations. The critical indium content for the initiation of plastic relaxation was determined through the onset of defect introduction. In order to determine the residual elastic strain along the nanowire axis, analysis of Moiré fringe patterns was employed. Shells in plastically relaxed nanowires exhibited extended defects relieving the misfit, such as lattice and partial dislocations whose density varied with the lattice mismatch. Nanowire bending was found to influence the plastic relaxation process. Circuit mapping [4] around interfacial defects unveiled their Burgers vectors and, subsequently, the plastic relaxation nano-mechanisms, which involved both dislocation glide and stacking fault formation.

Conclusions

An integrated methodology, combining atomic resolution electron microscopy with continuum and atomistic calculations, has been employed to achieve a comprehensive understanding of the intricate strain relaxation in GaAs/Inx(Al,Ga)1-xAs core/shell nanowires featuring narrow cores. The 3D strain field distribution in such nanowires has been determined experimentally for the first time along with the maximum sustainable elastic strain in the core, the critical lattice mismatch for plastic relaxation, and the associated mechanisms of defect introduction. These insights can be employed for further straining the core while mitigating the formation of defects that impede electron mobility and internal quantum efficiency.

Quantification and denoising of atomic-resolution EDX spectrum images using a Multiscale Bayesian Approach

Pau Torruella-Besa[1], Abderrahim Halimi[2], Duncan T. L. Alexander[1], Cécile Hébert[1]
[1]Electron Spectrometry and Microscopy Laboratory (LSME), Institute of Physics (IPHYS), Ecole Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland, [2]School of Engineering and Physical Sciences, Heriot-Watt University, Edinburgh, United Kingdom

Poster Group 1

While latest generation aberration-corrected microscopes have enabled atomic-resolution scanning transmission electron microscopy (STEM) imaging to be relatively straightforward and accessible, atomic resolution spectroscopy, and in particular energy dispersive X-ray (EDX) spectroscopy, remains a challenge. Aside from having a suitable aberration-corrected probe, the relatively long of acquisition times necessary for achieving reasonable signal-to-noise ratios (SNR) impose tougher constraints on stage stability, optics and beam stability, and the resiliency of the sample to beam damage and contamination. To tackle this challenge, microscopists will often apply a simple directive: “acquire faster”. This is the motivation behind the development of EDX detectors with an increasingly large solid angle. However, there is a second way to approach the problem: using more sophisticated data analysis to be able to reduce acquisition times.

In this work, we propose the use of a multiscale Bayesian estimation strategy to deal with the extreme noise and signal sparsity observed in atomic-resolution EDX data. The method, originally developed for noisy LIDAR data[1], relies on two factors. First, it assumes pre-known contributions to the EDX spectrum from each chemical element. In the present work, the elemental contributions to the spectra are obtained from the espm library[2]. It should be noted that, since the espm-generated priors are themselves scaled by the corresponding k-factors, their corresponding abundance maps enable proper atomic percentage quantification. Secondly, it adopts a multiscale model that accounts for the Poisson statistics of the data and exploits spatial correlation between pixels to provide robust abundance estimates of each element in each pixel, even in the presence of high noise. The outputs of the algorithm are maps of the X-ray signal quantified in atomic percentage, which are considerably denoised, and corresponding Bayesian uncertainty maps.

The method has first been tested using (non-atomic) simulated EDX datasets generated using espm, which allow comparison to a ground truth (Figure 1 left). The plot shows the deviation from the ground truth abundance maps as a factor of SNR or, equivalently, virtual acquisition time. These outputs are compared to those made using a commercial analysis software: Velox from Thermo Fisher Scientific. As can be observed, the Bayesian multiscale (BMS) analysis demonstrates better accuracy, especially in low SNR situations, where it is shown to converge more quickly to the ground truth.
Next, the analysis method is tested on a wide range of experimental EDX spectrum images, acquired from several types of samples. Figure 1 right shows an example, where both Velox spatial filtering and BMS are applied to an atomic-resolution EDX spectrum image acquired from a film of $LaVO_3$ grown epitaxially on a $DyScO_3$ substrate (see reference 3 for details). Raw integrated counts maps are also included for comparison. This case is especially interesting, since it demonstrates the conservation of spatial resolution through the multiscale approach. The results shown below show that the obtained quantified maps of X-ray yield keep atomic resolution even when reducing the

acquisition time by a factor 3. As can be observed in Figure 1 a–f, the spots in the Fourier transform of the calculated maps are still clearly visible for the BMS analysis at the lowest acquisition time, while they are lost for the spatial filtering of the Velox analysis, proving that our method enhances spatial resolution even under the most challenging conditions. (We note that these are not absolute maps of atomic columns, owing to scattering processes such as channeling and dechanneling.)

In summary, we present a novel strategy for the denoising of atomic-resolution EDX spectrum images, that incorporates both knowledge of spectral shape and Bayesian multiscale analysis. Testing of this algorithm on experimental data sets acquired from a range of samples shows a consistently better performance compared to quantification and denoising using state-of-the-art commercial software.

Figure 1 Left) Simulated EDX maps results: abundance maps mean error as a function of simulated acquisition time. Right) Overlaid elemental maps of Dy (green). Sc (red), La (orange) and V (Blue) from an $LaVO_3$ thin film on $DyScO_3$ substrate. Rows represent different acquisition times (obtained by reducing the number of frames used), while columns represent the different analysis methods tested: raw integrated peak counts, Velox quantification with 10 pixel Gaussian smoothing, and Bayesian multiscale approach. Fourier transform panels a, c, e correspond to the BMS analysis at the corresponding acquisition times, while b, d, f correspond to the Velox-filtered maps.

Observation of novel ferroelectric domain configurations in $PbTiO_3/DyScO_3$ epitaxial films

Pau Torruella-Besa[1], Chih-Ying Hsu[1,2], Ludovica Tovaglieri[2], Iaroslav Gaponenko[2], Cécile Hébert[1], Jean-Marc Triscone[2], Céline Lichtensteiger[2], Duncan T. L. Alexander[1]
[1]Electron Spectrometry and Microscopy Laboratory (LSME), Institute of Physics (IPHYS), Ecole Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland, [2]Department of Quantum Matter Physics, University of Geneva, Geneva, Switzerland

Poster Group 1

$PbTiO_3$ is a ferroelectric material with the perovskite structure that exhibits polarization below a Tc of 765 K. $PbTiO_3$ thin films are known to have complex domain configuration as a function of deposition temperature, epitaxial strain, film thickness and electrostatic boundary conditions. In this work, atomic resolution scanning transmission electron microscopy (STEM) characterization is used to investigate the ferroelectric polarization configuration in $PbTiO_3$ films grown under 0.2% biaxial compressive strain on a (110)o -oriented $DyScO_3$ substrate, separated by a $SrRuO_3$ bottom electrode.

Ferroelectric polarization in $PbTiO_3$ is commonly mapped by carefully monitoring small displacements of the Ti atomic columns relative to neighboring Pb columns in aberration-corrected high angle annular dark-field (HAADF) STEM images. However, the thickness of our film of interest is around 240nm, with domains of similar size. Following this approach therefore implies tracking the position of tens of thousands of atomic columns over many tens of nanometers with picometer precision, over large images having high enough pixel density that each atomic column is separated by ≥ 40 pixels. To this end, we acquire 8k x 8k pixel images at relatively low magnifications, while aiming to keep the associated scan distortions to a minimum and maintaining a probe with atomic resolution.

Even when the acquisition of these large experimental images is successful, the challenge of analyzing them remains. In this work, we innovate an approach where each large-scale image is split into sub-images, each containing just one perovskite unit cell. Compared to whole-image analysis, we find that tracking the positions of atomic columns in these sub-images is greatly facilitated. It further yields a dataset that is suitable for multivariate analysis (figure 1a-d); an approach analogous to that shown by Ziatdinov et al.[1,2].

The results are large-scale polarization maps that reveal novel a/c domain configurations in the form of needles, stacked a-domains (figure 1 g-h), as well as strongly and weakly charged 180° domain walls (figure 1 e-f). Interestingly, a potentially new type of line defect is observed, that may play a role in stabilizing the observed domain walls that we hypothesize to be of high energy.

In conclusion, we present ongoing analyses of novel domain configurations in strained films of ferroelectric $PbTiO_3$, where we combine large-scale atomic resolution STEM imaging with machine-learning analyses to identify and understand domain boundary and structural defects.

Figure 1 . a-d) Non-negative matrix factorization results on unit-cell subimages revelaing the complex structure of a-c configuration with both 90° and 180° domain walls. Scale bars correspond to 2 Å for panels a,c and 15 nm for panels b,d. e-f) Polarization angle of maps of different observed 180° domain walls across a and c domains. Polarization up, down, right and left directions correspond to

blue, red, black and white colors respectively. Scale bars correspond to 20 nm. g-h) Stacked needles configuration of a-c domains revealed by geometrical phase analysis.

Evaluation of diabetes-associated testicular morphology and the effects of MSC secretome as a therapeutic intervention

PhD Serbay Özkan[1]
[1]Izmir Katip Çelebi University, Faculty of Medicine, Histology and Embryology Department, Çiğli, Türkiye

Poster Group 1

Background incl. aims
Diabetes is a metabolic disease characterized by prolonged hyperglycemia, which causes various types of complications, including impaired reproductive function. Diabetes-related microvascular damages, oxidative stress and insulin resistance could bring about a wide range of endocrine organ damages associated with the secretion of reproductive hormones and lead to hormonal imbalance, seminiferous tubule injury, including disrupted spermatogenesis and dysfunction of Sertoli cells. Ultimately, diabetes impacts male sexual function by leading to issues like erectile dysfunction, reduced libido and sperm damage. Mesenchymal stem cells (MSCs) could be a potential therapeutic intervention for the treatment of diabetes and accordingly, associated disorders like dysfunction of the male reproductive system1. Conditioned media (CM) obtained from MSCs contain soluble and non-soluble factors, all of which are collectively considered as one of the best ways of conveying MSCs' therapeutic effects, including angiogenesis, anti-inflammatory and -apoptotic effects, immunomodulation, and promotion of tissue repair and regeneration. Preconditioning of MSCs with different strategies, like incubation in hypoxic or 3-dimensional (3D) cell culture conditions, could improve their therapeutic potential2. In our previous study, the application of CM collected from MSCs cultured in 3D microfabricated scaffold to diabetic rats improved beta-cell regeneration and immunomodulation in comparison to the one obtained in conventional 2D culture conditions3. In this research, it was aimed to investigate the effects of prolonged hyperglycemia on serum reproductive hormone levels and testicular morphology of Sprague Dawley rats with diabetes, and the possible therapeutic effects of systemic application of CM derived from MSCs.
Methods
MSCs isolated from the human umbilical cord by tissue explant method were used for the collection of 2D-CM and 3D-CM. 22 rats were intraperitoneally treated with multiple low doses of streptozotocin (STZ; 5 days, 20 mg/kg) to induce diabetes. By the injection of last dose of STZ, it was confirmed that all the rats were in the range of diabetes (blood glucose level >250 mg/ml). Following the 2nd week of the first dose STZ injection, equal volumes (1 mL) of 2D-CM and 3D-CM were intraperitoneally applied to the diabetic rats (D+2D-CM, n=8; D+3D-CM, n=8) for 4 weeks as 3 doses a week. After 1 week of injection of the last dose, blood samples were collected by cardiac puncture for serum analysis of the hormones. The rats were sacrificed, and testis were obtained for light and transmission electron microscopic (TEM) evaluations. Serum concentrations of testosterone, gonadotropin-releasing hormone (GnRH), luteinizing hormone (LH), and follicle-stimulating hormone (FSH) were determined with enzyme-linked immunosorbent assay (ELISA). Light microscopic evaluation was performed with hematoxylin + eosin (H+E) staining. Semiquantitative Johnsen's tubular biopsy score (JTBS) analysis was used to histopathologically evaluate spermatogenesis out of an average 40 seminiferous tubules (STs). In this respect, STs were scored from 1 (no cell in the tubule section) to 10 (complete spermatogenesis and perfect tubules) in accordance with the level of epithelial maturation. Histomorphometric analyses were executed with the Fiji ImageJ software program by measuring the shortest diameter of ST and length of seminiferous epithelium (SE) (the

distance between the basal lamina of SE and the closest spermatozoa to the lumen) out 10 STs for each specimen (n=3 for each group) at 40X magnification. Statistical analyses were performed using SPSS version 20.0 software. P<0.05 was accepted as statistically significant.

Results

ELISA analysis showed that serum LH and testosterone levels of experimental groups significantly decreased compared to the C group ($p < 0,05$). Serum GnRH and FSH levels were found to be significantly reduced in the D and D+2D-CM groups ($p<0,01$ and $p<0,05$ respectively), while there was no significant difference noted between the C and D+3D-CM groups. Our preliminary light microscopic analysis indicated that the JTBS values of experimental groups were significantly lower than the one of the C group while there was mild amelioration in D+3D-CM group in comparison to D group. On the other hand, our preliminary histomorphometric analysis of ST diameter and SE length did not show notable differences among the groups. TEM evaluation of SE revealed that the C group had normal ultrastructural morphology while spermatogonia with dispersed heterochromatin, primary spermatocytes having damaged mitochondria with loss of lamellar properties, cytoplasmic vacuolization in spermatogenic cell series and large intercellular spaces were noted in the D group. Additionally, assessments of spermatids at different stages of spermiogenesis demonstrated the presence of spermatids with disrupted chromatin condensation in the D group. In both treatment groups, such impairments were relatively fewer than the ones in the diabetic group and considerable restoration of ultrastructures of Sertoli and spermatogenic cells in seminiferous epithelium was observed.

Conclusion

In this diabetes model induced with multiple low doses of streptozotocin (5 days, 20 mg/kg), our preliminary light microscopic and TEM evaluations indicate that diabetes-associated damage in testis, specifically STs, was at a distinctive degree, and application of CM led to improvement in spermatogenesis and ultrastructural morphology of SE. On the other hand, when the differential changes in concentrations of serum reproductive hormones, including testosterone, GnRH, LH, and FSH, were considered, hyperglycemia seemed to affect the hypothalamic-pituitary-gonadal (HPG) axis by interrupting the feedback mechanism. The treatments with the CM, especially 3D-CM brought about considerable restoration of GnRH and FSH serum levels, but this was not enough to improve serum testosterone level, which is both a product and regulator of the HPG axis in males. The discrepancy between the morphological and hormonal analysis also suggests considering unrevealed mechanism of therapeutic action for MSCs derived CMs.

The effect of mesenchymal stem cell's secretome on hyperglycemia-related complications: focus on reproductive system disorders

Dr. Basak Isildar[1]
[1]Balikesir University Faculty of Medicine Histology and Embryology Department, Balıkesir, Türkiye

Poster Group 1

Background incl. aims
Type 1 diabetes (T1D) is characterized by insulin deficiency due to the autoimmune destruction of β-cells in the pancreas, which causes hyperglycemia. Although exogenous insulin is very effective in increasing the survival of patients, inadequately controlled hyperglycemia leads to secondary complications. One of the complications associated with T1D is reproductive disorders. In males with long-standing T1D, this can appear as sexual dysfunction or reproductive issues, primarily stemming from impaired spermatogenesis, reduced testosterone production and release, and changes in glucose metabolism within Sertoli cells [1]. Mesenchymal stem cells (MSCs) hold promise for handling the therapeutic requirements of T1D due to their involvement in the immunomodulation process and cytoprotective, antiapoptotic, and antioxidant properties. It is established that MSCs exert their therapeutic effects via paracrine mechanisms, releasing a diverse array of bioactive molecules termed the secretome, which includes growth factors, cytokines, chemokines, exosomes, and other bioactive factors. The composition of the secretome can be modified through various inductions, presenting significant potential for targeted therapy development. Among these induction types are a hypoxic cell culture environment, cultivating the cells on a three-dimensional scaffold, and using various chemicals. Conditioned media (CM) represents a tool to use the therapeutic benefits of the secretome exclusively, obtained by collecting the medium in which MSCs are cultured, free of cellular components [2]. The CM is important in the treatment of T1D due to the factors it contains [3]. Furthermore, the systemic application of CM could be crucial in preventing and repairing tissue damage caused by hyperglycemia in the body, despite this not being the primary treatment goal. This comprehensive approach is valuable as it addresses the entirety of T1D, which affects the entire organism. So, this study aims to investigate the effects of human umbilical cord MSC-derived CM, used for therapeutic purposes in the rat experimental T1D model, on testicular damage and the disrupted hormone mechanism, caused by hyperglycemia.
Methods
MSCs were isolated from human umbilical cord tissue by the tissue explant method, followed by characterization experiments. Two distinct CM types were obtained: CM obtained from MSCs cultured in normal culture (N-CM) conditions and CM obtained from MSCs preconditioned with a hypoxia mimetic agent, deferoxamine (150 µM) (DFX-CM). Sprague-Dawley rats were used for in vivo experiments, and the T1D model was induced using a single high-dose of streptozotocin (55 mg/kg). Experimental groups included control (C), diabetes (D), diabetes with N-CM treatment (D+N-CM), and diabetes with DFX-CM treatment (D+DFX-CM), with 6 rats in each group. Following the 4th week of the STZ injection, diabetic rats received intraperitoneal injections of equal amounts of N-CM and DFX-CM (each containing at least 15 µg of protein) four times a week for three weeks. Blood samples for hormone analysis were collected via cardiac puncture one week after the final CM dose injection, and the rats were sacrificed. After sacrification, serum levels of gonadotropin-releasing hormone (GnRH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), and testosterone were quantified via enzyme-linked immunosorbent assay (ELISA) for hormonal profiling. Testicular tissues stained with hematoxylin and eosin were used to perform Johnsen's scoring via light microscopy to

assess spermatogenesis. For this analysis, an average of 10 seminiferous tubule sections were analyzed in each rat (n=3). Seminiferous tubule diameter and epithelial thickness were also measured using the Image J analysis program. Finally, cellular ultrastructure was examined using transmission electron microscopy (TEM). All findings are presented as preliminary outcomes. Statistical analysis was conducted using the Kruskal-Wallis test, with p-values <0.05 considered significant.

Results

Upon examination of reproductive hormone levels in serum, statistical significance was identified among the groups for GnRH, FSH, and LH ($p<0.05$, $p<0.001$, and $p<0.05$, respectively). All hormone levels decreased in the D group. It was noteworthy that GnRH, FSH, and testosterone levels tended to increase in the D-DFX-CM group compared to the D group. Johnsen's scoring indicated impairment in spermatogenesis in the diabetes groups. On the other hand, the measurements of seminiferous tubule diameter and epithelial thickness did not reveal statistically significant differences. TEM analysis of seminiferous tubules revealed that the C group exhibited normal morphology. In contrast, the D group exhibited elevated lysosome levels in Sertoli cells, spermatogonia with dispersed heterochromatin, and primary spermatocytes with disintegrated nuclear membranes, alongside increased intercellular spaces. In both treatment groups, such defects were relatively less than in the diabetic group, and a substantial improvement in the ultrastructure of Sertoli and spermatogenic cells within the seminiferous epithelium was observed. Examination of spermatids showed that some in the diabetes group had impaired chromatin condensation. Axoneme structures were generally preserved (Fig.1).

Conclusion

Ultrastructural examinations revealed that the secretome of MSCs improved the seminiferous tubule epithelium by exerting a cytoprotective effect. Despite no significant impact on the hypothalamic-pituitary-gonadal axis, which is impaired by hyperglycemia, it is noteworthy that DFX-CM increased GnRH and testosterone release from the hypothalamus. However, this effect was insufficient, leading to no observable improvement in spermatogenesis. These preliminary findings underscore the necessity for further investigation into the observed ultrastructural improvement in the seminiferous epithelium and the need to uncover new cellular-level data elucidating the mechanisms of action of the secretome of MSCs.

Poster Group 2

Background incl. aims
Aluminum (Al) alloy additive manufacturing (AM) offers a groundbreaking approach to metal fabrication, providing unmatched design flexibility and material efficiency. However, achieving optimal performance hinges upon understanding and controlling microstructures. Microstructure analysis is critical for evaluating properties like grain morphology, size distribution, and phase constitution, which directly influence mechanical properties. By tailoring AM parameters and post-processing techniques based on microstructural insights, engineers can elevate the integrity and performance of Al alloy components. Careful microstructure analysis ensures AM-produced parts meet the stringent quality standards and reliability demanded by diverse industries, from aerospace, automotive, and beyond. Nevertheless, the rapid solidification and intricate thermal histories inherent in AM-produced Al alloys result in microstructures significantly different from conventional processes (e.g., casting), posing substantial challenges in accounting for microstructural elements across various length scales [1]. In this study, a scale-bridging approach [2] combining multiple techniques in scanning electron microscopy (SEM) and transmission electron microscopy (TEM) was employed for obtaining a clear microscopical picture of an Al-Si-Mg alloy [3] produced by Laser Power-Bed Fusion (LPBF).
Methods
Samples are prepared using electropolishing in combination with ion milling from the AM Al alloy. Conventional imaging and diffraction techniques as well as energy-dispersive X-ray spectroscopy (EDS) in both SEM and TEM are used to characterize the as-built microstructure (Figure 1). To reveal the underlying effect of additive manufacturing on the grain structure and phase distribution, a correlative approach for orientation imaging and phase mapping is then employed by using EBSD in SEM and ASTAR in TEM.
Results
Detailed microstructural features such as melting pools, grain structure and distribution/morphology of eutectic phases in the investigated AM alloy will be revealed and analyzed (to be continued).
Conclusion
This comprehensive approach will provide valuable insights into the microstructural evolution of AM-produced Al alloys, facilitating further advancements in material design and process optimization.

Towards 3D quantitative imaging in FIB-SEM for applications in battery materials

Stephanie Bessette[1], Prof. Raynald Gauvin[1]
[1]McGill University, Montreal, Canada

Poster Group 1

Background incl. aims
The development of more efficient and safer battery materials stems from the commitment to green energy initiatives. To fully understand the failure mechanisms of newly developed battery materials at the micrometer level and below, scanning electron microscopy is a technique of choice. Focused ion beam (FIB) combined with SEM broadens the characterization capabilities of electron microscopy by revealing sub-surface microstructure and phase distributions. The technique permits quantitative analyses from the reconstruction of volumes from collected 2D SEM datasets. Moreover, the collection of Energy-dispersive X-ray spectroscopy (EDS) and Electron Backscatter Diffraction (EBSD) maps from the generated x-rays and EBS patterns can help explain further the chemical and structural stability of the materials in 3D. Degradation over time during cycling can originate from alterations of the microstructure of particles, such as the apparition of cracks due to volume expansion, changes in grain morphology or activity at grain boundaries. This work aims to obtain quantitative information on the distributions of the different phases of lithium-based cathodes from field-emission (FE)-SEM datasets of 2D images, including porosity. Porosity is a critical parameter in battery design, since it directly affects electronic and ionic diffusion processes [1,2] and therefore battery performance. An interest will be given towards the changes in the phase distributions as a result of cycling, therefore pristine (uncycled) and cycled specimens will be compared including EDS and EBSD data.
Methods
Hitachi Ethos NX5000 FIB-SEM microscope located at the Facility for Electron Microscopy Research at McGill University will be used to prepare volumes using the slice and view technique of pristine and cycled cathodes. SE and BSE images will be acquired simultaneously at low voltage (2kV) during the slice and view routine to ensure the characterization of the fine pore structure from the small probe interaction volume. Ultim Max 100 SDD detector and Symmetry S2 EBSD (up to 4500 patterns per second collection) from Oxford Instruments will be used with 20 keV at given slices to collect chemical and crystalline information on the cathodes. Dragonfly software from Comet [3] is used to segment the 2D image datasets into 3 semantic phases (porosity, active material (particles) and binder (carbon)) using Deep Learning methods. Watershed algorithms are used to differentiate the labeled voxels in the phases and separate nearby voxels into individual elements for pore and active material to obtain statistical data on each phase.
Results
A preliminary dataset was obtained from a pristine lithium based cathode using Ga FIB milling with 3.5nA current with a slice thickness of 40nm. A total of 441 frames were collected with in-lens BSE(U) and BSE(L) detectors using simultaneous acquisition and a pixel size of 50nm. A volume of 19,6µmx20,5µmx17,5µm of the sample was reconstructed after registration of the slices and cropping. A U-net neural network was trained on a subset of the total stack manually segmented using thresholding on the mixed BSE U+L images, with 20% of the data retained for validation. It was found that 51,9% of the volume constitutes of carbon binder, 37,2% Li-based active material and 10,9% porosity. Histograms of the pore and active material populations were constructed after single

particle separation with the watershed algorithm. Following fractal geometry theory from Mandelbrot[4], the probability distribution of particles P is linked to the fractal dimension D with P(r>R)=AR^(-D). Deriving the equation to get the probability density ρ(R), the fractal dimensions D of both subsets can be extracted using the equation D=1/(m-1), knowing the radius R is expressed proportional to the volume V^(1/D) and m is the slope of the fitted straight line obtained from taking the logarithm of both sides of the derived equation. The fractal dimension of the pores yields D=0.60 and the active material is found to have D=0.99.

Conclusion

Preliminary image analysis using a FIB-SEM dataset on a pristine cathode showed the distributions of active material, carbon binder and pores. A neural network was trained to segment the cathode's phases and object analysis was used to study the pristine cathode. It was determined that the fractal dimension D of the pore medium in the cathode is 0.60, while the active material particles, containing Li, is set at 0.99. In both cases, the fractal dimension value is lower than one and therefore indicate that objects composing the phases are disconnected. Analysis of cycled specimens will enable us to observe the behavior of percolation pathways over time. The newly installed Ultim Max 100 SDD detector and Oxford Instrument's Symmetry S2 EBSD will be used to generate 3D volume reconstructions on pristine and cycled Li-based cathodes in addition to the image segmentation and quantitative results obtained from EM datasets. The addition of 3D chemical and crystalline information will give new insights into the effect of charge-discharge cycles on the distribution of phases and permit the observation of defects in 3D that can help explain battery failure mechanisms.

In-situ TEM study of ice nucleation and growth

Lifen Wang[1]
[1]Institute of Physics, Chinese Academy of Sciences, Zhongguancun, China

PS-07 (1), Plenary, august 29, 2024, 15:00 - 16:00

Ice is one of the most omnipresent solids on Earth, yet its crystallization is not fully understood. In particular, a long-standing debate is whether natural ice can form in a metastable pure-cubic phase. A mainstream view attributes the divergence to the stacking disordered ice (Isd) with a mixture of cubic and hexagonal sequences that preferentially nucleate and grow at low temperatures typically under 200 K, where complex kinetics in ice crystallization has also defied understanding thus far. This is due to that the direct and reliable determination of the structure of metastable ice requires ultra-high spatiotemporal resolution in an in-situ freezing environment, which remains a major outstanding challenge in the community. Here, through developing the in-situ cryogenic TEM, we directly tracked and unveiled the heterogeneous polymorphic ice nucleation and crystallization with molecular resolution during the water vapor deposition process at 102 K. We further pinpointed the atomic structure of polymorphic ice crystallites and identified distorted ice tetrahedral configurations as crystal defects with molecular resolution, which were not accessible before. Employing the electron beam as both the imaging probe and activation source, we were able to trigger and consequently monitor the kinetic transition process of stacking disordered ice (Isd) to ice Ic, demonstrating the unexpected meta-stability of ice Isd with respect to ice Ic. Our measurements shed new light on the structure and dynamics process determined heterogeneous nucleation of polymorphic ice. While a deep understanding of ice crystallization requires microscopic details, our realization of direct real-space imaging of growing ice crystallites at the molecular level is a key step towards reconciling experimental and theoretical investigations into the structure, nucleation, and crystallization based complex phenomena in ice family and polymorphic crystals.

IM-06 (3), Lecture Theater 1, august 30, 2024, 14:00 - 16:00

Background incl. aims
We set out to make the first position-resolved measurements of bonding electron density around a nanostructure in an inhomogeneous crystalline material.

All bonding electron density and potential studies to date have only involved homogeneous, single phased materials; however, most materials that serve us have hybridised properties because of the nanostructures that they contain, often by design. We also note that materials defects are ubiquitous and unavoidable, so the assumption that we can derive materials properties from notionally perfect regions of single, homogeneous crystal is limited in scope and "real" applications. This work aims to provide a new capability for interrogating bonding electron densities around nanostructures in nanostructured and inhomogeneous materials. Our first attempt involves nanovoids in nominally pure (99.9999+%) aluminium.

On the way to realising this aim, we have made several discoveries as a result of having to accurately map vacancy concentrations and determine the associated lattice contraction due to vacancies in order to be able to measure the Fourier coefficients (structure factors) of the crystal potential and electron density precisely and accurately (to <0.1% uncertainty).

Methods
Over the last 15 years, we have developed a multislice [1,2] approach to quantitative convergent-beam, electron diffraction (QCBED) refinements. We call this method QCBEDMS. This has facilitated the necessary analyses to generate the results summarised below. For more details regarding the method, please come to the talk – they will not be discussed here.

Results
From 45 CBED patterns collected through many different voids and the surrounding matrix, in different orientations and with different electron energies:

- We measured the volume of a vacancy with 5-fold less uncertainty than previous work.
- Observed that nanovoids in aluminium can "heal" even after significant beam damage.
- We mapped vacancy concentrations around aluminium nanovoids in 3 dimensions.
- We have shown that the bonding electron density around aluminium nanovoids is diluted by the elevated vacancy concentration surrounding these voids.

Conclusion
Our work and the results from it are a precursor to measuring and mapping bonding electron densities around many other types of nanostructures (eg. nano-precipitates) in other nanostructured, inhomogeneous materials. Furthermore, we are confident that our technique can be extended to mapping solute atom concentrations around such structures and that this will go together with accurate bonding electron density measurements within and surrounding these features in other nanostructured materials.

Transformation of Al2O3 to Cr-rich spinel during spark plasma sintering of alumina dispersed 316L steel

Dr. Zsolt Czigány[1], Dr. Haroune Rachid Ben Zine[1,2], Dr. Csaba Balázsi[1], Dr. Katalin Balázsi[1]
[1]Institute of Technical Physics and Materials Science, HUN-REN Center for Energy Research, Budapest, Hungary, [2]Faculty of Sciences and Technology, Mohamed Khider University, Biskra, Algeria

Poster Group 1

Background incl. aims
Dispersion of oxide particles in sintered steels is generally applied to improve the mechanical properties (e.g. fracture toughness, creep resistance) of steels. Spark plasma sintering (SPS) is a relatively new method [1] when a sequence of electric pulses are applied at high temperature and pressure. As an advantage, SPS offers rapid heating, limitation of grain growth, and efficient densification kinetics, which may provide benefits over hot isostatic pressing in certain applications. Manufacturing by SPS can also provide significant savings by increasing production volume and reducing energy costs.
Methods
Oxide dispersion strengthened (ODS) 316L stainless steel alloys with dispersed alumina were prepared by attrition milling and spark plasma sintering process at 900°C. The location and crystal structure of the oxide phase was investigated by a Cs corrected Themis (Thermo Fisher) transmission electron microscope including HRTEM, SAED [2] and EDS elemental mapping. TEM specimens were prepared by Ar ion beam milling at incidence angle of 4° at 10kV using a Technoorg Linda equipment [3]. The thinning procedure was finished at low-energy of 300 eV in order to minimize the possible ion beam damage.
Results
During sintering, the dispersed alumina transformed to spinel phase, dominantly with Cr2AlO4 composition. The spinel crystallites were observed between the grains of stainless steel in the sintered composites. The spinel crystallites were surrounded by an amorphous silica phase. The necessary Cr and Si may segregate from the stainless steel alloy at SPS conditions. The lattice parameter of the formed spinel phase is 8.36Å independent of the local composition variation as indicated by FFT of high resolution images.
Conclusions
The lattice parameter of the spinel phase is close to the high end among chromite related spinels which implies that octahedral sites of spinel structure are mainly occupied by Cr3+ or possibly Fe3+ cations [4]. These findings are consistent with literature describing geological formation of spinels in mafic or ultramafic rocks with low oxygen fugacity and assistance of silica phase in cation exchange [5].

Background incl. aims
In structural biology, Cryo-EM is one of the major imaging technologies. Even if the limits of the EM towards higher resolutions and faster data-collection have been really improved, the sample preparation step still remains poorly automated and difficult to manage for untrained and trained users (reproducibility issues). Many developments (e.g., Vitrojet1, Chameleon2) exist to make cryo-EM sample grid preparation easier, faster, and more reliable, and some of them also offer time-resolved module than remains a less user-friendly solutions (TrEM3, Joachim Franck's mixing/spraying method4). However, no machine currently offers a universal and easy solution. Several relative issues also exist in the field of X-ray imaging where there is no unique, reproducible sample preparation. This is the main reason why the instrumentation team of EMBL-Grenoble began the development of the EasyGrid5 device in 2017 that aims to provide a versatile tool that addresses most of the current difficulties encountered in the cryogenic preparation of diverse sample supports.

Methods & Results
This fully automated procedure (Fig.1a,b) uses in-line plasma treatment, picolitre drop dispensers, blotless liquid removal, ethane jet vitrification, automated cryo-storage and sample quality control at cryogenic temperature. The in-depth vitrification step is crucial to study native sample conditions for cells. Here we report initial results in two main domains; thin film sample vitrification for SPA experiments (cryo-EM), and whole-cell vitrification for cryo-ET/-XRF deep in large cells (Fig 1c,d,e).

Conclusion
EasyGrid proposes a versatile and robust multimodal sample preparation framework that can be easily adapted to a large variety of sample preparation protocols: cell freezing, classical SPA sample grid preparation, light triggered time resolved freezing, on-grid mixing, and this for diverse imaging modalities requiring different supports and conditions. The adherent cell vitrification protocol has been adapted for XRF using Si3N4 membranes (Silson), however, other supports can also be envisaged. The blotless liquid removal process allows for control of the ice layer thickness, a crucial parameter to optimise, to limit radiation damage on the sample during data-collection and maximise signal and contrast. The fully automated sample preparation procedure, leveraging precise robotics and an axis control system with sub-millisecond time-base, is highly reproducible. Hence, process optimization for different samples becomes accessible, and the screening of each process parameter can be reliably executed.

LS-04 (1), Lecture Theater 4, august 29, 2024, 10:30 - 12:30

Background incl. aims
While Electron Microscopy (EM) reveals extensive subcellular information in exquisite detail the technique has some limitations; lack of 3D cellular context, limited field of view and demanding sample preparation protocols compared to other techniques such as light or x-ray microscopy. To overcome these limitations correlative workflows have been developed that combine light with volume EM techniques such as focused ion beam scanning electron microscopy (FIB-SEM), serial block face scanning electron microscopy or array tomography, thus facilitating the localization of specific regions of interest within an extended sample volume. Nonetheless, these workflows remain largely confined to chemically fixed samples requiring labor intensive workflows, as the contrast from frozen-hydrated samples can be limited, making direct SEM imaging of native samples challenging. Soft x-ray tomography (SXT), on the other hand, is a unique x-ray imaging modality which enables imaging of frozen-hydrated specimens like entire mammalian cells or thick tissue sections with a few tens of nanometers spatial resolution and minimal sample preparation. The recent development of a laboratory scale SXT microscope opens the possibility of integrating this novel technique into light and electron imaging workflows. The SXT microscope features an integrated light microscope for overview imaging and fluorescence targeting, allows for swift acquisition of 2D and 3D images covering extensive areas on the specimen, and enables efficient and rapid identification of cells of interest. The (x,y,z) feature location can be recorded and the specimen passed to a cryo FIB-SEM for lamella extraction and subsequent cryo-ET imaging at ultra-high resolution.
Methods
Cryo SXT was used to identify target regions of interest within whole, frozen hydrated cells. Soft x-rays from 284 to 543 eV (2.34 to 4.4 nm) allow SXT to retrieve quantitative x-ray absorption information of protein content in biological cells with high native contrast. The resulting 3D datasets were imported to the correlative module in the TESCAN AMBER cryo FIB-SEM and used as a reference for targeted extraction of cryo lamella from the specimen.
Results
Resulting cryo-ET tomograms provide proof of concept for presented workflow.
Conclusion.
This workflow of correlative light, electron and soft x-ray microscopy (CLEXM) combines the strengths of both SXT and EM while also avoids any adverse effect of chemicals used for fixation in traditional EM methods, and therefore is particularly suited for studying rare events or features which cannot be labelled with fluorescent tags. We will discuss recent progress in this novel workflow development.

Electron-beam-induced surface diffusion of contaminants and growth of carbon contamination

Dr. Erich Müller[1], Mr. Arne Johan Schwartz[1], Mrs. Yolita M. Eggeler[1,2]
[1]Laboratory for Electron Microscopy, Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany, [2]3DMM2O - Cluster of Excellence (EXC-2082/1 – 390761711), Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany

PS-01 (2), Lecture Theater 3, august 28, 2024, 14:00 - 16:00

Background incl. aims
Carbonaceous contamination deposited on samples illuminated by a beam degrade the quality of images and aggravate structural and compositional analysis of the material. Contamination results from irradiation-induced polymerization of contaminants, which can be hydrocarbon molecules already present on the sample surface or molecules adsorbed from the residual gas of the instrument chamber [1]. Several authors concluded that the contribution of surface contaminants is dominant [2,3], but already earlier models consider an additional source from the residual gas in the instrument [4].
The goal of this work is to describe the flow of contaminants and their polymerization in the irradiated area with a number of parameters reduced to a minimum necessary. To analyze possible sources of contaminants, both, a surface diffusion process and the supply of contaminants from the residual gas are considered. It is hypothesized that the diffusion process is driven by the gradient of the surface density of contaminants, generated by the impact of the electron beam probe. The contribution of the residual gas atmosphere in the instrument is described by the tendency to re-establish an equilibrium surface density of contaminants.
A time-dependent reaction-diffusion model is elaborated to describe contamination growth on surfaces illuminated by an electron beam. The unknown parameters of the model are determined by comparing the theoretical predictions with experimental results. The experiments are designed such that the influence of each parameter can be unequivocally separated. Successive contamination measurements, performed at distinct time intervals allow to follow the dynamic of the process. Examination of the individual contribution of contaminants from the sample surface and from the residual gas of the instrument is facilitated by experiments with appropriate variations of these parameters.
Methods
Circular contamination patterns were grown in a FEI DualBeam Strata 400S on commercial thin (~10 nm) amorphous carbon films by illuminating the sample homogeneously with a defocused electron beam. The radius of the irradiation disk was chosen to be sufficiently large (~ 700 nm) to separate the influence of the distinct parameters on the contamination growth. Thus, the inflow of the surface contaminants by diffusion was noticed at the margin of the disk, while the residual gas contributed on the entire sample surface. The dynamical evolution of the process was followed by successive contamination measurements performed up to 20 minutes at time intervals of 5 minutes.
The local height and shape of the contamination rings were quantified by taking high-angle-annular-dark-filed (HAADF) images in scanning-transmission-electron-microscopy (STEM) mode between the irradiation cycles, and comparing their intensities with corresponding Monte-Carlo simulations. Both, irradiating and imaging, were conducted at electron beam energy of 20 keV and with a current of 120 pA.

To elucidate the supply of contaminants from the residual gas, the chamber pressure of the microscope was varied by different pumping periods and the usage of a cooling vessel trap. The initial density of the surface contaminants was altered by subjecting the sample to variable duration of in-chamber plasma cleaning.
Consideration of the main parameters of the process lead to a reaction-surface-diffusion model with an additional source term. It was supposed that the relative density of contaminants $n = N/N_0$, normalized to an initial density $N_0 = N(t = 0)$, changed locally due to polymerization to amorphous carbon contamination by the illuminating beam. The occurring gradient of n generated a surface diffusion process of contaminants, characterized by the diffusion coefficient D. The reaction of the irradiating electrons with the contaminants was described by the reaction-frequency σ. An adsorption frequency η of molecules from the residual gas considered for a source term with the tendency to re-establish the initial density of the surface contaminants. With these terms, the reaction-diffusion equation was elaborated as follows:
$\partial n/\partial t = D \cdot \Delta n - \sigma \cdot n + \eta \cdot (1 - n)$,
with Δ representing the Laplace operator in cylindrical coordinates for radial symmetry.
Comparing the predictions of this model with the time evolution of the experimentally grown contamination, the parameters of the process could be determined. All results were considered with respect to reference measurements, performed prior to the experiments with parameter variation.
Results
A surface-plot in Fig.1 a) shows the HAADF-STEM image intensities of contamination grown during 20 minutes of local irradiation with a defocused electron-beam of 20 keV. The modeled thickness profiles (continuous lines) in comparison with the measured radial profiles (dashed lines) of the contamination ring are depicted for distinct time intervals in Fig.1 b). Comparing the predictions of the reaction-diffusion model with experimentally grown contaminations, the diffusion of the surface contaminants was described by $D \sim 10^3$ nm²/s and the polymerization of the contaminants by a reaction frequency $\sigma \sim 1$ Hz. Small variations of D and σ for distinct measurements could be explained by local differences of the contaminants type of the corresponding experiments.
The contribution of contaminants from the sample surface and from the residual gas were separately determined by varying accordingly the experimental conditions by plasma cleaning, respective pumping and cooling of the instrument chamber. Already short plasma cleaning durations significantly reduced contamination growth and the exponential decay in time of surface contaminant density N_0 showed an effective removal of surface contaminants.
With higher chamber pressures, the residual gas supply of contaminants increased, as indicated by the raise of the adsorption frequency of contaminants. However, its value $\eta \sim 0.002$ Hz remained very low in comparison with the other parameters and contributed only with a small amount to the total contamination growth. Its direct influence in the illuminated area was relatively reduced, but became noticeable for contaminant adsorption outside the illuminated area and their subsequent diffusion into it.
Conclusion
In conclusion, it can be asserted that contaminants stem from the sample surface and diffuse into the illuminated area. This underlines the effectiveness of in situ plasma cleaning. The residual gas contributes less to direct contamination growth but should be considered for experiments of longer duration.

Poster Group 1

Introduction
High quality and defect free absorbers materials are usually essential for high performance solar cells. Different defects, such as point defects and grain boundaries (GBs), may strongly limit the performance of solar cells via enhancing the non-radiative recombination and impeding the charge carrier movement.1 However, Cu(In,Ga)S_2 (CIGS) solar cells exhibit a distinct scenario, in which polycrystalline absorbers with a high density of GBs can achieve high performance, exceeding 15% conversion efficiency.2 The fundamental physics underlying the high efficiency of polycrystalline CIGS solar cells, particularly the influence of different GBs, is still a significant question. In this research, we study the interplay between structural, electrical, and opto-electronic properties of GBs in CIGS solar cells absorbers by employing a multi-microscopy approach, integrating hyperspectral cathodoluminescence (CL), electron backscatter diffraction (EBSD), and tunnelling current atomic force microscopy (TUNA).
Materials and Methods
The CIGS samples were fabricated using a 3-stage co-evaporation process. All investigated samples were polished using a low energy broad Ar ion beam to achieve the low surface roughness essential for EBSD and TUNA measurements. We started the multi-microscopy investigation with a TUNA measurement conducted using a Bruker Dimension Icon AFM equipped with a Pt/Ir-coated SCM-PIC tip to minimise the impact of possible carbon contaminations in the SEMs. These measurements were then followed by EBSD measurements which were performed using a Zeiss GeminiSEM equipped with an Oxford Instrument Symmetry S3 detector. The initial EBSD datasets were indexed using Hough-based indexing, having a high density of mis-indexed pixels due to the pseudo-symmetry of the CIGS tetragonal lattice. The pseudo-symmetry arises from the subtle lattice parameter difference between c and 2a, which will significantly affect subsequent phase orientation analysis and grain boundary (GB) calculations. In order to mitigate the impact of pseudo-symmetry, we re-indexed the EBSD datasets with a tetragonal lattice system using a dictionary indexing approach. The open-sourced software, EMsoft, is used to create the master Kikuchi pattern using relevant lattice parameters of the investigated material and to carry out dictionary indexing on experimental EBSD patterns. Hyperspectral CL data was acquired using an Attolight Allalin 4027 Chronos dedicated CL-SEM. We employed Gaussian fitting to extract the CL emission intensity, energy, and full-width-half-maximum of each peak at each pixel from hyperspectral CL dataset. Direct correlation between the three techniques was achieved through sample markers and AFM images. AFM and TUNA data were processed and analysed by using Bruker Nanoscope Analysis software. Hyperspectral CL datasets were analysed by using open-sourced python packages Hyperspy and Lumispy. EBSD results were processed and analysed by open-sourced MATLAB package, MTEX.
Results
Analysing the EBSD maps we obtained structural information about the CIGS samples, including grain structure, phase orientation, and GB misorientation. We divided the GBs in CIGS into two categories,

twin boundaries (TBs) and random high angle grain boundaries (RHAGBs). TBs had a high relative frequency of more than 40%, and were observed with two distinct misorientation angles, 60° and 70°, corresponding to {112} and {110} planes, respectively. The CL spectrum shows two peaks, a strong emission peak at 1.6 eV corresponding to near band edge (NBE) emission and a weak and broad peak at 1.3 eV associated with defect-related emissions. Grain structure-like patterns were found from CL maps, wherein grains with strong NBE emission were separated by low emission intensity boundaries. Similar patterns, displaying strong current flows within grains and weak current flows at boundary positions, were observed in TUNA maps.
By using our multi-microscopy approach and correlating the CL and TUNA results with the EBSD maps for the same region, we were able to directly associate changes in the opto-electronic and electric properties to variations in the local sample microstructure. We found the strongest impact on the TUNA current and CL emission intensity and emission energy along RHAGBs, with distinct variations of the optical properties at some TBs. Inter grain variation was generally found to be weak and no correlation of either optical or electrical properties with grain orientation was found. Strong reductions in both TUNA current and CL intensity compared to the surrounding area were observed at all RHAGBs, suggesting that RHAGBs strongly inhibit the local charge carrier movement and locally enhance non-radiative recombination. The influence of TBs on local material properties is more complicated. Approximately 50% of the TBs appeared indistinguishable from the surrounding GI in both TUNA and CL maps, while around 25% of TBs behaved similar to RHAGBs with remarkably reduced TUNA current and CL emission intensity. An increase in emission intensity with weak redshift and narrower emission peak was observed from the remaining 25% of the TBs. No linkage between TB behaviour and misorientation angle has been found. The variation in both the electrical and opto-electronic properties likely links to the atomic scale structure of the different GBs. We attribute the reduction in both the TUNA and CL signal intensity at RHAGBs to a disruption of crystallinity and an agglomeration of point defects at the boundaries. The behaviour at TBs was found to be more complicated and we suggest a combination of imperfect TBs and local type-II quantum well like features to explain the varied optical response to TBs.
Conclusions
In conclusion, we carried out a directly correlated CL-EBSD-TUNA multi-microscopy study to comprehensively examine the electrical and opto-electronic behaviour of different GBs in CIGS on the nanoscale. Our findings demonstrate that all RHAGBs strongly inhibit the local conductivity and radiative recombination, while TBs were found with three different types of scenarios: behaving similar to surrounding GIs, strong reduction in CL intensity and TUNA currents, and showing enhanced radiative emission.

Blockwise Processing of Hyperspectral Analytical Scanning Transmission Electron Microscopy Data for Enhanced Analysis

Sebastian Cozma[1], Dr. Pau Torruella[1], Dr. Duncan T.L. Alexander[1], Prof. Dr. Cécile Hébert[1]
[1]Electron Spectrometry and Microscopy Laboratory, Institute of Physics, École Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland

IM-10 (2), Lecture Theater 3, august 29, 2024, 14:00 - 16:00

Processing the vast amounts of data generated by STEM spectroscopy techniques, particularly hyperspectral data obtained through energy dispersive X-ray spectroscopy (EDXS), poses significant computational challenges. Current approaches based on machine learning algorithms of the family of multivariate statistical analysis often struggle with the monolithic analysis of very large datasets that exceed available computer memory. A second challenge with very large datasets is that minority phases might be discarded with the noise if the dataset is treated in one block. Our research addresses these challenges by extending a monolithic, in-house, non-negative matrix factorisation (NMF) method specifically tailored for model-based treatment of EDXS data[1], called ESpM-NMF – that enables meaningful interpretation of the resulting spectral and spatial components – into a new tool where the dataset can be treated blockwise before a global reconstruction is performed.
First, we split the hyperspectral data into spatial blocks, the optimal size of which is based on the spatial structure of the initial dataset. Next, we perform principal component analysis (PCA) utilising singular value decomposition (SVD) to identify the number of relevant components within each block, by visual inspection of the SVD output. Subsequently, an initial NMF decomposition is performed with our ESpM-NMF algorithm on a blockwise basis, to estimate spectral components. In the following post-processing stage, we integrate a priori information concerning elemental composition, phase details, and chemical compound identification. The resultant spectral components are correlated using a custom spectral clustering algorithm to identify shared features across the different data blocks. With this step, we are able to reduce the number of spectral components to the exact total number of components to be expected for the whole dataset. Finally, we use the definitive spectral components relevant to the entire dataset to derive the corresponding spatial components capable of monolithically representing the input dataset by solving the least squares problem in a blockwise manner and concatenating the resulting blocks.
For the purpose of testing our algorithm, we generated a synthetic dataset with 5 spatially-separated phases using a previously-developed EDXS dataset simulation algorithm[2]. We use four spherical particles sitting on a silicon substrate. The substrate corresponds to a thickness of 10 nm, the sphere sizes are 10, 10, 20 and 50 nm for W, Pd, $ScVO_4$ and $SrTiO_3$, respectively. As shown by the comparison of monolithic to blockwise dataset decomposition in the figure below, our methodology shows clear improvements for processing large hyperspectral EDXS datasets. Through the integration of prior knowledge and the utilisation of blockwise NMF-based decomposition, we attain enhanced accuracy in separating spectral and spatial components, while also enabling the identification of minority phases that are not adequately detected in the monolithic approach. Leveraging spectral clustering aids in identifying shared spectral features across blocks with remarkable noise resilience, thereby improving results consistency, reliability and interpretability. Crucially, our approach enables efficient out-of-core processing, surmounting memory constraints and enabling the analysis of datasets previously deemed impractical without access to high-performance computing clusters.
In summary, we introduce a new tool for out-of-core hyperspectral data processing. Our NMF-based methodology not only overcomes memory constraints but also enables the detection of minority

phases that are not successfully retrieved using monolithic processing. This advancement opens avenues for more comprehensive and detailed analyses in STEM spectroscopy, paving the way for deeper insights into material structures and compositions. Progress is under way to publish the tool in an open-source format.

Poster Group 1

Background incl. aims
Mechano-biological measurements have the potential to distinguish healthy cells from pathological cells. Since 2007, a number of articles have shown that metastatic cancer cells have a Young's modulus (or elastic modulus) measured by atomic force microscopy (AFM) on living cells that is significantly lower than that of benign cells. However, cells are not inert and purely elastic materials, but dynamic and viscoelastic systems.
Methods
In order to measure these viscoelastic properties in living cells, we carried out dynamic mechanical analysis (DMA) measurements using AFM. After indenting a cell, we apply a strain and record the stress. The strain is proportional to the pulsation and therefore to the 6 frequencies we chose (from 1 to 200 Hz), and the stress is proportional to the phase shift of this pulsation. Knowing the strain and stress, we can then calculate G' (shear storage) in phase with the strain and G'' (shear loss) in phase with the strain rate. In our study, we sought to classify a population of cancer cells from a population of non-cancer cells. On each cell, 16 force curves (FC) and 19 characteristics/FC, corresponding to the viscoelastic properties and constituting a part of the mechanome, were calculated.
Results
All the FCs were then classified using machine learning (ML) tools with a statistical approach based on a fuzzy logic algorithm, trained to discriminate between non-malignant and cancerous cells (training basis, up to 51 cells/cell line). The proof of concept was carried out on non-malignant (RWPE-1) and cancerous (PC3-GFP) prostate cell lines.
Conclusion
After developing an algorithm to automate AFM measurements, we were able to measure 141 cells in dynamic mechanical analysis and demonstrated the ability of our method to correctly classify between 68 and 74 % of cells (31 cells in the test base/cell line).

Chitin in the cuticular capsule of tardigrade cysts

Mr. Kamil Janelt[1,2], Filip Wieczorkiewicz[1], Izabela Poprawa[1]
[1]Institute of Biology, Biotechnology and Environmental Protection, Faculty of Natural Sciences, University of Silesia in Katowice, Bankowa 9, 40-007 Katowice, Poland, Katowice, Poland,
[2]Department of Medical Genetics, Faculty of Medical Sciences in Katowice, Medical University of Silesia, Medyków 18, 40-752 Katowice, Poland, Katowice, Poland

Poster Group 1

Background incl. aims
Chitin is a biomolecule classified under carbohydrates, wherein N-acetyl-D-glucose-2-amino units are connected through β-1,4-glycosidic linkages, forming a polysaccharide biopolymer. It is a prevalent structural element in the body wall of various invertebrate groups, including nematodes, annelids, molluscs, onychophorans, and arthropods. This polysaccharide has also been observed in tardigrades, microinvertebrates commonly found in diverse habitats. Tardigrades are characterised by their ability to withstand unfavourable environmental conditions through cryptobiosis and diapause. Encystment, a form of diapause, is a natural process observed in some tardigrades, leading to the formation of a specific cyst form. Thulinius ruffoi (Tardigrada, Isohypsibioidea: Doryphoribiidae) is one of the species capable of undergoing encystment. During this process, the animal undergoes visible changes and produces a cuticular capsule composed of three layers – an outer, middle, and inner sheath. Additionally, the individual enclosed within the capsule possesses its own cuticle covering its body. This work aims to analyse the presence and localisation of chitin within the cuticular capsule of the cyst using selected methods for chitin detection on semi- and ultrathin sections.
Methods
Analyses were conducted using both light and electron microscopy. This study represents the first analysis of the composition of the cuticular capsule in tardigrade cysts. We adapted the 'chitosan-iodine' test to detect chitin indirectly on semi-thin sections. This method involved the deacetylation of chitin into chitosan, protonation of amine groups, and formation of the complex with iodine. Another method included the use of Calcofluor White, which specifically binds to β-1,4-linked polysaccharides. Control reactions in both cases involved specific enzymatic pretreatment using chitinase. Analyses were also conducted at the ultrastructural level. The first method involved a comparative analysis of material treated and untreated with chitinase. The second method utilised Wheat Germ Agglutinin (WGA) conjugated with gold particles to recognise and bind to chitin's N-acetylglucosamine (GlcNAc). The control reaction involved applying the method after prior chitinase treatment.
Results
The results revealed the presence of chitin in the cuticle of encysted animal. Also, the cuticular capsule inside which the animal was enclosed showed chitin localised within the middle and innermost sheaths of the cuticular capsule.
Conclusion
The methods used allow for an analysis of the presence and localisation of chitin on semi- and ultrathin sections, and those dedicated to transmission electron microscopy enable a more precise localisation of chitin. However, implementing the control reactions, such as treatment with chitinase, is necessary for a more specific verification of the obtained results. The analyses demonstrated the presence and precise location of chitin in the cuticle of the examined T. ruffoi. The research also allowed for the detection and analysis of the location of chitin in the cuticular capsule of tardigrade

cysts on the example of the studied T. ruffoi, which is the first analysis of the chemical components of the cuticular capsule in tardigrades.

The study was supported by the Polish National Science Centre (NCN Preludium 2020/37/N/NZ8/00170).

Mapping of interstitial atoms using super-resolution and optimized machine-learning techniques

Dr. Cyril Guedj[1]
[1]Univ. Grenoble Alpes, CEA, LETI, Grenoble, France

Poster Group 2

Abstract- Dedicated machine-learning techniques applied to superresolved HRSTEM images are used to map interstitial atoms with decananometric spatial resolution and picometric precision. This methodology is illustrated with the technologically-relevant case of etched GaN, used for power devices. In general, an average chemical concentration evolution close to a typical erf implantation profile is obtained, in agreement with atomistic simulations.

Keywords: imaging, super-resolution, superresolution, machine-learning, mapping, interstitials, TEM, STEM, HRSTEM

I. BACKGROUND AND GOALS

The interstitial atoms have a potential impact on the performance and reliability of microelectronic or electro-optic or quantum devices, but the precise mapping of their distribution is a very difficult task. In the field of MOSc-HEMT power devices, the etching steps may induce a detrimental ion implantation at critical interfaces in the case of recessed hybrid processes. These defects might potentially induce parasitic leakages currents and a detrimental reduction of breakdown voltages. The local defectivity increase due to such technological steps usually occurs in an ultrashallow range (nanometric or below), which is very difficult to precisely estimate. To tackle this major characterization challenge, novel methodologies have been developed, patented [1], and will be detailed here.

To map the chemical concentration profiles, many state-of the art techniques are currently used, such as secondary ion mass spectrometry (SIMS), electron energy loss spectrometry (EELS) or Energy dispersive X-ray analysis (EDX) among others, but all the techniques have their intrinsic limitations. For instance, it is usually very difficult to distinguish between substitutional and interstitial atoms with these characterization methods. Interstitial atoms are so small that they are generally very difficult to detect by conventional transmission electron microscopy [2]. Hence, it is often preferable to use aberration-corrected scanning transmission electron microscopy (HRSTEM or 4D-STEM) in HAADF mode (Z-contrast imaging) for heavy atoms and annular bright filed (ABF) or customized imaging modes for lighter elements [3],[1]. Light atoms such as H, Li or O play an important role in energy devices, and their mapping at the picometer level is useful to assess their potential electrical activity. In this presentation, we use our patented tools to extract the precise positions of interstitial atoms from superresolved HRSTEM images and optimized machine-learning algorithms.

II. METHODOLOGY

The original HRSTEM-HAADF images are obtained by aberration-corrected electron microscopy using the FEI Titan Themis microscope operated at 200 keV.

All the details of the methods are provided in the following patents. The patent EP4020378B1 is used to denoise the image by convolution.

The patent EP 4020379A1 provides the superresolved image, with a resolution typically increased by a factor of 5 compared to the original image.

Then the patent EP3671190B1 is used to obtain the positions of the interstitials using machine-learning based methodology with 3 binary classes: interstitial atoms, substitutional atoms and elsewhere. Only 3 areas are sufficient for an efficient supervised training with the Fast Random Forest algorithm [4], based on tree bagging and feature sampling.

III. RESULTS AND DISCUSSION

A typical result of atomic mapping is displayed on Fig. 1, in the case of etched GaN. The substitutional atoms are represented in grey, whereas the interstitial atoms are colorized. The spatial Abbe resolution is estimated from the superresolved diffractogram. The pic (-6,12,0) provides an horizontal resolution of 27 pm while the presence of the (0,0,13) reflection implies a vertical resolution of 38 pm, which is close to the record obtained by ptychography [5].

The vertically-averaged profiles are typical of implantation profiles, in agreement with atomistic simulations (Fig. 1 bottom). These results are consistent with the energetics of the plasma etch, when ion bombardment is expected. The possible vertical alignment of interstitials is attributed to possible channeling effects inside the implantation tracks.

This approach, validated by simulations and atomistic modeling, provides a universal methodology to map the interstitial atoms at the atomic scale, with a spatial resolution around 30 pm or even better in the case of ultrathin (about 20 nm thick) TEM lamellae with sample preparations close to perfection.

IV. CONCLUSIONS

Using super-resolution and machine-learning, it is possible to obtain accurate maps of interstitial atoms from high-resolution electron microscopy images, to analyze and optimize the technological processes involving ion implantation or surface damage. This method is universal, and the spatial resolution achieved by these combined techniques is close to the best currently achievable.

Reducing user-interaction in the processing of electron energy-loss spectra

Mr. Daen Jannis[1,2], Dr. Wouter Van den Broek[3], Mr. Jo Verbeeck[1,2]
[1]University of Antwerp, Electron Microscopy for Materials Research (EMAT), Antwerp, Belgium, [2]University of Antwerp, Nanolab Center of Excellence, Antwerp, Belgium, [3]Thermo Fisher Scientific, Eindhoven, Netherlands

Poster Group 1

Background
Conventional processing of electron energy-loss spectra (EELS) relies heavily on user-determined parameters, like for instance location and width of a background window, or choice of fine structure region. This makes results operator-dependent, more subjective and harder to reproduce.
Here we introduce a model-based processing of EEL spectra that relies on a linear model for which physical constraints are derived and subsequently imposed with the aid of quadratic programming. The model's linearity ensures fast convergence and the absence of local optima. Since the model includes all relevant EELS-features---background, atomic cross sections, fine structure, and multiple scattering---minimal user-interaction is required.
Methods
The background is described as a sum of 4 to 5 power-laws with fixed exponents ranging from -1 to -5. During the fit the coefficients are subjected to constraints that ensure non-negativity, monotonous descent and convexity. This background was proven to hold for energy ranges up to 1500 eV and to be superior to the conventional power-law background model [1].
The atomic cross sections are taken from a data base [2] that contains all edges of all elements up to atomic number 108. They were obtained from numerical relativistic solutions to the Dirac equations.
The fine structure is modeled as a quadratic spline with either linearly or quadratically spaced sample points. Working out the Bethe sum rule, assuming independent atomic shells and the dipole approximation, shows that the fine structure must have a weighted sum of zero. This constraint, too, is enforced through quadratic programming.
Results
In the figure the elemental maps of a TbScO3 sample are shown, in order to compare our approach to three alternative methods:
1. Unconstrained fit, with fine structure, no energy ranges excluded from fit.
2. Unconstrained fit, without fine structure, fine structure region excluded from fit.
3. Conventional approach: background region in front of each edge, background extrapolated and subtracted.
These 3 methods require a substantial amount of user choices, which we made to the best of our abilities. In comparison, our unsupervised approach yields the highest-contrast elemental maps, while offering a better precision, as demonstrated in the concentration histograms in the figure.
Conclusions
Imposing physical constraints on the EELS model through quadratic programming---in this case non-negativity, monotonous descent and convexity for the background, and the Bethe sum rule for the fine structure---greatly improves the quality of the result and removes most of the user-dependent input from the fitting process.

IM-05 (3), Lecture Theater 3, august 27, 2024, 10:30 - 12:30

Background incl. aims
To understand the structure-property relationship in nanostructured materials, we need to probe their crystal structures and compositions at the atomic scale. Advanced materials typically consist of multiple elements in a complicated structure. Significant challenges remain to disentangle the contributions of composition and thickness in STEM due to dynamic scattering, necessitating detailed simulations. However, the combination of the computational cost of the multislice calculation and the enormous ordering possibilities for a given composition makes the quantification of mixed columns almost impossible. To address these challenges, we here report the development of the atomic lensing model for the fast prediction of ADF-EDX scattering cross-sections of mixed columns [1].

Methods
The channelling effect originates from the fact that a fast negatively charged electron will be attracted by the positively charged atomic nuclei. As a consequence, an atomic column with periodically spaced atoms along the beam direction acts as a waveguide dynamically focusing the electrons. This leads to a non-linear signal as a function of depth for atomic resolution ADF and EDX, which significantly complicates elemental quantification. Based on the channelling theory of incoherent imaging, the so-called atomic lensing model was therefore developed to take the ordering of multiple elements into account [2]. In the atomic lensing model, dynamical scattering is treated as a superposition of individual atoms focusing the incident electrons. This model predicts the ADF scattering cross-section of a mixed column from the libraries of pure elements. Based on the incoherent imaging of ADF and EDX signals, this model has been shown to work for EDX as well and allows us to predict mixed column cross-sections with any atomic ordering efficiently. The validity of the atomic lensing model was verified numerically with frozen phonon multislice simulations. The speed and accuracy of the atomic lensing model were compared against multisclice and PRISM algorithms. For instance, the atomic lensing model is the only feasible approach that can explore all the ordering possibilities for a 20-atom-thick binary alloy column, taking 30 s to loop over 1 million orderings with an accuracy of ± 1 atom.

Results
We explained the linear dependence between ADF and EDX cross-sections from scattering theory and examined it numerically with multislice simulations, which is the basis for the extension of the atomic lensing model to both signals under the incoherent imaging mode. As shown in Fig.1 for a Au@Pt nanorod, one cannot distinguish the elements with adjacent atomic numbers from an ADF image but can fingerprint them with EDX. The predictions, based on the atomic lensing model, are in good agreement with multislice simulations and significantly deviate from the linear model in which a

simple scaling with the number of atoms is assumed. Based on the atomic lensing model and the correlation between ADF-EDX due to signal incoherence, we are able to count the number of atoms from an experimental ADF-EDX dataset of a Au@Ag core-shell nanoparticle [2]. We also demonstrated that this model can reliably predict EDX values for an Al-Ag-Pt-Au high entropy alloy up to 10 nm. Beyond this thickness, the contribution of neighbouring columns becomes significant.

Conclusion
The atomic lensing model significantly accelerates the prediction of ADF-EDX scattering cross-sections. It enables exploring atomic arrangements in multi-elemental materials with high throughput and opens new avenues for quantitative analysis in materials science.

Poster Group 1

Background incl. aims
The rich information obtained from EELS originates from the complex inelastic scattering process, wherein fast electrons transfer energy and momentum to atoms, exciting bound electrons to higher unoccupied states. To quantify compositions using EELS, the common practice is to fit the observed spectrum with the scattering cross-sections calculated from experimental parameters and the general oscillation strength (GOS) database [1]. A common commercial solution uses GOS tables obtained from the Hartree-Fock solution of atomic orbitals [2]. Here, almost 40 years after, we attempt to go beyond some of the limitations of this database by including the full relativistic effects and making use of dramatically improved computation capabilities in calculating a tabulated GOS solving the Dirac equation (Dirac-Hartree-Slater method within the local density approximation).
Methods
We calculated the transition density matrix using Fermi's golden rule, with the core orbital's bound state as the initial state and the continuum state as the excited state.
We assume a single independent atom, ignoring the solid state effects on the density of states and therefore the rich fine structure that is present in experimental EELS cross sections. We use the frozen core approximation, which assumes the potential remains unchanged after ionizing the core-shell electron to the continuum state, to ensure the orthogonality of the initial and final states. Both large and small components of the Dirac solution are needed to compute the transition matrix element. The convergence is checked by including the final states until the contribution of GOS of the last three states falls below 0.1%.

Results
A complete GOS database was constructed for all elements with atomic number Z=1-118 and all shells, which resulted in 2143 entries for which we store a tabulation of the GOS as a function of energy and momentum with fine sampling. We chose an energy range sampling from 0.01 - 4000 eV with 128 sampling points and a momentum range of 0.05-50 with 256 sampling points, both using a logarithmic sampling scheme. The database was saved in HDF5 file format [3] and will be supported in various software (e.g. Digital Micrograph, Hyperspy and pyEELSModel) so that users could switch easily between different flavours of GOS. As shown in Fig.1(a), the newly developed database has a much larger coverage of energy-momentum space with fine sampling for EELS cross-section quantification. It includes the effects of spin-orbital coupling, e.g. for the Ti L shell [Fig. 1(b)] and shows a good agreement with experimentally measured ionization energies across the periodic table [Fig. 1(c)]. We evaluated the computed spectrum based on different atomic calculations for the experimental spectrum fitting and elemental mapping [Fig. 1(d-f)]. We also considered the relativistic electrodynamics of the fast incoming electron on the orbital transition when computing the EELS cross-sections.

Conclusion
The accuracy of EELS quantification relies on the accuracy of the cross-section calculations represented in the GOS database as a function of energy loss and momentum transfer. In this study, we developed an open-source Dirac-based GOS database for all elements and shells for large energy and momentum space with fine sampling. The open-source Dirac-based GOS database [4] is expected to bring benefits to the EELS community for both academic use and industry integration.

Atomic transitions analogue in phased-shaped electron energy-loss spectroscopy

Simon Garrigou[1], Mr. Arnaud Arbouet[1], Mr. Hugo Lourenço-Martins[1]
[1]CEMES-CNRS, Université de Toulouse, CNRS, Toulouse, France

IM-03 (2), Plenary, august 28, 2024, 14:00 - 16:00

Background incl. aims
Electron energy-loss spectroscopy (EELS) has proven its efficiency in probing nano-optical excitations down to the atomic scale e.g. plasmonic resonances, excitons or plexcitons. However, EELS being directly proportional to the magnitude of the electric field, it is unsensitive to a plethora of important properties of nano-optical excitations - such as e.g. their phase, chirality, field lines symmetry.
Over the last decade, several routes have been explored to enhance the EELS scheme and enable the detections of these so-far hidden properties. One solution – first proposed in 2014 [1] – consists in shaping the amplitude and phase of the electron beam before its interaction with the sample and sorting the final electron states after. This EELS scheme based on state preparation-selection is generally called phase-shaped EELS (PSEELS) and has attracted both a strong theoretical [2,3] and experimental interests [1,2]. Most of these efforts have been focused on the measurement of the chirality of matter through dichroic PSEELS measurements [1,2] and several other properties of matter remain to be explored through the prism of this technique.
In this conference, we will present our latest work on PSEELS aiming at giving a different physical perspective on this technique as well as exploring its application to the probing of multipolar resonances.
Methods
In a first part, we will show that most of the theoretical results found in the literature [1,2,3] can be demonstrated using a different approach treating the shaped and post-selected electron beam in an analogue way to an electron bounded to an atom. More precisely, we will demonstrate that PSEELS is physically equivalent to a spontaneous transition between two bounded electron states - known as Purcell effect – where the initial and final state are in our case shaped and post-selected electron states. This reformulation of the problem provides an elegant and intuitive derivation of the standard result of PSEELS [1,2,3], without the need of complex derivations.
Results
In a second part, we will focus on PSEELS transition between Hermite-Laguerre-Gauss states, which have drawn a strong experimental interest over the last years [4,5]. For this family of states, our formalism enables an exact formal analogy between PSEELS and transitions in a two-dimensional harmonic oscillator – a standard textbook problem. This enables us to express the PSEELS problem in a 2nd quantization language (using ladder operators) and derive closed-form expressions for the PSEELS transition probabilities. This approach has the benefit of directly highlighting the conservation rules of physical quantities such as the linear and angular momentum, thus giving an intuitive interpretation of PSEELS.
Conclusions
In a last part, we inject a multipolar development of the electromagnetic field into the previous formalism. Thus, we demonstrate that, by carefully selecting the in and out free electron states, one can directly measure the different multipolar moment of the electromagnetic field in PSEELS. We numerically illustrate our finding by simulating a PSEELS experiment on a plasmonic quadrupolar field using a boundary element method – as shown on figure 1. In particular, we show that simply by using

1st and 2nd order Hermite-Laguerre-Gauss beams (demonstrated experimentally [4]) one can selectively measure the in-plane quadrupolar field component, as well as the twist of the electric field lines, thus revealing the 3D field topology in EELS.

Poster Group 1

Background incl. aims

Electrocatalytic processes are a prerequisite for efficient decarbonization, i.e. by providing green energy via green H_2 synthesis or chemical precursors via CO_2 upconversion. However, this requires a profound understanding of these processes and a complete characterization of the materials employed in these technologies to reveal and prevent potential degradation mechanisms. Nowadays, in situ characterization techniques that use irradiation sources such as electrons or X-rays gained interest since mechanisms can be temporally and spatially resolved giving insights into the atomic scale of such complicated electrochemical reactions. [1]

The challenge that remains when using these techniques is the inevitable interaction of the irradiation source with the specimens in study. An effect widely studied is the generation of radiolytic species that alter the chemical environment, whether evolving beam-induced redox chemistry, or altering the solution/electrolyte acidity. [2] However, a so far overseen aspect when performing liquid-phase electron microscopy (LP-EM) experiments is the design of the three-electrode setup used for these experiments.

A common setup consists of utilizing noble metals like platinum (Pt) as working, counter, and reference electrodes. By having this configuration, effects like increased inelastic scattering, galvanic corrosion effects [3,4], changes in electrochemical response by variation of electrolyte flowrate, or interferences on the reference electrode signal [4] have been suggested. These effects need to be understood and considered as unrelated to the electrochemical reactions to avoid misinterpretations as degradation mechanisms.

Methods

To investigate into these proximity effects, 10 mM silver nitrate ($AgNO_3$) solution flowed (0.8 µL/min) through a pattered Pt three-electrode microchip in a DENSsolution Stream system. The specimen was constantly irradiated with a Thermo Fisher Scientific Talos F200i at 200 kV acceleration voltage in STEM mode (dwell time of 2 µs, and beam current of 533 pA). The Pt working electrode was biased until electrochemically Ag dendrite growth was observed and then stopped to observe the evolution of the process.

Results

Our work reveals that electrochemically grown Ag dendrites etch radiolytically as function of electrode distance. Particularly, the structures closest to the working electrode showed an accelerated dissolution (Figure 1: (a) Electrochemically grown Ag dendrites at time = 0 s, (b) Radiolytically etched Ag particles at time = 71 s, green area marked showing accelerated Ag dissolution when closer to the Pt working electrode.). This is supported by DSSIM analysis [5].

We discuss several possible mechanisms, including secondary electron-based local dose rate increases, Pt-catalyzed generation of oxidative species, as well as galvanic corrosion. Additionally, we report irradiation-driven potential overshoots when irradiating in the proximity of the reference electrode during electrochemical experiments.

Conclusion

In summary, we explore effects associated with the proximity and irradiation of the electrodes to further increase the control over and understanding of in situ analysis of electrochemical processes.

A twist to superlubric sliding in bilayer graphene uncovered by in situ TEM

Dr. Xin Zhou[1], Dr. Mingjian Wu[1], Prof. Erdmann Spiecker[1]
[1]Institute of Micro- and Nanostructure Research (IMN) & Center for Nanoanalysis and Electron Microscopy (CENEM), Friedrich-Alexander-Universität Erlangen-Nürnberg, Erlangen, Germany

PS-01 (1), Lecture Theater 3, august 28, 2024, 10:30 - 12:30

Background incl. aims

Twist in two-dimensional (2D) Van der Waals (vdW) bilayers, which results in the formation of moiré superlattice, has garnered attractive interest and can lead to unprecedented exotic physical properties including superlubricity.1 The twist angle (θt) offers not only a new and unique degree of freedom for modulating the properties, but also small and local variations in θt can result in exceptional differences in these properties.2 Indeed, it was discovered that the superlubricity in graphite is intimately dependent on the interlayer twist angle (thus incommensurability), interfacial cleanliness, and thickness. Fruitful experimental exploration on the superlubric features in artificially stacked graphite surfaces at a wide range of twist angles has been achieved and the underlying mechanism has been readily explained as the twist-related incommensurate stack between the sliding layers using a rigid-body model. 3,4 However, the scenario of the transition to superlubricity becomes more complex due to atomic scale structure relaxation and reconstruction at a small twist angle regime ($\theta t < 4^{o}$), thus normal rigid-body model fail to predict. Meanwhile, the existing experimental approaches fail to capture the details of superlubric sliding, and direct insight with high precision measurement into how the interface between two atomic layers undergoes transitions from structurally reconstructed bilayers to incommensuration to approach superlubricity is still lacking.

In this work, we report the observation of the superlubric sliding between two monolayer graphene in free-standing bilayer graphene (BLG) by the implementation of an in situ transmission electron microscopy (TEM) tensile straining setup combined with 4D scanning transmission electron microscopy (4D STEM) to probe local twist angle and strain.

Methods

We transfer bilayer graphene samples (ACS materials, 1cm×1cm) to a homemade Cu support with a small window, and then clean the Poly (methyl methacrylate) coating by acetone. Tensile straining was imposed by using a single-tilte Gatan straining holder 654 and in situ TEM experiments were carried out using a ThermoFisher Scientific Spectra 200 microscope operated at 80 kV. Dark-field TEM (DF-TEM) images, selected area electron diffraction (SAED) patterns, and ($1\bar{1}\bar{1}20$) DF-TEM image series were recorded throughout the straining process to visualize the dynamics of basal plane dislocations during straining. The mechanical loading was paused in between to carefully characterize the basal plane dislocations and to acquire 4D-STEM datasets (Fig. A). The 4D STEM experiments was carried out using micro-probe mode with a nominal convergence half-angle of 0.47 mrad and the data acquired using a Ceta-S camera running at ~300 fps. These datasets were analysed using py4DSTEM package and custom codes. A similar straining experiment and data acquisition process was succeeded for a second BLG sample. Both straining experiments were terminated until fully detachment of the monolayers.

Results

We realized the strain experiment on graphene samples with a monolayer-bilayer-monolayer (MLG-BLG-MLG) configuration (Fig. B). Before straining, basal plane dislocation with line direction parallel to the straining direction was observed (Fig. B), which is likely resulted from film buckling. After an

incubation period during straining, where the width of the bilayer region decreased, we observed nucleation of new basal plane dislocation with line direction perpendicular to the straining direction, indicating initiation of twist between the monolayers. Further straining resulted in continuous nucleation of dislocations and a dramatic increase in the density of these dislocations, thus the increase in twist angle (Fig. C and D). Using 4D STEM analysis, we quantified the twist angle within the bilayer region by measuring the angular difference of Bragg disks in the local nano-beam diffraction (NBD) patterns, which are extracted from the left-side and right-side monolayer regions. Similarly, the local elastic strain in the monolayer regions was determined by analysing the displacement of Bragg peaks throughout all datasets, referencing a free region near the edge of MLG as zero strain. The established relationship between twist angle and strain, derived from extensive measurement points in both samples, clearly disclosed a consistent tendency of decreasing in strain with increasing twist angle. Leveraging the strain-twist angle correlation, and employing the quasi-kinetic equilibrium force model alongside the elastic properties of monolayer graphene (Fig. A), we investigated frictional properties associated with twist angle in bilayer graphene. Notably, a smooth reduction in the coefficient of friction (CoF) was observed as a function of twist angle, with the CoF dropping below 0.01 for twist angle exceeding 1.5^{o}, implying the approach of superlubricity in bilayer graphene.

Conclusions

Our study delved into the phenomenon of twist-modulated superlubric sliding between monolayer graphene by directly visualizing the dynamic transition from commensurability to incommensurability in marginally twisted bilayer graphene. These findings provide the direct experimental observation of superlubric feature between atomic graphene layers and open a new avenue to build up twist angle gradients in 2D materials for investigating their twist-related exotic properties.

Background incl. aims
We propose a method which combines 3D electron diffraction (3D ED) [1] and nanotexture analysis in a TEM to characterize small impact ejecta (usually spherules of few hundred microns) with the aim to identify new mineralogical phases and to understand their formation mechanism/conditions. The method of analysis consists of: a FIB thin section preparation on an area of interests determined by SEM imaging and EDS analysis; identification of the crystal structures of the main phases through 3D ED, a single crystal diffraction technique on nanometric grains; texture and phase analysis using a scanning diffraction method known as PACOM (Precession Assisted Crystal Orientation Mapping) [2].
Methods
The FIB section is usually inspected both by Z-contrast STEM imaging and EDS analysis to identify areas and crystal grains of interest. For identifying the phases present in the sample, fast 3D ED data collections, covering just 30°-40° of reciprocal space, are collected on selected crystal grains with the aim of unit cell determination and consequent phase identification. If the phase determination is uncertain a wider angular range (<80°) 3D ED data collection can be employed for its structure solution. The relative phase relations and possible coherent growth are then determined by recording a sequence of ED patterns while the electron beam is scanning the area of interest with a spatial resolution of a few nanometers. Those patterns are then indexed with a cross correlation algorithm employing banks of ED patterns (using the software of the ASTAR Nanomegas system) created on the bases of the determined crystal phases present in the sample.
We applied this methodology to two sets of samples: impactite ejecta belonging to the Australasian tektite/microtektite strewn field and Fe-Ni oxide spherules generated by the impactor which created the Kamil crater (Egypt).
Results
In the case of the Australasian ejecta 3D ED allowed the identification and structure solution of the TIO2-II high pressure polymorph, which resulted to be a Zr-free srilankite endmember. The texture analysis indicates that TiO2-II is usually surrounded by well-ordered rutile grains which retains a topotactic relation with the embedded TiO2-II suggesting a partial transformation due to P-T waves during the impact.
In the case of the spherulites from Kamil crater it has been possible to depict a complex scenario in which a matrix of Fe-Ni oxides grains showing fine exsolution of two different phases (STEM HAADF image in the right picture) is permeated in the interstitial volume by a Si rich fluid which, in most of the cases, is amorphous. PACOM and HREM imaging revealed that the two exsolved Fe-Ni oxide phases have a trevorite (the Fe-rich component) and a bunsenite (the Ni-rich component) structure and that inside each micrometric grain they are coherent. The amorphous interstitial part usually separates into two components: SiOx amorphous droplets and a second silicic component rich in Fe

and P. This second component has been found both in an amorphous and in a crystalline form. When crystalline, 3D ED identified it as olivine with a P content as high as 3%-4%at. The full crystallochemical characterization at the nanoscale depicts a formation model in which the Ni-Fe-P melt from the meteorite oxidizes and mixes with the melted quartzite from the target. The oxidized Fe and Ni crystallizes in Fe-Ni oxides micrometric grains which, upon cooling, exsolve the two abovementioned phases (bunsenite in green and trevorite in light blue in the left picture). The remaining Fe with all the P enriches the silicic melt which form a glass that fills the interstitial void. This glass further separates into two components: one depleted in Fe and P which stays amorphous and a second which, depending on its thermal history, can or cannot crystallize forming P-rich fayalite.

Conclusions

The combination of 3D ED with PACOM allows at the same time the discovery of new crystal phases present in micrometric planetary materials and obtaining a full crystallochemical charaterization which is essential for understanding the thermal history and for building a formation model of the retrieved sample. We envisage a crucial application of this methodology to any kind of planetary material coming from sample return missions.

Probing the chiral behavior of nano-optical near-fields through angular momentum resolved PINEM

Simon Garrigou[1], Mr. Arnaud Arbouet[1], Mr. Hugo Lourenço-Martins[1]
[1]CEMES-CNRS, Université de Toulouse, CNRS, Toulouse, France

IM-08, Lecture Theater 2, august 28, 2024, 10:30 - 12:30

Background incl. aims
Usually performed in a ultrafast transmission electron microscope (UTEM), photon induced near-field electron microscopy (PINEM) consists in mapping the magnitude of an optical near-field pumped by a laser with a fast electron beam [1]. Benefiting from the sub-nm spatial resolution of TEMs as well as the high fluence and energy resolution of ultrashort lasers, this technique can probe deep-subwavelength structural details of the optical near-field in resonant and non-resonant structures.
Methods
In addition, and contrary to electron energy-loss spectroscopy (EELS), PINEM displays a high degree of selectivity thanks to the laser illumination. For example, by properly tailoring e.g. the wavelength and polarization of the laser, one can selectively excite individual optical modes [2]. This idea can be extended to probe the chirality of nano-optical near-fields. Indeed, as first demonstrated by Harvey and collaborators in 2020 [3], one can perform a so-called “chiral PINEM” experiment – where a right- and left-handed polarized laser beam is sequentially used to excite the structure and measure the differential PINEM signal. In that configuration, spin angular momentum (SAM) of the incoming beam is tuned so that this technique is denoted as SAM-dichroic PINEM (see figure 1).
Nevertheless, by shaping its phase profile, a laser beam can also carry orbital angular momentum (OAM), and a long-standing question remains on the difference between OAM- and SAM-based dichroic experiment [4]. A natural candidate to tackle this issue is thus a combined SAM-dichroic and OAM-dichroic PINEM experiment – an experimental scheme that we will refer to as angular momentum resolved PINEM (AM-PINEM).
Results
In this conference, we will present our latest work on angular momentum resolved PINEM, showing its application to the probing of the coupling between chiral light and optical near-fields. In a first part we will show that the theoretical framework based on the local density of states (LDOS) used to explain EELS and CL experiments [5] can be extended to PINEM, combining in an elegant way these three main TEM spectroscopies. In particular, we will demonstrate that AM-PINEM can be connected to the concept of chiral radiative LDOS.
In a second part we will focus on the numerical simulation of AM-PINEM experiments using pyGDM - an electrodynamics simulation toolbox based on the green dyadic method that we enhanced to simulate polarized electron spectroscopies. The large library of different illuminations allows for simulation of both SAM- and OAM-resolved PINEM experiments. We will focus on practically realizable structures such as the gold trimer (see figure 1) in which OAM- and SAM-dichroism present clear differences.
Conclusions
In a last part, we will show our first experimental results on SAM-dichroic PINEM realized with a new cold field emission UTEM on simple achiral structures, revealing dichroic behaviors at the deep sub-wavelength scale. Finally, we will present our preliminary work towards the realization of the OAM-dichroic PINEM experiments.

Impact of oxidation state on copper nanoparticle stability in industrial Cu/ZnO/Al2O3 hydrogenation catalyst

Xiansheng Li[1], Henrik Eliasson[1], Rolf Erni[1]
[1]Empa-Swiss Federal Laboratories for Materials Science and Technology, Dübendorf, CH

Poster Group 2

Background
The escalating concentrations of atmospheric CO2 represent an urgent challenge for the global climate system, driving intensive research efforts aimed at mitigating this trend through innovative strategies for CO2 reduction, conversion, and sequestration. The catalytic conversion of CO2 into liquid fuels and high-value chemicals emerges as a pivotal area of focus within the realm of environmental stewardship and energy efficiency. Among these strategies, the hydrogenation of CO2 to methanol stands out as a particularly promising avenue for the effective large-scale deployment of CO2 utilization technologies. The production of methanol through the conversion of CO2 using green hydrogen obtained from sustainable energy sources like wind, solar, and biomass, serves the dual purpose of CO2 utilization and the storage of renewable energy into chemical compounds.
The standard methanol catalyst Cu/ZnO/Al2O3 has been industrially applied for more than 50 years. Still, its efficacy is marred by exceeding 50% decline in activity within the initial weeks of operation, primarily due to thermal sintering and structural reconfigurations. It underscores the critical need for an in-depth exploration into the mechanisms underlying catalyst deactivation, with the ultimate goal of engineering more resilient catalyst systems. Previous studies attribute this deactivation to the sintering of copper, a process intimately linked to the dynamics and stability of Cu nanoparticles (NPs).
In the quest to elucidate the dynamic behaviors and migration patterns of NPs, electron microscopy stands as the method of choice. Specifically, in situ Transmission Electron Microscopy (TEM) offers unparalleled insights into catalyst structures under near-industrial operational conditions, including the intricate dynamics of nanoparticulate entities. This study, therefore, harnesses the power of in situ TEM to meticulously examine the behaviors of Cu NPs on industrial Cu/ZnO/Al2O3 catalysts throughout the entire CO2 hydrogenation lifecycle, spanning activation, steady-state operation, and eventual deactivation. By focusing on the oxidation state of copper under varying operational conditions, this investigation seeks to unravel the complex interplay between the chemical state and the mobility of Cu NPs, with the overarching aim of fostering advancements in catalyst design and CO2 conversion technologies.
Methods
In situ TEM experiments were carried out using a windowed gas cell nanoreactor (Climate, DENS solutions) comprising of two electron-transparent Si3N4 windowed chips. Commercial Cu/ZnO/Al2O3 catalyst (Alfa Aesar, 45776) was dispersed in ethanol and deposited on the bottom climate chip before constructing the climate holder and sealing the nanoreactor. The nanoreactor consists of a top and bottom chip of 50 nm and 30 nm thickness respectively. The internal temperature of the microreactor was accurately controlled by a 4-point probe method.
Microscopy measurements were conducted using a probe aberration-corrected FEI Titan Themis microscope operating at 300 kV. The beam convergence angle was set to approximately 26 mrad. EEL spectra were recorded with an ELA hybrid pixel direct electron detector from Dectris that was retrofitted with a CEFID energy filter from CEOS. The energy dispersion of the ELA detector was 0.747 eV per channel, and the dwell time was set to 1 s.

Results
Upon careful reduction following standard industrial procedures, the catalyst was activated, demonstrating significant changes in the behavior of Cu NPs across various stages of treatment, as monitored by in situ STEM and complemented by EDS and EELS analyses.
Initially, under high vacuum at room temperature, Cu NPs exhibited stability with no discernible movement; the only observable change was the slight contraction of the overall catalyst structure. EELS indicated a pronounced white line, suggesting an oxidized state of copper.
Heating to 180°C under a 1 bar N2 atmosphere triggered dynamics within Cu NPs, extending them towards the sample's edge to form larger entities. EDS data revealed Cu's segregation from Zn, highlighting Cu's higher mobility. This segregation could contribute to deactivation, as the Cu-Zn synergy is deemed crucial for catalytic activity. Notably, areas not subjected to electron beam exposure did not exhibit similar changes, suggesting that temperature or gas composition, in conjunction with beam interaction, might facilitate these dynamics. Post-sintering, EELS data suggested a reduction in Cu, with a diminished white line intensity and reduced mobility.
At 260°C in a 1 bar H2 atmosphere, Cu NPs demonstrated sintering with no alteration in the white line intensity of Cu EELS before and after observation, indicating a stable oxidation state that was reduced compared to the initial state but more oxidized than beam-induced sintered NPs. Some level of dynamic behavior was still observed, albeit less than in N2. Significant movements, such as approaching beyond the edge of the specimen, are indiscernible, suggesting that the beam-demage is minimized in H2 atmosphere.
Exposure to a 1 bar CO2+H2 atmosphere at 260°C resulted in immediate stabilization of Cu NPs, with EELS revealing a lower white line intensity, approaching that of beam induced sintered NPs.
Finally, under a 1 bar O2 atmosphere at 260°C, Cu NPs were re-oxidized, regaining high mobility. The presence of O2 also facilitates the redispersion of Cu NPs.
Conclusions
The comprehensive investigation delineates the nuanced mobility hierarchy within the catalytic system, conclusively establishing that the mobility of copper is positively related to its oxidatino state. The discovery holds significant importance within the realm of Cu/ZnO/Al2O3 deactivation, as corroborated empirically that deactivated Cu/ZnO/Al2O3 catalysts exhibit the presence of partially oxidized copper. The study further corroborates the role of oxygen in facilitating the reoxidation of Cu to CuO, a process that significantly contributes to the sintering, underscoring the detrimental impact of oxidation processes on catalyst longevity and performance. The mobility difference between copper and zinc could potentially cause their segregation and contribute to deactivation, as the Cu-Zn synergy is deemed crucial for catalytic activity. Moreover, the addition of CO2 to the hydrogen flow enhances the reduction power, likely through the formation of CO by Reverse water gas shift. Collectively, these insights not only advance our understanding of the dynamic interplay between catalytic components under varying environmental conditions but also pave the way for the development of more resilient and robust hydrogenation catalyst systems.

Damage reduction in amorphous ice by a non-conventional scan strategy in cryo-STEM

Abner Velazco Torrejón[1], Mr. William Bowles[1], Dr. Maud Dumoux[1], Dr. Judy Kim[1], Prof. Angus Kirkland[1,2]
[1]Rosalind Franklin Institute, Harwell Science and Innovation Campus, Didcot, United Kingdom, [2]Department of Materials, University of Oxford, Oxford, United Kingdom

IM-11 (1), Lecture Theater 5, august 29, 2024, 10:30 - 12:30

Background
For many important classes of materials, electron beam damage in transmission electron microscopy (TEM) has a detrimental effect that limits the capability of the instrument to obtain information at different scales, atomic or structural scale, for instance. Organic and biological materials are among the most beam sensitive materials. Biological samples are commonly studied using cryo-TEM, where the samples are preserved in amorphous ice and illuminated by a parallel beam. Unfortunately, the ice matrix is also sensitive to the electron beam. For these reasons, electron doses in the order of only 10's of e-/Å² are usually employed in cryo-TEM. Potentially, scanning transmission electron microscopy (STEM) offers some benefits over TEM such as the compositional contrast, through the high angle annular dark field (HAADF) signal, and the capability to observe thicker specimens [1]. In STEM, it is well known that beam damage can extend over an area larger than the size of the scanning probe so areas that come later in the scanning sequence can be damaged prior to observation with the probe. This effect can have many physical sources, which can depend heavily on the material itself: diffusion of heat, diffusion of radicals, delocalized inelastic scattering, electrostatic charge, etc. [2]. Some of these effects are dynamic in nature and have both a spatial and a temporal scaling parameter. It has been shown that this behavior can be modeled as a diffusion process and that beam damage can be mitigated by changing the temporal distribution of the electron dose [3]. In this work, since evidence of a diffusion type damage behavior was found in vitreous ice, we compare beam damage when using an interleaved scan, see Figure 1, and the conventional raster scan with the aim to mitigate damage effects and increase the applicability of cryo-STEM on biological samples.
Methods
To make the experiments reproducible, vitreous ice served as a test sample. A JEOL ARM300F2 microscope operated at 300 kV and equipped with an external scan generator was employed to scan two adjacent areas using raster and interleaved scan. In an effort to perform the experiments in areas of relatively uniform thickness, the experiments were carried out close to the center of the holes of quantifoil grids filled with ice, see Figure 1. An electron dose budget approximately 100x higher than in conventional cryo-TEM was used in order to make the effect of damage more evident and easier to quantify. The quantification was done from images acquired using the HAADF analog detector where darker areas indicate more damage after mass removal when scanning. The electron dose was fractionated by sequential acquisitions for both scan methods and also compared to single acquisitions, maintaining a constant total dose.
Results
A significant reduction of beam damage of more than 20% is observed when using interleaved over raster scan when scanning with long dwell times (more than 250 µs) and only a few passes (two or less); as shown by the use of line profiles in Figure 1. However similar amounts of damage occurred

when using a short dwell time (20 µs) and several passes (around 25). Our results also show that the damage rate increases as the vitreous ice thickness decreases.

Conclusion

Our observations support the diffusion like process, at least for this specific material. It shows that beam damage is not only proportional to the total electron dose, but also the distribution in time and space plays an important role. Further work is required to identify the physical nature of the diffusion process and its link to beam damage.

Poster Group 2

Background
Metal halide perovskite semiconductors have emerged as a focal point of research due to their potential applications in solar cells, characterized by exceptional power conversion efficiencies, extended carrier lifetimes, reduced recombination rates, and cost-effective manufacturing techniques. Despite their considerable potential, challenges such as structural instability, ion migration, hysteresis, and defect intolerance are impeding their practical application. There is a critical need for a detailed atomic-scale understanding of the processes that control these properties and performance, however, atomic-scale electron microscopy studies have been relatively limited due to the extreme sensitivity of these materials to the electron beam. Here we develop and apply low dose electron microscopy methods to provide new insights into the structure-property relationships of these materials, including the role of nanoscale heterostructures, octahedral tilts, and point and planar defects, that are critical to their distinctive properties.

Methods
Transmission Electron Microscopy (TEM) offers valuable insights into the local atomic structure of materials. The application of TEM in the study of perovskite solar cells is extremely challenging due to their extreme sensitivity to electron irradiation, which can lead to rapid changes to their pristine structures with doses as little as a few electrons per Å2, far below conventional techniques, including STEM, EDX and EELS. To circumvent this limitation, we have developed and applied a suite of specialized TEM protocols encompassing specimen preparation, inert atmosphere transfer, diffraction pattern and image acquisition, and data interpretation.

Results
Our study reveals the sequence of subtle, atomic-level structural transformations leading to the degradation of mixed-cation Cs1-xFAxPbI3, beginning with the formation and ordering of ion vacancies and followed by a composition-dependent octahedral tilt. Additionally, we elucidate the atomic configurations of planar defects, including twins and Ruddlesden-Popper phases, and establish a correlation between these defects and solar cell performance. Our findings indicate that certain types of twin defects adversely affect solar cell efficiency, and their removal markedly enhances device performance.

Conclusion
The insights gained from our study into ion loss, ion migration, octahedral tilt modes, and the influence of A-cations shed light on the atomic-scale structural mechanisms responsible for the

instability of perovskite solar cells. By correlating specific atomic defect structures, including planar defects, with optoelectronic properties, we outline strategies for the amelioration of perovskite solar cells through defect engineering, paving the way for their improved performance and stability.

Poster Group 1

Stable sources of ultra-short electron pulses are an important issue in the development of time-resolved electron microscopy. Here we report on experimental investigation of static and pulsed electron emission from single crystal diamond needles and LaB6 nano-tips, fabricated by focused ion beam milling [1-2]. Diamond attracted a lot of attention due to its unique properties: chemical inertness, mechanical stability and high thermal conductivity [3]. LaB6 has been traditionally used as a thermionic electron source for electron microscopes, but has been hardly put to practical use as cold field emitter (CFE) [4]. In the present work we study the emission properties of diamond and LaB6 nano-tip under static electric field (static emission) and under femtosecond laser illumination using infrared laser (at 1.04 □m and 2.25□m, wavelength) and high repetition rate ranging from 40 kHz to 13 MHz.

Field emission measurements were performed in an ultrahigh vacuum system at a pressure of 4 × 10−10 mbar at room temperature. A negative bias voltage Vtip is applied to the sample. The electron kinetic energy spectrum is measured with a retarding field energy analyzer using concentric hemispherical grids with a resolution of about 0.2% of Vtip. The detector is composed of a stack of two micro channel plates (MCP) coupled with a phosphorescent screen each of 8 cm in diameter. A CCD camera is used to recorded the impacts on the phosphorescent screen. This setup enables the measurement of the 2D map of the emission pattern. The MCPs have a hole in the center of 0.5 cm in diameter. The laser beam is focused on the tip emitter through a spherical mirror of numerical aperture NA = 0.3 and a working distance WD = 25 mm.

Conductive diamond and LaB6 emitters show significant increase of electron emission current under laser illumination. Electron spectroscopy measurements suggest multi-photon nature of the electron emission processes. The increasing of the laser intensity strongly modifies the emission pattern, leading to the emergence of a new emission region at high peak power [2-5].
In particular, the field emission pattern, when compared with the field ion microscopy image of the LaB6 surface, suggests that electrons are emitted from the [001] pole and [011] poles under strong laser illumination. By further increasing the laser power, a transition from multiphoton to optical field emission occurs, emitting electrons of energy higher than the Fermi level.

Figure. Ultra-fast diamond-based photofield emission source. (a) Schematic view of the emission dynamics. (b) Electron emission microscopy (EEM) pattern and (c) energy spectra of the sites 1 (black dots), 2 (red dots) and 3 (green dots) defined in (b), at Vtip = 300 V under laser illumination at Ipeak =

13 GW cm-2. The (X, Y) coordinates indicate the position on the CCD camera in number of pixels. The colors map corresponds to the normalized density of impacts.

Poster Group 2

Background incl. aims
Dielectric photonic cavities can store light efficiently and have proven capable of spatially confining light far below the diffraction limit, making them promising building blocks for integrating photonics and electronics.[1] The small mode volumes realized in these structures reveal the limitations in spatially resolving the optical modes by conventional optical characterization techniques. In comparison, transmission electron microscopy (TEM) can reach sub-nanometer spatial resolutions, making this technique attractive for characterizing nanophotonic structures.[2] In particular, the swift electrons in an electron microscope can couple to the optical modes of nanostructures, leading to electron energy losses.[3] The electron's energy loss can be measured by electron energy loss spectroscopy (EELS) with high spatial resolution when combined with scanning transmission electron microscopy (STEM). This contribution aims to visualize the fundamental mode at 1550 nm wavelength of a topology-optimized photonic cavity with extreme dielectric confinement (EDC).
Methods
Si-based dielectric photonic cavities are designed by an inverse design process using topology optimization and are subsequently fabricated by dry etching techniques in the cleanroom.[1, 4] The dielectric photonic structures are lifted out individually from the substrate using a plasma focused ion beam (PFIB)/scanning electron microscope (SEM) and attached to a TEM-compatible grid. The lifted out cavities are examined using a Thermofisher TEM instrument equipped with a monochromator and an aberration corrector, giving energy and spatial resolutions better than 0.1 eV and 0.2 nm, respectively. EELS spectrum images are acquired at various sample tilt angles, revealing information about the optical modes' evolution in space. The EEL spectra are analyzed using different fitting approaches after a Richardson-Lucy deconvolution of the zero loss peak to produce the electron energy loss maps for the mode of interest at approximately 0.80 eV. EEL spectra are simulated using a quasinormal mode expansion of the electromagnetic Green tensor to facilitate a detailed analysis of the experimental data.[5]
Results
STEM images acquired in the tilt range 0°-90° show the structure of the dielectric photonic cavity used for the present study (Figure, panel a). EEL spectrum images acquired for each tilt angle reveal the excitation of different cavity modes, with the fundamental mode at 0.80 eV being most strongly excited at the highest tilt angle, which is visualized by EELS intensity maps (Figure, panel b) and sum spectra from the bowtie region of the photonic cavity (Figure, panel c). This observation agrees well with the simulations and is caused by the in-plane polarization of this mode tailored by the inverse design process. EELS intensity maps of this mode confirm its tight confinement in the center bridge of

the bowtie of the cavity structure. Besides the fundamental mode, additional optical modes with different energies, polarizations, and spatial confinements are observed. The simulated EEL spectra for different sample positions agree very well with the experimental results.

Conclusions

The results of this contribution showcase the application of EELS in nanoscale imaging of optical modes in dielectric photonic cavities and its potential for gaining deeper insights into light's interaction with matter and confinement at deep sub-wavelength dimensions.

Unveiling Atomic-Scale Defects and Optical Properties within Quasi_2D Perovskite single crystals

Xinjuan Li[1]
[1]University of Cambridge, Cambridge, United Kingdom

Poster Group 2

Perovskite materials have emerged as a transformative force in the field of optoelectronics, particularly in the development of solar cells, light-emitting diodes, and photodetectors. While three-dimensional (3D) perovskite thin films exhibit exceptional optoelectronic properties, their performance can be hampered by issues such as grain boundaries, surface roughness, and stability concerns. In this context, the advent of perovskite 2D single crystals offers a promising avenue to address these challenges and optimize the morphologies of 3D perovskite thin films. Unlike their 3D counterparts, 2D perovskite crystals are characterized by their ligand divided atomically thin-layers nature, a chemical formula of L2An-1BnX3n+1,1 which often leads to large exciton binding energy with enhancing radiative recombination rate and hinder ion migration to improve stability. Understanding the growth dynamics, nucleation processes, and crystallographic orientations of these 2D structures is critical for harnessing their full potential in optoelectronic applications. Despite their potential, the atomic-scale defects influencing their optical behaviour remain poorly understood. While previous studies have individually explored either the structural or optical aspects, a comprehensive correlation between the two is lacking. This study aims to bridge this gap by combining cutting-edge microscopy techniques to unravel the nanoscale origins of optical properties in 2D perovskite single crystals.

Poster Group 1

Background
Topological insulators such as Bi_2Se_3 have interesting transport properties, including undamped transport via topologically-protected surface electronic states[1]. Manipulation of surface plasmons has been previously demonstrated using magnetic dopants, but these cannot be altered after growth. In contrast, the use of organic molecular overlayers such as C_{60} could be advantageous because it is possible to 'gate' the C_{60} interaction through electrical biasing and thereby develop tunable devices[2]. Here, we investigate plasmonic interactions at the interface of an as-deposited thin film sample of Bi_2Se_3/C_{60} using electron energy loss spectroscopy (EELS). We show changes in the characteristic plasmonic behaviour of the Bi_2Se_3 surface in the presence of C_{60}, providing greater understanding of the topological insulator-organic interface.
Methods
Bi_2Se_3 thin films were grown on a c-plane sapphire substrate by molecular beam epitaxy (MBE) with immediate subsequent deposition of C_{60} overlayers to avoid interfacial contamination. Cross-sections were extracted from the thin films by focused ion beam techniques and thinned to an electron transparent thickness of 35 nm for imaging. STEM and EELS were carried out on a mono-chromated instrument at 60 kV (the Nion UltraSTEMTM 100MC 'HERMES' instrument at the UK SuperSTEM facility).
Momentum-resolved EELS was used to map the plasmon dispersion with a convergence and collection semi-angles of 2 mrad and 1.1 mrad respectively. Spectra were collected containing only electrons scattered with specific momentum transfer from the lattice at momenta 0.0±0.3, 0.7±0.3, 1.0±0.3 and 1.4±0.3 1/Å along the ΓM direction of the first Brilliouin zone of Bi_2Se_3 to map the dispersion.
Results
EELS data and plasmon dispersions were obtained across two interfaces Al_2O_3/Bi_2Se_3 and Bi_2Se_3/C_{60} and are presented in figure 1. Panel is a HAADF STEM image of the stack, showing excellent film quality that includes clear crystallinity in the C_{60} layers. EELS spectra of bulk Bi_2Se_3 from the centre of the thin film (annotated blue in figure 1a) revealed two volume plasmons, at 7.2 and 17.3 eV, as well as two Bi core-loss edges between 25-28 eV (not shown). The dispersion of the 17.3 eV volume plasmon is shown in figure 1d and follows a parabolic trendline as expected from literature implying the classical nature of this plasmon.
A surface plasmon from Bi_2Se_3 was observed at 5 eV, localised to the Al_2O_3/Bi_2Se_3 interface, as shown in figure 1b. Its plasmon dispersion was observed to follow either a linear or root trend, plotted in figure 1e, which is similar to that predicted for π-electrons in graphene[3] and suggests the presence of a strongly confining interfacial potential. Comparison with simulations suggests that the nature of this surface plasmon could be a result of Bi_2Se_3 π-electrons confined in 2D to the surface[3]. The

carrier density obtained from a fit of the surface plasmon dispersion concurs with the predicted number of carriers arising from Bi_2Se_3 π-electrons by DFT simulations.
At the other side of the thin film, additional features could be isolated as originating from interaction with C_{60} due to their absence at the Al_2O_3/Bi_2Se_3 interface. Across the Bi_2Se_3/C_{60} interface, the surface plasmon energy was shifted higher in energy to 5.9 eV, shown in figure 1c. This interface contained features from bulk Bi_2Se_3 and C_{60} along with the additional surface plasmon. In bulk C_{60}, three interband transitions were observed, at 3.6, 4.7 and 5.8 eV, consistent with literature[4]; these exhibited very little dispersion with increasing momentum. At the Bi_2Se_3/C_{60} interface, some contribution of these non-dispersive interband transitions remained present. In momentum-resolved EELS spectra of this interface, dispersion of the observed surface plasmon was more difficult to map due to the additional spectral features present, however, the spectra could be decomposed into a linear combination of distinct contributions, revealing the presence of a dispersing feature, localised at the interface and that we identify as the interfacial plasmon.
Unusual plasmon dispersion of the Bi_2Se_3 surface plasmon was observed by momentum-resolved EELS similar to dispersion of 2D π-electrons in graphene. Upon fitting, an agreement in carrier concentration suggests the surface plasmon origin could be from the 2D confinement of Bi_2Se_3 π-electrons to the surface. Through the introduction of organic molecules such as C_{60}, the surface plasmon of Bi_2Se_3 was altered. Further work will characterise the interface between Bi_2Se_3 and other organic molecules such as H_2Pc.

AI Automation for Transmission Electron Microscope Alignment

Loïc Grossetête[1], Cécile Marcelot[3], Christophe Gatel[1], Sylvain Pauchet[2], Martin Hytch[1]
[1]I3EM, CEMES-CNRS, Toulouse, France, [2]LII, Fédération ENAC ISAE-SUPAERO ONERA, Université de Toulouse, Toulouse, France, [3]Plat. Structures et Propriétés, CEMES-CNRS, Toulouse, France

IM-02, Lecture Theater 3, august 27, 2024, 14:00 - 16:00

Background incl. aims
Transmission electron microscopes, like other scientific instruments, are becoming increasingly complicated. Consider the I2TEM in Toulouse, a dedicated TEM for electron holography and in-situ research (HF-3300 C from Hitachi) which has a cold-field emission gun, 9 lenses, 4 apertures, 3 biprisms, 18 pivot points to align, and nearly as many elements in the corrector. The operation involves more than one hundred configurable parameters, but with approximately 10^300 theoretically possible configurations, one wonders if the instrument is used to its full potential. Furthermore, appropriate microscope alignment takes between 20 minutes and an hour each day, depending on the experiment and the microscopist's effectiveness. We propose to explore the use of artificial intelligence to automate the alignment, therefore tackling the complexity and reducing the time taken by the task.
Methods
To address this complexity, we first developed full computer control of the microscope. Hitachi provided access to every single element (including aperture positions, deflector currents and alignment) as well as details about the communication protocol. This enabled us to develop dynamic automation of the microscope to stabilize the specimen and hologram alignment through traditional control and feedback loops in real-time [1]. But to go further, we wondered if the computer could take complete control of the microscope according to the user's needs using artificial intelligence (AI).
Machine Learning, such as Convolutional Neural Networks (CNN) [2] is gradually replacing older forms of automation in various industries. We developed an Application Programming Interface (API) to automatically change the microscope parameters while acquiring images (Figure 1). This allowed us to create training datasets for matching the configuration to the images produced by the microscope. Because most configurations would not create an image on the screen, we first aligned the TEM before randomly shifting the parameters around their respective values. This ensures that we stay close to a configuration producing an image and by knowing the difference between the aligned value and the shift we can form a dataset linking the image to the shift. This allowed us to predict image characteristics based on the microscope configuration, as well as configurations that met specific image characteristics. In parallel, we have developed a realistic simulation of the I2TEM to produce a dataset of virtual experiments [3] which allows us to test models on various scenarios without the associated cost of directly using the microscope.
Results
This allowed us to train models for each step of the alignment process on the I2TEM (aperture alignment, condenser astigmatism correction, pivot points correction, eucentric position correction and focus correction). The only remaining step is to correct the objective lens astigmatism, which is handled by the corrector using a different API than the rest of the microscope. Each step of the correction, while not as good as human performance yet, takes up to twenty seconds at most, reducing the correction time to less than two minutes. Figure 1 depicts the first step in the alignment: aperture correction.

Conclusion
The results show that AI allows for TEM alignment automation, and while precision is still not on par with human levels, the complex task of finding a good alignment is met, allowing for much faster alignment overall. The method could be extended to other microscopes if they can be controlled via an API and the captured images can be processed in real-time. Additionally, the method used could be modified to address issues like object stabilization, or the calibration of new components.
The aim is to integrate the entire solution into an application that allows microscopists to use the automation functions seamlessly while also allowing them to easily generate or strengthen new automation routines. We are also considering developing a reinforcement learning [4] model that can achieve or maintain a set of meta-parameters according to the user's needs. The meta-parameters are the microscope's parameters that users are most interested in, such as beam size, beam position, focus and magnification, rather than the microscope configuration itself. We intend to encode the image in the meta-parameter space using a constrained variational auto-encoder [5], with limitations to ensure that they either coincide with a previously identified parameter, such as the focus or are at least intelligible to humans. The user can then manipulate the encoded image, and the model will change the configuration accordingly for the microscope to produce an image meeting the user's needs.

Background incl. aims
Minerals in polycrystalline rocks on Earth have formed over durations spanning solar system formation up to our present geosphere and cryosphere. The conditions of rock and ice formation are recorded in the relative crystallographic orientations, sizes, shapes, defects, and distributions of their crystals or grains that, together with chemistry, chronicle planetary dynamics over timescales of seconds to billions of years. The three-dimensional (3D) mineral architectures are therefore fundamental to understanding celestial bodies and the solid earth, while providing crucial context within which we explore the origins of life on our planet and the interactions between its cryosphere, biosphere, and atmosphere. Observations, however, have long been restricted by 2D analyses and the destructive sample preparation required for 2D analytical techniques, as well as an inability to directly observe textural or mineralogical evolution. Maintaining 3D and time-dependent contexts of microstructures is vital to fully understand the dynamic formation and efficient exploitation of earth materials, both as recorders of earth processes and to support environmentally sustainable innovation.

Methods
Minerals are defined by both composition and crystallographic structure. X-ray absorption contrast tomography (ACT) is ideally suited to derive information on porosity and to characterize boundaries between higher- and lower-density phases. However, many minerals have similar X-ray attenuation, and some mineral systems have little or no variation in mineral type (e.g., ice), leading to minimal image contrast. Complimentary to ACT, lab-based diffraction contrast tomography (DCT) produces 3D maps of the grain morphologies and crystallographic orientations for the different constituent phases. ACT and DCT, both non-destructive in nature, can be performed on the same micro-CT system, and combining the two can provide earth and planetary scientists with unprecedented new knowledge – in 3D – while keeping the often rare or precious samples intact.

Results
We present different examples of combined ACT and DCT studies on earth and space materials to illustrate some of the current imaging capabilities. Results from an olivine chondrule inside a carbonaceous chondrite, a type of meteorite that can host organic compounds thought to contain the ingredients for life, reveal previously unobserved relationships between grain shape, size, composition, and chemical zoning that inform models of melting during short heating events in the proto-planetary disc. Ice is also explored with the goal of characterizing the 3D microstructural and porosity evolution of glacial ice, which contextualizes chemical and isotopic measurements used to extract climate records from ice cores.

Conclusion
Together, quantitative ACT and DCT can be combined to create 3D petrography: a non-destructive method of identifying and characterizing multiphase materials (rocks, alloys, etc.) without a priori knowledge. As a step towards that goal, this work is developing the utilization of joint ACT and DCT in addressing different challenges in geoscience.

Effect of electron microscopy sample preparation protocol on the preservation of liposomes in cell culture

Associate Professor Paul Kempen[1], Nikoline Lykke Faurschou[1], Jonas Rosager Henriksen[2], Andrew urquhart[2]
[1]DTU Nanolab, Technical University of Denmark, Kgs. Lyngby, Denmark, [2]DTU Health Tech, Technical University of Denmark, Kgs. Lyngby, Denmark

Poster Group 1

Background: Liposomes are powerful vehicles for the delivery of a broad range of drugs and other compounds to specific locations within the human body. This has made them a versatile, and often used, nanoformulation within the pharmaceutical industry. Accurately localizing these liposomes within cells and tissue is vital to understanding the uptake mechanisms and ultimately the efficacy of the liposomes. Electron microscopy is the ideal tool to localize liposomes within cells and tissue, however there are numerous challenges that must be addressed. 1st, Liposomes exhibit a pronounced sensitivity to their surroundings, and the harsh conditions often employed to prepare cells for electron microscopy may result in the dissolution of the liposome of interest. 2nd, Liposomes are composed of carbonaceous material much like the surrounding cellular matrix, making it difficult to distinguish. In this work we aimed to characterize the effect that sample preparation has on the preservation of liposomes within a cell culture sample.

Methods: 100 million CT26 colon carcinoma cells were incubated unloaded stealth liposomes for 3 hours to allow for uptake. The cells were then divided into 4 groups for further processing. Group 1 was processed using a standard chemical fixation, staining and dehydration protocol. The cells were placed in 4% paraformaldehyde, 2% glutaraldehyde in 0.1 M Na Cacodylate Buffer for 1 hour at room temperature. The cells were then pelleted, suspended in 10% gelatin, and stained with 1% osmium tetroxide in water at 4 C for 1 hour. The cells were then stained with 1% uranyl acetate in water overnight before being progressively dehydrated in ethanol and propylene oxide. After dehydration, the cells were embedded in EMBED 812 epoxy resin.

Groups 2-4 were all high pressure frozen using a Leica EM-ICE and underwent 3 different freeze substitution protocols using the Leica AFS2. Group 2 underwent a standard freeze substitution protocol in a 1% osmium tetroxide in acetone solution over the course of 3 days. This was followed by room temperature staining in 1% uranyl acetate for 1 hour before embedding in EMBED 812 Epoxy resin. Group 3 underwent a quick freeze substitution protocol over the course of 4 hours in a 1% Osmium tetroxide, 1% uranyl acetate in acetone solution before being embedded in EMBED 812 Epoxy resin. Group 4 underwent freeze substitution with a 1% uranyl acetate solution and low temperature embedding in Lowicryl HM20 at -50 C.

Ultrathin sections from each sample were prepared and imaged using a Tecnai T12 at DTU Nanolab.

Results: All 4 samples were successfully prepared into 100 nm sections for imaging. Liposomal structures were observed for all 4 samples with the samples undergoing freeze substitution exhibiting qualitatively the best-preserved liposomes. Imaging is ongoing to obtain enough data to try and definitively state which freeze substitution method will result in the best preservation.

Conclusions: Freeze substitution appears to provide better preservation of liposomes in cell culture. Additional characterization is ongoing and necessary to determine which freeze substitution method provides the best results for preserving liposomes. Even with improved preservation of the liposomes, it is still very often difficult to ensure that the object being imaged is a liposome and not some other vesicular body within the cell.

Thermal vibrations in inverse dynamical electron scattering

Ziria Herdegen[1], Dr. Benedikt Diederichs[2], Prof. Dr. Knut Müller-Caspary[1]
[1]Depart. Chemistry, Ludwig-Maximilians-Universität München, Munich, Germany, [2]Institute of Biological and Medical Imaging, Helmholtz Zentrum München, Neuherberg, Germany

IM-03 (4), Plenary, august 29, 2024, 14:00 - 15:00

Background incl. aims
Inverse multislice (IM) schemes have enabled structure retrieval in the presence of dynamical scattering, extending the applicability of electron ptychography assuming single scattering. This allows structure determination for thick specimens with super-resolution, to date only limited by the thermal atomic vibrations [1]. These thermal vibrations cause thermal diffuse scattering (TDS) which becomes partly dominant at elevated specimen thickness. Since the TDS governs the darkfield in diffraction patterns (DP) which contains crucial information about the atomic structure and chemical composition, its correct consideration in IM is a prerequisite for accurate specimen retrieval. Because various IM approaches evolved, differing by their implicit or explicit consideration of TDS, studying the impact on specimen structure reconstructions suggests itself. For this purpose different slicing concepts are studied as to the effect of TDS on the reconstruction and on the capabilities to yield atomic types and thermal mean square displacements, thus local temperature, quantitatively [2].
Methods
The multislice approach calculates momentum-resolved STEM data by propagating an electron wave through a set of slice transmission functions (STF), mathematically performed by iteratively multiplying the wave function with one STF and then propagating it to the next slice, e.g., formulated as an artificial neural network [3]. The inverse model then applies a loss function to the calculated DPs and those of the reference data set and minimizes the loss by optimizing the STF to reconstruct the specimen structure. To this end the home-built, gradient-based TorchSlice program utilizing the PyTorch framework was used [4]. We discuss the influence of TDS on three different optimization models performing reconstructions of simulated momentum-resolved STEM data for an SrTiO3 crystal as the ground truth. To incorporate TDS in the simulation we used the frozen phonon (FP) model which incoherently averages multiple diffraction patterns calculated from different phonon ensembles. First we optimize one slice transmission function pixel-wise which is reused to describe the interaction in each slice, precluding any ensemble averages thus being incapable to incorporate TDS correctly. Second, 50 slices are optimized pixel-wise and individually, providing the opportunity of incorporating TDS by allowing displacements of atomic potential maxima from their equilibrium position from slice to slice [5]. Third, a parameterized approach [4] is used which constrains the STF to be a sum of atomic potential functions, and a set of specimen parameters characterizing the STF is optimized every iteration. This model incorporates a full FP simulation ensuring physically correct inclusion of TDS within the FP approximation using the Einstein model.
Results
Optimizing wrapped slices pixel-wise the STF's phase grating (PG) shows stripe-like artefacts superimposed to the atomic structure (Fig. 1a), not being physically reasonable but reproducing the diffuse intensity in the corresponding DPs (Fig. 1b). It is shown that the strength of the artefacts and the cutoff angle up to which the loss is calculated are directly correlated. Restricting the solid angle such that TDS is excluded from the loss calculation, or using different regularization methods was found to successfully suppress the artefacts in the PG, however, suppressing the diffuse intensity in the DPs, too (Fig. 2). Optimizing each STF individually, the diffuse intensity was reconstructed very

accurately (Fig. 3a). The phase maxima at the atomic sites are displaced from their equilibrium position, following a slightly narrowed Gaussian function (Fig. 3b) having, however, a standard deviation of only 28% and 12% of the theoretical values for the Sr and the O columns, respectively. Still showing artefacts in the PG, the diffuse scattering within this model is produced via both, physically reasonable but too small thermal displacements and artificial phase noise to achieve numerical consistency with the ground truth. The parameterized optimization approach achieved the smallest DP error compared to the other optimization methods, and could retrieve the atomic phases very accurately which has been observed case-dependent for pixel-wise approaches. Also the mean thermal displacement could be received with an accuracy of at least 89%. The accuracy of both parameters is shown to increase with increasing number of phonon ensembles underlining the importance of incorporating TDS correctly. A final simulation study examining the sensitivity of the loss to the atom type and the mean thermal displacements clarifies the observed accuracy of these parameters and is used to outline the capability of IM to map the local chemistry by including TDS-affected Z-contrast in the inverse FP multislice model.

Conclusions

Different IM slice optimization concepts show a varying accuracy of reconstructed parameters among the models i.e. maximum atomic phases and mean thermal displacement and, when explicitly precluding thermal displacements from the model, the occurrence of physical unreasonable phase artefacts. We show various ways for suppressing these artefacts to achieve a smooth PG. In particular, we also demonstrate that for retrieving quantitative information on temperature and chemical composition, including TDS in IM within the FP approach is essential.

Poster Group 1

Background:

Solid-state lithium-ion batteries (ASSBs) hold great promise for delivering higher energy density and safer performance than conventional lithium-ion batteries. Lithium metal is a highly studied choice for the anode due to its high energy potential. However, its use in ASSBs is hindered by the issue of dendrite formation and growth. Conversely, silicon offers a capacity that is tenfold greater than that of graphite, presenting itself as a cost-effective and promising substitute for lithium metal.[1] Unfortunately, the potential of Si as an active anode material hasn't been fully tapped in ASSBs. Recently, solid electrolyte (SE) free Si anodes have been found to have improved performance compared to their SE-containing counterparts;[2] however, there is still considerable room for improvement. One of the ways to enhance these electrodes is to have detailed insights into the microstructure concerning various electrochemical treatments.

Methods:

Si particles (mixed with 0.5 wt % of polyvinylidene fluoride binder) are first pressed to form a pellet. This electrode is cycled against an In/InLi counter electrode using LPSCl as an SE. We utilize cryo aberration-corrected scanning transmission electron microscopy (AC-STEM) to characterize the microstructure of SE-free Si anodes after the 1st cycle. Since ASSB samples are air and moisture-sensitive, the cells are dissembled in an Ar-filled glove box, and the Si electrodes are retrieved. The sample is transferred from the glove box to a plasma FIB (PFIB) in an argon atmosphere. It is prepared at approximately -190 °C using an Ar-ion beam from the Helios 5 Hydra CX PFIB to thin and polish the specimen. Afterward, the samples are moved back into the argon atmosphere of the glovebox. The sample is then mounted onto a double-tilt Atmos Defend Holder from Melbuild within the glove box. This holder is capable of transporting the sample from the glovebox to the S/TEM under an argon atmosphere, reaching temperatures of about -170 °C during measurements. At the S/TEM, the samples are measured at roughly -170 °C employing multiple techniques, such as HR-S/TEM, energy dispersive X-rays spectroscopy (EDXS), electron energy-loss spectroscopy (EELS), four-dimensional STEM nano-beam diffraction and precession electron diffraction (4D STEM NBD/PED), etc., under cryogenic conditions.

Results:

Figure 1(a) is a STEM high-angle annular dark field (HAADF) image of pristine Si particles. The cloudy contrast on the edges of the particles shows SiOx particles (confirmed vis EDXS, not shown here).

Figure 1(b) is a cryo-STEM HAADF image of the bulk electrode after the 1st cycle. A massive microstructure transformation is observed with Si particles showing an amorphous structure (confirmed by PED, not shown here). Figure 1(c) is a cryo-STEM HAADF image of the region marked in Figure 1(b), showing a unique texture of the Si amorphous structure, commonly found after 1st cycling. A cryo-STEM HAADF tomography has also been performed in this region, showing a sheet-like structure (not shown here). Figure 2 shows Li and Si cryo-STEM EELS maps of a selected region after the 1st cycle. SiOx consumes a considerable amount of irreversible Li at the surface of the Si particles.

Conclusion:

Though the detailed analysis of the samples after subsequent electrochemical treatments is still underway, the drastic evolution of the Si electrode structure after 1st cycle is critical to finding the lithiation behavior of novel SE-free Si electrodes for ASSBs.

Poster Group 2

Background
Stacking and intercalation are crucial for modifying and engineering the properties of two-dimensional (2D) van der Waals (vdW) materials [1, 2]. Stacking, as a control parameter, involves varying the lateral registry or twist angle between adjacent layers to realize, for example, exotic electronic phases in a moiré superlattice [3]. Intercalation refers to the insertion of atoms or molecules into the vdW gap between two layers [4]. This can be achieved by synthetic routes or electrochemistry, potentially leading to emergent superconducting or magnetic states. While the individual potentials of stacking and intercalation have yet to be fully explored, a natural progression is to investigate the synergistic combinations of these two tuning parameters. Understanding the interplay between stacking and self-intercalation is therefore important. However, current knowledge of the interplay between stacking polytypes and intercalation is often based on macroscopically averaged probes, which fail to accurately identify the exact atomic position and chemical state of the intercalants in real space. Atomic-scale observation of the cross section of vdW materials is essential for further clarification.

Methods
In this work, utilizing atomic-resolution electron energy-loss spectroscopy (EELS) in a scanning transmission electron microscope, we systematically investigate the atomic and electronic structures and local chemistry in epitaxial transition-metal dichalcogenide Nb1+xSe2 films grown by "hybrid" pulsed laser deposition and Nb1+xSe2 crystals grown via chemical vapor transport techniques. Density functional theory calculations were performed to evaluate the roles of thermodynamics and kinetics in these observations.

Results
Using high spatial resolution scanning transmission electron microscopy (STEM), we observe that thin films with an average x ~ 0.29 comprise a nanoscale phase mixture of NbSe2 layers stacked with both 180° and 0° in-plane rotations. The 180°-stacked layers exhibit significant self-intercalation with Nb at the octahedral interstitial sites, likely reaching several tens of percent occupancy, whereas the 0°-stacked layers contain few detectable intercalants at their octahedral interstitial sites. Our findings extend beyond merely imaging intercalants or different stacking structures to establishing a correlative relationship between the two. Density functional theory (DFT) confirms that the energetically favored stacking orientation transitions from 0° to 180° when the self-intercalation exceeds a threshold of approximately x ~ 0.25. However, achieving this threshold appears to necessitate kinetic pathways distinct from those in the thin films. Efforts to replicate these

observations with Nb1+xSe2 crystals grown via chemical vapor transport (CVT) yield a homogeneous phase of intercalated, 0°-stacked layers with an average x of at most ~0.20. The presence of Nb intercalants reduces the size of the Fermi hole pockets and suppresses superconductivity in NbSe2, and these altered properties may provide a foundation for fabricating junctions and nanostructures with more precise control over stacking and self-intercalation.

Conclusion
Using STEM and EELS, we have directly visualized a stacking-selective self-intercalation phenomenon in epitaxial Nb1+xSe2 films. Our results offer not only renewed mechanistic insights into stacking and intercalation, but also open up prospects for engineering the functionality of TMDCs via stacking-selective self-intercalation. Atomic Imaging of Lattice and Electron Ordering in Tensile-Strained LaCoO3 Films

Dr. Hongguang Wang[1], Dr. Bonan Zhu[2], Prof. David O. Scanlon[2], Prof. Peter A. van Aken[1]
[1]Max Planck Institute for Solid State Research, Heisenbergstr. 1, 70569, Stuttgart, Germany,
[2]Department of Chemistry, University College London, London WC1H 0AJ, United Kingdom

IM-05 (1), Lecture Theater 3, august 26, 2024, 10:30 - 12:30

Background
Strong multiple interactions between degrees of freedom (spin, orbital, charge, and lattice) in complex oxides give rise to rich electronic phase diagrams and thus to intriguing macroscopic functionalities, such as ferromagnetism, superconductivity, and multiferroicity [1, 2]. A famous example is LaCoO3 (LCO), in which unexpected ferromagnetism occurs in tensile-strained epitaxial LCO thin films, in contrast to paramagnetism in bulk LCO [3]. However, the underlying mechanism of emergent ferromagnetism and spin-state transitions remains controversial, with the tensile strain-induced ferroelastic deformation and oxygen vacancy ordering are known as two possible driving forces. Previous density functional theory (DFT) calculations on the ferromagnetism of tensile-strained LCO have shown that the tensile strain-induced changes in lattice constants are insufficient to stabilize the long-range ferromagnetic order [4]. Suppression of CoO6 octahedral rotations should be considered to modify the eg orbital order configuration and induce a spin-state transition to a ferromagnetic state. To date, no direct experimental evidence has been reported to support this theoretical prediction.

Methods
In this work, we systematically investigate the atomic and electronic structures, and their correlation with the spin-state transition and the ferromagnetic insulating state of high-quality LCO epitaxial films grown by pulsed laser deposition.

Results
Scanning transmission electron microscopy (STEM) and electron energy-loss spectroscopy (EELS) were used to examine the 6 uc and 25 uc thick LCO films for comparison. High-angle annular dark-field STEM results support the appearance of dark stripes only in the 25-uc thick LCO film, showing well-ordered dark stripes with a period of ~ 3 uc in the interior part of the film (Fig. 1). EELS maps of the interface region show a sharp interface between LCO and STO without the formation of any misfit dislocations. Energy-loss near-edge structure analysis was performed to investigate the electronic structures of the LCO films at the atomic scale. In the dark stripes, the pre-peak of the O-K edge almost disappears, and the intensity of the O-K edge peaks is significantly reduced. Meanwhile, the peak positions of the Co-L2,3 edges shift to lower energies, and the Co-L3/L2 ratio is larger in the dark stripes than in the bright regions. These features fingerprint a reduction of the Co valence state in dark stripes due to the formation of oxygen vacancies. Quantitative analysis of annular bright-field STEM results reveals previously unreported long-range suppression of CoO6 octahedral rotations throughout 25-uc thick LCO epitaxial films, inducing an increase in the angle βCo-O-Co from bulk 163.5o to 172.5o. DFT calculations further unravel the underlying physical mechanism of the spin-state transition to induce an emergent and robust ferromagnetic insulating state.

Conclusion

This work provides new insights into how the interplay between degrees of freedom drives the ferromagnetic insulating state in tensile-strained ferroelastic LCO epitaxial films [5].

Poster Group 2

Electrochemical CO2 reduction reaction (eCO2RR) is one of the most promising and sustainable approaches to CO2 conversion to reduce atmospheric CO2 concentrations and mitigate the impacts of climate change [1]. For this purpose, the use of metallic nanoparticles (NPs) as electrocatalysis is on the rise, with Cu/Ag bimetallic interfaces being particularly popular for enhancing the eCO2RR towards CO and C2 products [2]. However, the electrochemical performance and product distribution of Cu@Ag core-shell configurations can change drastically under reaction conditions, particularly during the first few minutes of the reaction. In this study, our goal is to reveal the underlying structural changes these NPs experience at the critical first steps of the eCO2RR to understand their structure-properties relationship.

In this study, we utilized EDS analysis and high-resolution electron tomography to characterize the evolution of the Cu@Ag core-shell NP structure. The electrochemical measurements were performed in a homemade two-compartment, three-electrode cell, where the TEM grid was used as the working electrode, allowing for direct observation of the NPs before and immediately after the crucial first minutes of the reaction.

The Cu@Ag core-shell NPs used were found to be oblate and not homogeneously covered by Ag, with atomic-sized pinholes that expose the Cu core. Based on 3D characterization of various nanostructures found after current application, we hypothesized a transformation pathway. We observed an enlargement of these pinholes, most likely caused by the catalytic activity of the Ag shell, resulting in Cu leaching and, subsequently, a complete structural transformation of the NPs. Remarkably, the transformed Cu-Ag core-shell structure almost doubles the production of CO, presumably due to the combined effect of the different structures at various stages of transformation, as these transformations do not occur simultaneously [3].

Through the combined use of electrochemistry and advanced electron microscopy techniques, we have gained a better understanding of the relationship between the structure and electrochemical properties of Cu@Ag core-shell NPs, and how this affects their electrocatalytic performance. This research enhances our knowledge of Cu@Ag core-shell configurations and provides insights into other largely immiscible metal combinations. The study emphasizes the significance of the crystallinity of the central metal nanoparticle in deciding the formation of a complete and uniform second metal shell, which will be the key parameter towards nanoparticle stability.

IM-10 (3), Lecture Theater 5, august 30, 2024, 14:00 - 16:00

Background
Spatially correlated multimodal microscopy allows an experimentalist to gain a holistic understanding of their sample by compiling complementary information from separate imaging modalities. This however relies on the robust registration of images between techniques- a difficult task with differences in the contrast mechanism, resolution and presence of artefacts all posing unique challenges. Furthermore, these problems are exacerbated by state-of-the-art instruments which produce high dimensional datasets (often upwards of hundreds of gigabytes), making the nuanced evaluation of scientific hypotheses challenging. Herein we present a general approach to coregister and interpret spatially correlated scanning electron diffraction (SED) and hyperspectral photoluminescence (PL) measurements performed on hybrid perovskites, an emerging class of semiconductor used as active layers in solar cells, LEDs and radiation detectors. SED, a variant of 4D-STEM, allows for information on crystallographic phase, orientation, and defects to be uncovered, whereas hyperspectral PL provides information on optoelectronic characteristics and performance. Given the fact that hybrid perovskites show striking spatial heterogeneity in both structure and performance, the spatial correlation of crystallographic information and PL is motivated by the prospect of unequivocally linking structure-property relationships in these materials.

Methods and Results
To find common areas between separate microscopes, gold fiducial markers are synthesized and deposited onto a thin film similarly to the work of Jones, Osherov and Alsari et al. [1]. Due to the resolution differences between SED (typical probe size ~5 nm) and hyperspectral PL (resolution diffraction limited to ~100s of nm) we record multiple contiguous SED scans before they are stitched together during post processing. To stitch the SED scans together virtual bright or dark field images are formed which act as a proxy for the 4D dataset. A keypoint detection and matching algorithm is then applied between the images; classical choices for this include the scale invariant feature transform (SIFT) or binary robust invariant scalable keypoints (BRISK) algorithms, commonly implemented using OpenCV [2]. Although these are undoubtably valuable tools, it has been empirically found that pretrained neural network-based approaches, such as Key-Net-AdaLAM implemented using Kornia, provide improved mappings [3]. Once the keypoints are detected, the random sample consensus algorithm (RANSAC), or variants thereof, is used to define an affine transform which stitches one image onto the other while capturing differences in rotation, shear, and translation [2,3]. To make these tools accessible a Python based GUI has been developed.

The registration of hyperspectral PL and stitched SED datasets is now considered. Due to the differences in pixel size between the two techniques the hyperspectral PL is upsampled via linear

interpolation to match the SED pixel size. To coregister the resultant datasets several options are available. 1) An image transform can be defined by finding where the normalized cross correlation is maximal between the two images. Due to the differences in contrast mechanism a mask can be applied such that only the Au fiducial marker is considered during this process. 2) The Python package AntsPy, primarily built for the registration of medical images can be utilized [4]. AntsPy uses 'multi-resolution gradient descent' and metrics such as cross correlation or mutual information to define the mapping. Importantly, as all image transforms are known we can then calculate where each 'pixel' from a SED scan corresponds to in the hyperspectral PL data.

Once the two datasets are coregistered the interpretation of any interrelationships between them poses a further separate challenge. Merely considering the SED data the scale of the problem becomes apparent— if 50 SED scans are acquired, each of which contains 512 x 512 diffraction patterns (typical during one experimental session), this amounts to a total of 13,107,200 individual patterns. To rapidly reduce data dimensionality, we have adapted the simple linear iterative clustering (SLIC) algorithm prevalent in the field of remote sensing and applied this to the SED data [5]. This approach allows us to reduce hundreds of thousands of individual diffraction patterns to ~100 single crystal patterns obtained by averaging diffraction patterns over individual grains of the polycrystalline halide perovskite film. SLIC can be thought of as a variant to K-means clustering and provides a general, intuitive, robust, and computationally inexpensive methodology to cluster SED data. Key principles underlying the algorithm are to remove points on your detector which have a low dynamic range or variance prior to clustering such that burdensome computation is only performed on a reduced subsection of the data. Additionally, cluster centroids only consider data in their close vicinity meaning unnecessary computation is further reduced. The spatial and channel Euclidean distances are combined into a single distance measure, with a weighting value being used to define the importance between them. This encodes intuition that 'pixels' close together likely belong to the same cluster. Finally, clusters which are highly correlated are combined before being used to calculate the mean diffraction patterns from the original data. Remarkably this approach proves exceptionally computationally efficient with typical compute times taking approximately a minute using a standard desktop machine (32Gb RAM, 11th Gen Intel(R) Core(TM) i5-11400 CPU). An automated indexing procedure of the clustered SED patterns can then be employed to obtain phase and orientation maps at low computational cost.

Conclusion

The toolkit introduced herein can elucidate structure-property relationships in state-of-the-art optoelectronic materials and provides a robust framework to perform correlative microscopy in related fields.

Molecular Microscopy by Thermo-Fisher-Scientific: FTIR-Imaging of a Tintoretto-Fresco and Raman-Imaging of the Strain-Distribution in Semiconductors

Dr. Maximilian Ries[1,2], Barbara Bravo[1], Eleonora Balliana[3], Fabian Heisinger[2], Imad Limame[2]
[1]Thermo Fisher Scientific, , Germany/Italy, [2]Technische Universität Berlin, , Germany, [3]Ca' Foscari University of Venice, , Italy

Poster Group 1

Background incl. aims
Molecular spectroscopy tools are employed to investigate the vibrational properties of a wide variety of samples. The chemical composition and physical properties of materials are stored in the molecular bonds and can be read from the vibrational spectrum. Fourier transform infrared (FTIR) spectroscopy has long been utilized to investigate materials present in artwork. This study of Tintoretto's work at the Scuola Grande di San Rocco (Venice, Italy) aims to understand the composition of its pictorial layers. The second part of this talk is dedicated to the influence of a buried stressor on the strain-dependent site control of InGaAs quantum dots. Raman spectroscopy is highly sensitive to subtle changes in the crystal lattice structure. Under strain, its molecular bonds shift slightly, altering the vibrational frequencies of the lattice. The resulting shifts in Raman peaks contain information about the amount and type of strain present.

Methods
The cross-section of the Tintoretto painting sample was embedded in resin to assess the five layers. The sample was analyzed in several regions using a Thermo Scientific Nicolet RaptIR FTIR microscope in corroboration with scanning electron microscopy with energy-dispersive x-ray spectroscopy. All mappings were performed in ATR mode with a Germanium micro-ATR. The quantum dot sample was analyzed with a Thermo Fisher Scientific DXR3xi Raman imaging microscope and a 532 nm laser. The results are correlated with atomic force microscopy assessments of the sample height profile.

Results
The cross-section of the painting revealed the existence of a lipidic preparation layer and finishing layer. The preparation layer contains traces of proteins, pointing to the use of animal glue. The sandwiched layers contain different pigments and filler materials. The study confirmed assumptions and knowledge on the use of materials and techniques in the 16th century. In contrast, semiconductor nanostructures are state-of-the-art technology of the 21st century. InGaAs quantum dots grow at sites exhibiting a considerably larger strain than their surrounding. Tuning of the buried stressor size results in the precise control of the distribution, emission, and density of the quantum dots. The overlay of Raman strain mappings with atomic force microscopy height profiles allows for a deeper understanding of the physical properties. In combination with computational simulations, the results forecast the design of new devices with distinct emission patterns.

Conclusion
All materials that were expected to be found in the paint sample were successfully identified using the Nicolet RaptIR FTIR Microscope, combined with the multicomponent search function of OMNIC Paradigm Software. Besides the chemical composition, Raman spectroscopy is powerful in assessing the physical properties such as the strain in semiconductors. The power and beauty of these

spectroscopic techniques are pivotal in the creation, conservation, consolidation, and understanding of materials across all scientific fields.

Assessing the Precision of Local Temperature Measurement by Plasmon Energy in In-Situ Heating Electron Microscopy

Yi-Chieh Yang[1], Luca Serafini[2], Nicolas Gauquelin[2], Johan Verbeeck[2], Joerg Jinschek[1]
[1]Nanolab, Technical University of Denmark (DTU) , Kongens Lyngby, Denmark, [2]EMAT, University of Antwerp, Antwerp, Belgium

IM-05 (2), Lecture Theater 3, august 26, 2024, 14:00 - 16:00

Background incl. aims
In-situ transmission electron microscopy (TEM) has become increasingly important in the characterization of microstructures in functional and structural materials when real-time observation under application conditions is required to reveal underlying structure-property relationships [1]. With the advancement of microelectromechanical systems (MEMS) technology for the application of stimuli on the materials, the high sample stability and precise control of the stimuli, especially in elevating temperature with a local accuracy within 4% [2], enable atomic-scale resolution in such in situ TEM experiments. However, uncertainty remains regarding the exact temperature profile across a TEM sample itself, which limits the interpretation of observed structural phenomena in in-situ TEM heating experiments.
Methods
Here, we exploited plasmon energy expansion thermometry (PEET), detecting temperature-dependence of the bulk plasmon peak in an energy electron loss spectrum (EELS) [3] and testing its validity and accuracy using tungsten (W). The reasons to assign W as the model material come from the high melting temperature which is above 3000 °C and the sharp plasmon resonance in EELS, as shown in figure(a). These advantages benefit PEET through improved precise EELS peak determination over a wide implementation temperature range.
For sample preparation, W lamellas with varying sample thickness of 30 to 70 nm were prepared using a ThermoFischer Hydra Plasma FIB (Xe plasma at 30 kV) and were mounted on a DENS Wildfire heating chip [2] using W-gas assisted deposition. Two types of FIB-cut W lamellas were prepared: One is placed at the center of the spiral heater where we expect a homogeneous temperature distribution, as shown in figure(b). The other one is placed at an off-central position where we expect a thermal gradient [4].
Ex-situ temperature measurements were conducted using Raman spectroscopy with a 532 nm laser of beam size less than 1 µm. Si particles of 45 nm diameter were drop-casted on the heating chips. Exploiting the temperature dependence of the bonding vibration, the local temperature can be obtained by the Raman frequency of the Si-Si bond, which shifts with temperature at approximately 0.0232 cm-1 per °C.
For the in-situ heating experiments, both a ThermoFischer Themis (at EMAT) and Spectra (at DTU) S/TEM equipped with X-FEG mono have been operated at an accelerating voltage of 300 kV. For our PEET experiments, the monochromator was excited to achieve an energy resolution of 0.12eV. The effect of the STEM convergence semi-angle (3.6 to 18 mrad) as well as of the EELS collection semi-angle (6 to 70 mrad) was investigated in the PEET mapping experiments. The bulk plasmon peak was collected using Quantum 966 Gatan Image Filter with a dispersion of 0.01 eV per pixel and dwell time of 0.1 second per pixel.
Results
PEET mapping on the W lamella at the center of the spiral heater (figure(a)) reveals a temperature-dependent plasmon energy shift of 1.8 eV as the temperature progressively increases from room

temperature (figure(c)) to 1100 °C (figure(d)). Correspondingly, the standard deviation when measuring at multiple positions also considerably increases, from 0.027 eV at room temperature (figure(c)) to 0.471 eV at 1100 °C (figure(d)), respectively. To understand this variation in plasmon peak energy, we attempt to correlate the PEET mapping and the local estimated sample thickness (using the log-ratio method in EELS) and find a noticeable correlation as one factor responsible for this large deviation.
Leveraging these findings as calibration data, we further extended the application of PEET for detecting the temperature difference over space. The profound temperature gradient of the off-central W lamella was predicted by COMSOL simulation and verified by ex-situ Raman measurements. The results show that the thermal gradient can reach approximately 106 °C /m (from 667 to 772 °C within a 10 µm length) at a set temperature of 1000 °C. Interestingly, on the PEET map of the off-central W lamella at the same set temperature of 1000 °C, the plasmon energy shifts to higher values as the position moves farther away from the spiral center. By using the calibration data for correlating the plasmon energy to the local temperature, the data from the PEET map closely matched the thermal gradient observed in the ex-situ Raman measurement and simulation results.
Conclusion
Our study demonstrates that PEET is capable of obtaining quantitative temperature measurement results with the consideration of the sample thickness. Moreover, it effectively identifies pronounced thermal gradients within the sample. The improvement of the temperature determination in PEET provides a more reliable analysis of structure-properties correlation under various thermal conditions.

Enabling discovery by in-cell structural biology

Dr Julia Mahamid[1]
[1]European Molecular Biology Laboratory, Heidelberg, Germany

IM-11 (2), Lecture Theater 5, august 30, 2024, 10:30 - 12:30

Most structural biology focuses on the structure and function of individual macromolecular complexes, but falls short of revealing how they come together to give rise to cellular functions. Here, cryo-electron tomography (cryo-ET) provides a unique opportunity for obtaining structural information across a wide range of spatial scales - from intact cells, 3D cultures, tissues and model organizms frozen in their close-to-native state, to individual macromolecular assemblies embedded in their native functional environments. We develop and employ advanced sample preparation techniques for in-cell cryo-ET, including cryo-focused ion beam thinning guided by 3D correlative fluorescence microscopy. Preparations of such site-specific ‘electron-transparent windows’ in appropriate cellular model systems visualizes molecular structures directly from three-dimensional stills of intact cells and can reveal their molecular sociology. Using the genome-reduced human pathogen Mycoplasma pneumoniae as a minimal cell model, we further demonstrated the synergistic application of whole-cell crosslinking mass spectrometry and cryo-ET to determine an in-cell integrative structural model of actively transcribing RNA polymerases coupled to translating ribosomes. Recent computational breakthroughs now allow resolving these molecular machines to near-atomic resolution directly inside the cell, reveal small molecule antibiotics bound to their active site in ribosomes within the intact pathogen, and provide snapshots of their structural dynamics along reaction cycles. We will discuss novel technologies that extend these applications and depth of information to mammalian cells and tissues. These cutting-edge methodologies unlock an enormous potential for system-spanning discovery enabled by label-free in-cell structural biology.

PS-03 (2), Lecture Theater 2, august 30, 2024, 10:30 - 12:30

Background incl. aims
Hybrid organic-inorganic metal halide perovskites have shown great potential as semiconductors for new optoelectronic devices, such as photovoltaics, light-emitting diodes, and X-ray detectors. Their outstanding optoelectronic properties, including a tunable bandgap, high charge carrier mobility, high photoluminescence quantum yield, and low recombination rate of photogenerated carriers, have contributed to their rapid development.(Dey et al. 2021) The structure of metal halide perovskites (MHP) is described by the chemical formula ABX3, where A is a monovalent organic cation (e.g. formamidinium (FA+) [CH(NH2)2+] or methylammonium (MA+) [CH3NH3+]) or a metal cation (e.g. Cs+), B is a divalent metal cation (typically Pb2+or Sn2+), and X is a halide anion (X = Cl-, Br-, I-). The perovskite structure consists of [BX6]4-octahedra that are connected through the corner halides. The octahedral network structure is closely linked with the polymorphic nature of MHPs, which is of great importance since phase instability is still one of the major roadblocks for long-term applications of MHPs. Only the “black” phase demonstrates photoactive properties, which dramatically decrease once the MHPs convert to the “yellow” phase. From the high-symmetry cubic phase, the transition to the lower symmetry phases can be described by rotation or shearing of the octahedra. It is crucial to understand the role of the octahedral network to unravel the structure-property connection and correlate it to transformations during degradation. Transmission electron microscopy (TEM) is an excellent method for investigating the local structure of nanocrystals (NCs), even down to the atomic level. Nevertheless, when applied to MHPs, their sensitivity to the electron beam is highly challenging. Irradiation with the electron beam easily causes degradation of the MHP NCs with PbX2 and Pb as resulting products.
Methods
In this study we utilize four dimensional scanning transmission electron microscopy (4D-STEM) to obtain phase contrast image reconstructions to investigate the local structure of colloidal FAPbBr3 NCs, which were synthesized following a hot injection method. Phase contrast imaging is beneficial for materials in which both heavy and light elements are simultaneously present, such as organic cations and lead in perovskites. Moreover, 4D-STEM is superior with respect to information-richness and dose-efficiency as compared to high-angle annular dark-field (HAADF) STEM, where only electrons scattered to relatively high angles are used. The 4D-STEM datasets were acquired with a custom-made Timepix3 detector, which is an event driven hybrid pixelated direct electron detector. To retrieve the phase information from the recorded 4D datacube, we applied a recently developed convolutional neural network (CNN).(Friedrich et al. 2023) The CNN was trained based on a large

synthetic dataset, using atomic structures extracted from the materials project database. Moreover, to analyze the local structure we fitted the shape of the projected atomic columns. For this purpose, a parametric model was used which consists of a sum of two-dimensional elliptical Gaussians, each centered on the atomic column positions. Additionally, the experimental STEM results were compared with a series of molecular dynamics (MD) simulations at constant temperature and pressure, which were performed using a machine learning potential trained on underlying Density Functional Theory energies and forces.

Results

The high dose efficiency of the CNN reconstruction enables to study these beam-sensitive NCs with an electron dose that is sufficiently low to avoid the formation of Pb-rich clusters due to electron beam irradiation while maintaining a high signal-to-noise ratio. It is noteworthy that at a total electron dose below 50 e-/A2, all atomic columns, including the light formamidinium cations and Br anions can be clearly detected in the CNN reconstructions (see panel (a) in Figure 1). Moreover, a close inspection of the projected Br columns revealed deviations from perfect round projections. A possible reason are alternations in the position of the Br atoms along the viewing direction. The ellipticity ratio for the projected Br atomic columns was obtained by fitting elliptical Gaussians. In panel (b) the arrows illustrate the ellipticity ratio of the projected Br atomic columns and the overlay represents the different atomic columns ((Br = purple, Pb-Br = blue, FA = orange). This indicates that the Br atoms have a small flexibility in the octahedral network structure and can be displaced perpendicular to the Pb-Br-Pb bond, which is schematically illustrated by the red arrows in panel (c) in Figure 1. Furthermore, the performed MD simulations confirmed the displacement of the Br atomic columns. This observation is also in good agreement with previous synchrotron XRD measurements of FAPbBr3 NC, where the measured Pb-Br-Pb bond angles deviate up to 15 ° from the ideal 180 ° angle due to local disorder caused by displacement of Br anions.(Yazdani et al. 2023)

Conclusion

Thus, our approach via low-dose phase image reconstructions enables to study the local octahedral network structure of perovskites and could be transferred to in situ experiments in the future to investigate degradation mechanisms under environmental triggers.

In-situ beam driven experiments by Electron time-correlation microscopy of amorphous structures

Dr. Martin Peterlechner[1], Olivia Vaerst[2], Prof. Gerhard Wilde[2]
[1]Karlsruhe Institute of Technology, Laboratory for Electron Microscopy (LEM), Karlsruhe, Germany,
[2]University of Münster, Institute of Materials Physics, Muenster, Germany

Poster Group 2

Background & Aims
Amorphous materials are widely present and not straight-forward to study. However, similar to X-ray photon correlation spectroscopy (XPCS) the method of electron correlation microscopy (ECM) was introduced [1]. This approach using the time correlation of diffracted or dark-field intensities was applied at elevated temperatures. However, it was shown that this way of data analysis gives also proper materials parameters at room temperature (RT) [2]. Besides that, also pure materials made amorphous by ion implantation were recently studied [3]. To understand the influence of the beam and the measured signals, results from different materials are compared and discussed. In this work, the imaging and analysis conditions are examined to understand the arising quantitative signals, and to be able to compare ECM data obtained at elevated temperatures to that of electron time-correlation microscopy (EtCM) obtained at any temperature, even at RT where the thermal activation is small.

Methods
The analyzed materials are on the one hand metallic glasses as FeNiP or PdNiP, and on the other hand pure elements as Si or Ge. The metallic glasses were processed by rapid quenching techniques, and the pure elements were synthesized by ion implantation. EtCM is used to probe the dynamics and relaxation times from RT up to the glass transition temperature. The samples for the heating experiments were prepared using a focused-ion beam (FIB) and the lamellae were mounted onto a in-situ heating chip. Additionally, all samples were also structurally characterized using diffraction including fluctuation electron microscopy (FEM). Besides a basically disordered structure, also a preferred length-scale for ordering within the amorphous phase can be given. This number should typically not change during the EtCM experiments.

Results
The analysis of time series of dark-field images enables to measure the intensity variation over time, related to a structural relaxation time. The function of the intensity correlation can be given for every image pixel, thus also a relaxation time constant and a stretching exponent can be deduced. The measurement needs a certain amount of time and dose to achieve reliable numerical values. Different materials show different numbers, however, all materials show that the electron beam and its dose-rate or cumulative-dose are relevant for the achieved numerical values. The dose-rate can be even too high, to induce crystallization at RT. Thus, the dose-rate is measured and given for all experiments.

Conclusion
The imaging conditions during EtCM matter for the numerical values and further treatment of the result. Best results are obtained using low-dose settings and long measurement times. However, it must be noted that amorphous structures show relaxation times on basically all time scales, from

atomic jumps on the pico-second scale up to bulk relaxation in terms of (millions of) years. Experimentally, the maximum measurable time scale is less than half of the overall experimental time, and the minimal measurable time scale depends on the frame time for two frames. It can be concluded, that EtCM experiments at RT are beam driven relaxation studies, helpful to understand the intrinsic time scale for relaxation in any amorphous matter.

Poster Group 1

Many industrially relevant steels are ferromagnetic such as ferritic-pearlitic steel characterized in this study. Ferritic-pearlitic steels are commonly used, for example, in automotive components. Microstructural features of ferromagnetic materials influence their mechanical and micromagnetic properties. Traditionally, the microstructure, for example, cementite (Fe_3C) content, has been studied with destructive methods. To save time and money, destructive methods should be replaced with non-destructive testing (NDT) techniques. One of the potential NDT methods is magnetic Barkhausen noise (MBN) testing. It is used in industry to detect for example localized microstructure and stress variations. MBN testing is based on the motion of magnetic domain walls in ferromagnetic materials exposed to a time-varying external magnetic field. The motion of domain walls is hindered by the microstructural pinning sites such as carbides, grain boundaries, and dislocations. In the varying magnetic field, domain walls stop and finally jump over the pinning features, causing discontinuous and abrupt changes in the magnetization of the workpiece. These changes result in electromagnetic burst-like signal, i.e., Barkhausen noise, measured with an inductive coil. However, the applicability of the Barkhausen noise method is currently limited due to the stochastic nature of the phenomenon itself. Thus, more scientific knowledge is needed. Recently, we mimicked and visualized the Barkhausen noise measurement by in-situ Lorentz microscopy. This study gives general information about the behavior of domain walls in ferromagnetic steel. In addition, we have utilized magnetic force microscopy and micromagnetic simulations to deepen our knowledge on the magnetic behavior of steels.

In this study, we used multi-instrumental and computational approach. Traditional microstructural characterization of ferritic-pearlitic steel was carried out by SEM-EBSD-TKD and (S)TEM-EDS. The magnetic structure of the thin sample was studied by Lorentz microscopy (Fresnel mode), while the bulk sample was studied by magnetic force microscopy (MFM). The dynamics of domain walls were studied by in-situ Lorentz microscopy. A varying, external magnetic field was generated by a normal objective lens of TEM, and the images were collected in LOW MAG mode using objective mini lens. The recorded frames of each sample were jointly post-processed as a single video using video denoising and frame alignment procedures. To measure a single point magnetic flux density generated with different excitation values of the normal objective lens inside the TEM, we used a custom-made holder equipped with a Hall-effect sensor. We also run micromagnetic simulations to verify domain wall dynamics in certain magnitudes of magnetic fields.

Our multi-instrumental characterization, dynamical in-situ Lorentz microscopy studies, and micromagnetic simulations with the complex ferritic-pearlitic structure revealed the interaction of different domain walls and pinning sites. Thus, we could visualize and verify hypotheses related to

the origin of Barkhausen noise signal. Comparing Lorentz microscopy and MFM results, we indicated that thin and bulk samples studied have similar magnetic structure. So, TEM studies are also relevant from the industrial point of view, although usually bulk samples are used in industrial applications. To measure the magnetic field strength generated by the normal objective lens of TEM in dynamical in-situ studies, we built a custom-made Hall-effect sensor holder. It measures the flux density at the same location as the TEM sample. Based on the measurements, the objective lens of our TEM has almost linear response to the magnetic field strength, and when the objective lens is switched off, the magnetic field in the sample area is close to 0 mT.

Based on our studies, the carbides are very strong pinning sites for domain walls. In addition, larger globular and thicker lamellar carbides can have their own magnetic structure. In the increasing magnetic field, domain walls in the ferritic matrix perpendicular to the lamellar cementite carbides begin to move first. Then, the domain walls inside the carbides start to disappear. Finally, domain walls parallel to the lamellar carbides move. However, some of them are very strongly pinned by carbides. When the magnetic field is decreased back to 0 mT, the domain walls appear in the opposite order. We simulated the magnetization dynamics where microstructural information is extracted from the SEM-TKD and (S)TEM results. To explain the domain wall behavior in certain magnitudes of the magnetic field as observed using in-situ Lorentz microscopy, we ran dynamical micromagnetic simulations to reproduce the domain wall disappearance in the globular carbide. In general, the simulations supported very well the interpretation of the experimental findings, although the re-appearance of the domain walls with decreasing field could not be reproduced. In the next step, our multi-instrumental and computational approach will be extended by transport of intensity equation (TIE) method and off-axis electron holography. These results will be reported in the near future.

Imaging methods and micromagnetic simulations have their own limitations. Despite using multi-imaging techniques, it is probable that not all magnetic features can be visualized by microscopes and on the other hand, simulations cannot always reproduce all events observed experimentally. However, our combined multi-instrumental and computational approach gives novel knowledge on how iron-based carbides affect magnetic domain wall dynamics in ferromagnetic steel.

Thapsigargin induces non-apoptotic programmed cell death in RBL-1 cells

Dr. Philip Steiner[1], Mr. Hubert Kerschbaum[2], Mrs. Ancuela Andosch[1,2], Mr. Korollus Melek[3], Mrs. Susanna Zierler[1,4]
[1]Institute of Pharmacology, Johannes Kepler University, Linz, Austria, [2]Department of Biosciences and Medical Biology, Paris Lodron University, , Austria, [3]Institute of Biochemistry and Molecular Medicine, University Bern, , Switzerland, [4]Walther Straub Institute of Pharmacology, Ludwig Maximilians University, Munich, Germany

Poster Group 2

Background and aims:
Thapsigargin (TG) is a potent sarco/endoplasmic reticulum (ER) Ca2+-ATPase (SERCA) inhibitor and, accordingly, elevates intracellular Ca2+ levels. Recent studies demonstrate that TG induces cell death in a variety of cancer cells. While it is assumed that TG triggers cell death by apoptosis, our cytological studies on rat basophilic leukemia cells (RBL-1) indicate a non-apoptotic mode of cell death.
Methods:
Since the ultrastructural hallmarks of TG-induced cell death are only sparsely described, we studied the morphological consequences of TG exposure in RBL-1 cells using 2D transmission electron microscopy (TEM) and 3D TEM tomography in correlation with laser scanning microscopy (LSM). To visualize and quantify the effects on different organelles, live-cell fluorescence markers such as ER-tracker, HOECHST, endocytosis-tracker and MitoTracker were used.
Results:
TG-exposed RBL-1 cells showed prominent ballooning of the perinuclear space, vacuolization, increased vesicle formation, mitochondrial enlargement and degradation as well as ER- swelling and anomalies. In particular, the TEM data failed to show apoptotic hallmarks such as nuclear fragmentation or the formation of apoptotic bodies in TG-exposed RBL-1 cells.
Conclusion:
Contrary to the prevailing theory that TG triggers apoptosis, our results suggest a non-apoptotic programmed cell death. Moreover, numerous non-apoptotic morphological hallmarks were found, which are reminiscent of autosis and paraptosis. Thus, while TG represents a potential tumor therapeutic agent, the underlying mechanisms of cell death are still ambiguous and might differ in distinct cell types.

PS-08 (1), Lecture Theater 2, august 27, 2024, 10:30 - 12:30

Background incl. aims
The onset and properties of long-range ordering in solids come from a fine interplay between different order parameters. Materials featuring magneto-structural phase transitions constitute optimal systems for investigating the interplay of structural, electronic, and magnetic order parameters. The equiatomic FeRh alloy is a prototypical system undergoing a first-order magneto-structural phase transition from antiferromagnetic (AF) to ferromagnetic (FM) order upon heating (350 – 380 K), that is accompanied by a lattice parameter expansion [1]. Broad options for the tunability of the transition temperature via doping, strain, magnetic field, or controlled disorder make the system attractive for micro- and nanoscale spintronics [2], magnetocalorics, and sensors. The fullfilment of the application potential however requires the understanding of the phase coexistence, phase boundary properties, and transition dynamics at nanoscale. Here we demonstrate broad possibilities of controlling and sensing different ordering parameters of the FeRh phase transition using TEM.

Methods
TEM investigations are performed in free-standing FeRh thin fims which were epitaxially grown on MgO substrates via magnetron sputtering and subsequently released by chemically dissolving the MgO substrate. Different external stimuli are applied in-situ in TEM to drive the FeRh transition, namely, magnetic field, stage-induced static heating, or fs-laser-induced heating [3]. Other stimuli are applied ex-situ to locally tune the transition properties, such as ion irradiation. The induced structural and magnetic order modifications in FeRh are then explored using different TEM-based techniques, such as Lorentz TEM (LTEM), Transfer of Intensity (TIE) reconstruction of LTEM [4], Differential Phase Contrast (DPC), Electron Magnetic Circular Dichroism (EMCD) [5], or Selected Area Electron Diffraction (SAED).

Results
The studied free-standing FeRh film exhibits a well-defined phase transition as evidenced by the thermal evolution of the magnetic and structural ordering parameters that vary between AF and FM phases, as shown in Fig 1(a). TEM enables unprecedented nanoscale visualization of the evolution of the phase transition upon following magnetization via LTEM or lattice parameter from SAED. For instance, Fig 1(b) shows the temperature dependence of the FM phase domain content as measured via LTEM. Apart from stage-driven static heating, the AF-FM transition in FeRh can be driven by fs-laser light or locally by ion irradiation as can be seen in Fig 1(c) and 1(d), respectively. High-resolution vectorial magnetic reconstruction can be done either using TIE-LTEM or DPC as shown in Fig 1(e) and (f), respectively.

Conclusion
Overall, we demonstrate that multimodal TEM represents a unique experimental platform to tackle state-of-the-art challenges in probing the interplay between different order parameters in magnetic systems at the nanoscale. In particular, we show that in combination with different stimuli, nanoscale phase coexistence of structural and magnetic orders in FeRh can be uniquely probed and disentangled. Furthermore, high-resolution magnetic imaging using STEM-DPC represents a unique tool for investigating magnetic phases and their boundaries at the nanoscale.

Poster Group 1

Background incl. aims
Proton exchange membrane fuel cells are an alternative to fossil fuel-powered engines in the mobility and energy sector. They use hydrogen as fuel and do not directly generate greenhouse gas emissions. However, the cost of the electrocatalyst for the oxygen reduction reaction (ORR) still poses an issue, as it commonly contains scarce platinum. Currently, supported Pt-alloy nanoparticles are commonly used to lower the amount of Pt but retain good ORR performance. Despite numerous studies on structure-property relationships of such electrocatalysts, the effects of selected structural features on the catalytic activity and stability remain unexplored. Ensembles of supported metallic alloy nanoparticles typically vary in size, shape, composition, crystal structure, presence of defects, and other structural subtleties, all of which impact catalytic performance. Therefore, advanced characterization methods are needed to obtain average and local information about the catalyst structure to correlate it to its properties [1]. The study aims to provide an accurate description of the presence and type of defects and crystal ordering in carbon-supported platinum-copper nanoparticles and an insight into how advanced microscopy complements electrochemical methods in terms of answering questions about the structure-property relationship.
Methods
Various analogs of carbon-supported platinum-copper nanoparticles were synthesized using a wet impregnation method and subsequent thermal annealing in a tube furnace using specified temperature-time profiles and atmospheres. X-ray diffraction, scanning transmission electron microscopy (STEM), 4D-STEM, and electrochemical measurements were used to characterize the samples. Simulated X-ray and electron diffraction patterns and images were used to interpret experimental results. 4D-STEM datasets were collected for individual nanoparticles of a selected sample. Virtual detectors were used to construct real-space images from the 4D dataset, and clustering and matrix factorization were used to segment the dataset and determine commonly occurring patterns that can be associated with specific structural features within the catalyst.
Results
The platinum-copper alloy with a composition close to $PtCu_3$ crystallizes as an ordered or disordered alloy, depending on the annealing temperature. For analogs that were annealed in a reductive atmosphere at a temperature at a transition between the two well-known phases, diffraction patterns revealed the presence of periodic anti-phase boundaries, separating ordered alloy crystallites. The modulated unit cell was previously reported for a bulk material, but not in the context of nanomaterials. Based on differences in column intensities, an anti-phase boundary was observed in real space on an atomically resolved STEM micrograph, where the expected column intensities were confirmed with STEM image simulations, as seen in the Figure. The presence of anti-phase boundaries has not proven itself critical in determining the catalytic activity of the investigated material. For an analog, exhibiting a mix of the ordered and disordered alloy phases, a 4D-STEM investigation of individual nanoparticles provided diffraction patterns containing information on the

local crystal structure. The data analysis enabled the discovery of notable features within the data without explicitly specifying what diffraction signal they should cause. In the case of platinum-copper nanoparticles, it revealed a spatial distribution of the signal, associated with the ordered alloy phase, which is one of the factors previously shown to govern the catalytic activity towards the ORR.

Conclusion

The investigation resulted in a quantitative description of periodic anti-phase boundaries in platinum-copper nanoparticles following a specified thermal annealing protocol [2]. Simulated data for both powder diffraction patterns, as well as STEM images, helped explain experimental results. 4D-STEM proved itself useful in providing local crystal structure information, which can be inferred from the dataset in an unsupervised way. This imaging modality can bring added value to studies, probing the complex structure-property relationships of nanoparticulate electrocatalysts.

Whole-brain 3D quantification of alpha-synuclein spreading and toxicity in a mouse model of Parkinson's disease

Phd Student Frederikke Lynge Sørensen[1,2], Annika Højrup Runegaard Thomsen[1], Urmas Roostalu[1], Jacob Lercke Skytte[1], Evi Alexiou[1], Jacob Hecksher-Sørensen[1], Poul Henning Jensen[2], Yasir Gallero-Salas[1], Henrik Björk Hansen[1]
[1]Gubra Aps, Hørsholm, Denmark, [2]Biomedicine and DANDRITE, Aarhus University, Aarhus, Denmark
LS-05, Lecture Theater 5, august 26, 2024, 14:00 - 15:00

Background & Aim: Progressive spreading of alpha-synuclein (aSyn) aggregates in the brain plays a key role in the prodromal phase of Parkinson's disease (PD). While several preclinical models of synucleinopathies have been developed for studying the neurotoxicity of prion-like aSyn aggregate spreading, they remain to be systematically explored with regards to early pathological events that could potentially be targeted to slow down or prevent progression of PD. Using whole-brain light sheet fluorescence microscopy (LSFM), the present study aimed to provide a detailed 3D map of progressive pathological aSyn spreading and tyrosine hydroxylase (TH) expressing neurons and projections in the aSyn pre-formed fibril (PFF) mouse model of PD.

Methods: 8-weeks old C57BL/6 male mice received two unilateral, intrastriatal injections of murine aSyn PFFs (5 µg per injection). Mice were terminated at 1, 4, 8-, 12-, 16-, or 26-weeks post-injection (wpi), whole-brains were dual immunolabelled for aSyn phosphorylated at serine-129 (pS129-aSyn, marker of aSyn aggregation) and TH, optically cleared (iDISCO+) and scanned using LSFM at cellular resolution. AI-based computational analysis enabled automated whole-brain mapping and quantification of pS129-aSyn and TH fluorescence intensity across 840 individual brain regions using a custom mouse brain atlas.

Results: Distinct spatiotemporal phases of endogenous aSyn aggregate spreading observed in aSyn PFF mice over time. The phases included progressive spread of aSyn aggregates to primary seeding regions (amygdala, substantia nigra, and several cortical areas) and secondary seeding regions (entorhinal area and hippocampal formation) based on their interconnectivity to the injection site (striatum), followed by redistribution of aSyn aggregates in specific brain regions. In parallel, TH expression was progressively downregulated in the nigrostriatal pathway, suggesting axonal damage in terminal areas preceding dopaminergic neuronal loss in the aSyn PFF mouse model.

Conclusion: We here report a complete whole-brain map of aSyn aggregate spreading in an industry-standard aSyn PFF mouse model of PD. The anatomical complexity of aSyn aggregate spreading in the model underscores the unique applicability of whole-brain 3D LSFM imaging to fully capture spatiotemporal dynamics in aSyn and TH expression, making the model highly instrumental for the evaluation of therapeutic modalities that may prevent aSyn aggregate spreading and dopaminergic neuronal loss.

IM-10 (1), Lecture Theater 3, august 29, 2024, 10:30 - 12:30

Background incl. aims
Nanoparticles (NPs) have important use cases in catalysis, nanomedicine, photonics and plasmonics, and their properties are very dependent on elemental composition, structure, size, and shape. Reliable characterization methods are, therefore, very important in developing these technological areas. With X-ray-based scattering methods, large volumes of NPs can be probed, which gives volume-averaged ensemble characteristics. (Scanning) transmission electron microscopy ((S)TEM) on the other hand can give detailed information about the individual particles, but thousands of NPs must be analyzed to get statistically significant information about the sample. This calls for automatic NP characterization. Although numerous approaches exist, many require choosing the right combination of segmentation parameters or training machine learning algorithms. Here, we present NP-SAM [1], an easy-to-use segmentation and analysis software for NP characterization with advanced filtering based on NP characteristics and with the ability to run with varying degrees of human intervention.
Methods
NP-SAM is based on the Segment Anything Model (SAM) developed by Meta AI Research [2]. We have implemented SAM into NP-SAM and added extra functionalities such as a user-friendly mask filtering mechanism, overlap handling, core-shell analysis, and automatic generation of different types of useful output. The figure shows the general workflow of NP-SAM. Electron microscopy image(s) are first segmented with SAM, resulting in a mask for every segmented particle in different colors. Unlike most other segmentation methods, masks can overlap the same regions, making it possible to analyze neighboring NPs that overlap to a certain degree. An optional graphical user interface (GUI) allows undesired masks to be easily filtered based on the most relevant characteristics such as area, intensity, overlap, etc. For advanced users, even more advanced filtering is possible. Finally, NP-SAM produces different kinds of output: 1) Histograms and statistics of user-chosen characteristics, 2) an overview .pdf file for quick sharing that contains the histograms and summarizes the segmentation and filtering parameters (for reproducibility), 3) a .csv file with the particle characteristics, e.g. area, perimeter, orientation, etc., 4) a flattened binary mask image of all the particles found, and 5) a mask for every individual particle enabling further advanced workflows of i.e. core-shell particles or hyperspectral data.
Results
We have tested NP-SAM on various electron microscopy images including high-angle annular dark-field (HAADF) and bright-field TEM images. 24 HAADF images of PdCu NPs were analyzed, and 2352 NPs were analyzed in about 11 minutes. The size distribution found with NP-SAM agrees with manually measured sizes. NP-SAM's segmentation can be adjusted depending on the accuracy needed and the computer power available. Four segmentation model weights are available: Huge,

large, base, and fast, with huge being the most accurate but also computationally heaviest and fast being lightweight and less accurate [3]. Segmenting the 24 HAADF images with the fast model weights took 3 minutes, and 1925 NPs were found to give a size distribution that again resembles the manually measured one.
The segmentation is based on a grid of points determining where the segmentation model searches for objects. For a HAADF image of very polydisperse Ag NPs and with many small NPs, a finer grid helped find more NPs. We have also implemented a feature called crop and enlarge that can help detect small NPs by dividing the image into four enlarged and segmented sections individually.
One of the exciting features of NP-SAM is its ability to handle overlapping NPs. The overlap between masks is calculated since masks are allowed to occupy the same pixels. This overlap is an important filter parameter, and the user can freely choose the amount of overlap tolerated. This is shown with a HAADF image of AgCuIrPdPt NPs with complicated HAADF contrast.
NP-SAMs sensitivity and ability to handle overlapping masks also enable advanced analysis of core-shell NPs. With core-shell NPs being segmented as two masks, one being the entire particle and the other being the core within the particle, the core and shell can be analyzed individually, and their characteristics can be linked. For example, we can plot shell thickness as a function of core diameter.
NP-SAM is available at our GitLab at https://gitlab.au.dk/disorder/np-sam with installation instructions, source code and user-friendly example notebooks. It is written in Python and can easily be installed using pip after installing PyTorch. A CUDA-compatible GPU speeds up computations significantly, and 8 GB of VRAM is recommended for the huge model weights. NP-SAM can also be run in a cloud-based Google Colab notebook where GPUs are often available. The segmented masks can then be downloaded and filtered locally using the GUI. Finally, we have also developed NP-SAM as a .exe file that runs NP-SAM through a user-friendly interface, not requiring any Python knowledge.
Conclusion
NP-SAM is a powerful tool for quick, user-friendly, and semi-automatic NP segmentation and analysis. Several images can be segmented in less than a minute per image, facilitating quick and reproducible analysis of thousands of NPs. In general, the size distributions found with NP-SAM resemble those found manually. Because NP-SAM can handle overlap, this allows for useful filtering and advanced analysis workflows such as the analysis of core-shell particles.

Towards advanced polymer membranes for hydrogen technologies through dose-optimised Focused Ion Beams

Dr Ofentse Makgae[1], Dr Martha Briceno de Gutierrez[1]
[1]Johnson Matthey Technology Centre, Reading, United Kingdom

Poster Group 2

Background & Aims
Understanding the properties of membranes applied in the CCMs of electrolyser and fuel cell technologies is crucial to advancing the commercialisation and deployment of these technologies to the market. The cross-sections of these membranes are typically studied using a Focused Ion Beam (FIB). A FIB is a technique in which accelerated (Ga) ions spatter material away upon interaction.[1] This technique is used mainly for electron-transparent transmission electron microscopy sample preparation, FIB tomography, or cross-sectional analysis of materials such as semiconductors, ceramics, metals, polymer thin films, and biological specimens. Unlike conductive materials such as ceramics and metals, polymer membranes are non-conductive and thus susceptible to beam-induced heating during ion beam milling.[2] Ion beam-induced heating in polymer membranes creates 'melt-like' artefacts that smear the pristine structural details of the membrane along the cross-section. In addition, it is also shown that accelerated Ga ions can result in the chemical alteration of the membrane's chemical structure, which affects the properties of the membrane. [3] This ion-beam-induced damage is typically circumvented by dose-controlled milling or lowering the specimen temperature via cryogenics. Here, we aim to optimise the milling parameters for polymer membrane cross-section milling by determining the optimum current, accelerating voltage, and dwell time required to minimise beam-induced heating in polymer membranes.
Methods
Polymer membranes were mounted on SEM-FIB stubs and sputter-coated with a conductive layer of carbon. A series of cross-sections were milled using a Zeiss Crossbeam 550 dual-beam at a varying current, accelerating voltage, dwell time, and ion dose. The actual values will be presented with the results.
Results and conclusions
Preliminary results show that reducing the dwell time at low milling currents and high voltage reduces the beam-induced artefacts in the membrane cross-sections. The results of this study will help understand the pristine microstructure of polymer membranes in a standardised and reproducible routine cross-sectional analysis, and ultimately lead to the development of novel membranes for applications in hydrogen technologies.

NBED investigations of coaxial (Al,In,Ga)As nanowires

Alina Friemel[1], Dr. Tore Niermann[1], Dr. Laura Niermann[1], Dr. Paul Schmiedeke[2], Dr. Gregor Koblmüller[2], Prof. Dr. Michael Lehmann[1]
[1]Technische Universität Berlin, Berlin, Germany, [2]Technische Universität München, Munic, Germany

Poster Group 2

Background incl. aims
GaAs-based semiconductor nanowire (NW) lasers exhibit many advantageous properties for telecom-band data communications and sensing applications, like e.g. their ultra-compact size and their compatibility to Si-based photonics. In comparison to other III-V semiconductors, GaAs allows a fairly mature Au-free NW growth on Si. However, within the coaxially grown multiple quantum wells (MQW) the strain resulting from lattice mismatch accumulates during the growth. This problem can be mitigated by the introduction of an InAlGaAs buffer layer in between the GaAs core and the active region of the MQW-stack [1].
For process control and further engineering of NW laser structures, the strain in the resulting devices must be monitored. We report on strain investigation by means nanobeam electron diffraction (NBED) for such structures.
Methods
GaAs NW cores were grown via a vapor-liquid-solid growth mechanism on pre-patterned Si substrates along the [111] direction. Subsequently, an In0.3Al0.3Ga0.4As buffer layer, followed by an In0.3Ga0.7As QW, an In0.23Al0.23Ga0.54As barrier layer, and a GaAs cap layer were grown coaxially onto the side walls of the GaAs core. A cross-sectional lamella was prepared from the NW using focused ion beams.
HAADF, EDX and eventually NBED measurements were performed using a JEOL GrandArmF2 microscope, operated at 300kV. The NBED data was recorded using the Quantum Detector's Merlin detector.
Results
We applied a custom algorithm to determine the base vectors for the reciprocal lattice visible in the individual diffraction patterns for each scan point. Starting with an initial guess for the base vectors and the origin of the pattern, the algorithm consists of several steps: (i) for each lattice point spawned by the base vectors, a sub-region of the diffraction pattern is extracted; (ii) within each subregion the position of the reflection is determined with sub-pixel projection; (iii) a new set of base vectors is calculated by weighted linear regression, using the inverse precision from step (ii) as weights; (iv) unless the resulting set of base vectors has converged to a predefined precision, the algorithm is repeated from step (i) again. From the resulting base vectors of the reciprocal lattice observable in the diffraction patterns, the strain components can be calculated in reference to the GaAs core.
In comparison of the resulting strain data with finite element calculations short-scaled variations of the determined strain components are observed in areas where smooth strain components are expected. We attribute these variations to dynamical diffraction effects stemming from small specimen inhomogeneities created during preparation, for example from thickness variations. We discuss the influence of experimental and evaluation parameters, like the convergence angle or the method used to determine the reflection position, on the precision of the obtained strain components.
Conclusion

NBED generally allows the evaluation of strain data with nanometer precision. However, the resulting strain maps suffer from dynamical diffraction effects, which can be further mitigated by optimized experimental parameters and optimized evaluation procedures.

PS-01 (1), Lecture Theater 3, august 28, 2024, 10:30 - 12:30

Background incl. aims
Surface polarity dynamics profoundly influence the electronic and structural properties of oxide thin films. This study aims to investigate the atomic structure and electrostatic characteristics of partially reduced nickelate films to elucidate the mechanism behind strong surface reconstruction.

Methods
Advanced STEM techniques, including annular bright field (ABF) imaging, four-dimensional scanning transmission electron microscopy (4D-STEM), and electron energy-loss spectroscopy (STEM-EELS), were employed to probe the atomic and electronic structures, along with the near-surface electrostatic charge distribution.

Results
Surface analysis revealed a polar distortion coupled with octahedral rotations in both fully oxidized and partially reduced nickelate films. A stronger polar distortion was observed in the reduced sample, indicating a relationship with oxygen vacancies generated during topochemical reduction (Fig. 1a,b). Direct evidence of homogenous Sr doping and distinct valence variations of Ni atoms near the surface were provided by 4D-STEM imaging. EELS analysis confirmed changes in Ni valence and oxygen concentration, consistent with the observed surface reconstruction.

Conclusions
This study bridges the gap in experimental examinations of surface effects in oxide thin films, providing crucial insights into the nuanced interplay between surface polarity, electronic structure, and structural transformations. The observed surface reconstructions, influenced by oxygen vacancies, impact electronic transport properties, contributing to the understanding and engineering of surface polarity at the atomic scale in functional materials [1].

IM-10 (1), Lecture Theater 3, august 29, 2024, 10:30 - 12:30

Background
Functional properties of nanomaterials depend to a large extent on the underlying structure and chemical composition. An example are hetero-aggregates in which nanoparticles of two different materials are mixed. The mixture of titanium-dioxide (TiO2) and tungsten-trioxide (WO3) nanoparticles shows enhanced functionality if applied as a photo-catalyst compared to pure TiO2[1]. The performance of the material depends on the mixing. Best photo-catalytic activity is achieved in completely mixed hetero-aggregates[1].
Improvement of functional properties requires a characterization of structure and mixing. In conventional STEM, two-dimensional (2D) projection images of the samples are acquired, information about the third dimension is lost. This drawback can be overcome by STEM tomography, where the three-dimensional (3D) structure is reconstructed from a series of projection images acquired using various projection directions. However, 3D measurements are expensive with respect to acquisition and evaluation time. Hence, the measurement of 3D-reconstruction can only be done for a limited number of hetero-aggregates.

Methods
TiO2-WO3 hetero-aggregates are generated in a double-flame spray pyrolysis setup. Precursors of the two materials are sprayed and combusted in the two separate flames. Nanoparticles form by nucleation and coagulation and aggregate to clusters of the same material. After a certain distance both flames intersect and clusters of both materials form hetero-contacts. The length of the intersection distance has an influence on the mixing.
To obtain statistically relevant results, information on many hetero-aggregates has to be gathered. Positions of many nanoparticles have to be determined in 2D and 3D data. This can be challenging especially in regions where many particles overlap in crowded regions in 2D-projection data. In recent years, it was demonstrated that the application of artificial intelligence (i.e. convolutional neural networks, CNNs) outperforms a manual measurement or classical object detection algorithms[2,3]. The application of CNNs requires a training of the network first. To this end, many training images in which particle positions and material types are known are required. In the present contribution, we simulate realistic 2D-projection and 3D-reconstruction data of computer-generated virtual hetero-aggregates, in which particle positions and material types are known. We evaluate the trained CNNs using simulated data that has not been used during the training process and apply the networks to experimental 2D-projection and 3D-reconstruction data. For evaluations of 2D-projection data we train a Mask R-CNN[4], for evaluation of 3D-reconstructions we train a StarDist-3D network[5].

Results

An example evaluation is shown in the figure. Part (a) shows a STEM image of a TiO2-WO3 hetero-aggregate. Part (b) shows particles detected by the Mask R-CNN, where TiO2 and WO3 are represented in red and green, respectively. The material discrimination shows a good agreement with the energy dispersive X-ray spectroscopy (EDXS) map in (c). The nanoparticles as detected by the StarDist-3D network in the STEM tomography reconstruction is shown in (d). The material discrimination is in good agreement with the EDXS map in (c) again.
To correlate structure and chemical composition with functional properties it is required to obtain quantitative information from 2D-projections and/or 3D-reconstructions. In the present contribution, we evaluate the number of particles, the WO3 mass fraction, particle size distributions and the fractal dimension, which is a measure for the hetero-aggregate structure. To quantify the mixing, we measure the heterogeneous coordination number, i.e. the average number of neighbour particles of a different material. A higher heterogeneous coordination number indicates better mixing. We show that for a measurement of mass fractions and for the characterization of mixing, the evaluation of less expensive 2D-projection data is sufficient, whereas for a measurement of the fractal dimension a 3D-reconstruction is required.

Conclusion
Results of the present contribution will help for future characterization of nanoparticle hetero-aggregates, if only the less expensive 2D-projection data is available. In these cases, results of this contribution will provide the possibility to relate 2D-projection evaluations with the 3D structure of the samples.

Investigation of metal-to-metal hydride phase transformations in magnesium thin films using STEM techniques

Dr Gopi Krishnan[1], Herman Schreuders[2], Lars Bannenberg[2], Joerg Jinschek[1]
[1]DTU Nanolab, Technical University of Denmark, Lyngby, Denmark, [2]Faculty of Applid Sciences, Delft University of Technology, Delft, The Netherlands

PS-01 (3), Lecture Theater 3, august 30, 2024, 14:00 - 16:00

Background incl. aims
In the pursuit of a decarbonized society and economy, hydrogen (H2) stands out for its zero-emission potential as a fuel, energy storage medium, and chemical feedstock. However, achieving compact hydrogen storage, especially in safe, solid forms such as metal hydrides, remains a significant challenge.
Enhancing storage efficiency requires a deep understanding of the nano/atomic-scale dynamics of, e.g., the metal-to-metal hydride transformation, including nucleation, growth, and the effects of stress, strain, and defects on hydrogen storage properties. Therefore, to pave the way for improved storage solutions, we must develop a deeper understanding of hydrogen sorption and desorption dynamics through the real-time observation of the transformation process in scanning/transmission electron microscopy (S/TEM).
Methods
We used magnesium (Mg) thin films as a model system to study metal-to-metal hydride phase transformation. The Mg films were grown using a DC magnetron sputtering to a thickness of 500 nm with an 8 nm adhesion layer of Titanium (Ti) and a catalyst layer of Palladium (Pd) of 100 nm. A ThermoFisher Hydra plasma-focused ion beam (PFIB, Xe, 30kV) was used to prepare the TEM lamellas. Structural investigations were performed using a ThermoFisher Spectra Ultra equipped with an X-FEG mono and a Gatan Image Filter (GIF) Continuum HR. These phase transformations were studied under both in-situ and ex-situ conditions using STEM, low-loss plasmon electron energy loss spectroscopy (EELS), and electron diffraction (ED).
Results
The hydrogen absorption/desorption process in Mg is observed using the bulk plasmon shift in EELS due to a structural change from a hexagonal closed-packed (HCP) to a tetragonal crystal structure. During absorption, TEM dark-field imaging confirms that the Mg thin film loses its initial morphology and transforms into nanocrystalline particles, which is attributed to volume expansion. Low-loss EELS further confirms that the hydride phase transformation occurs through nucleation and growth, distinguishing it from the desorption process. The desorption process starts with the formation of pores/voids at the interface between Mg and Ti, followed by crack formation that initiates Mg formation. The Complete H2 desorption in thin films results in a fully porous structure, with subsequent coalescence leading to void formation in Mg. The thin film's increasing porosity and void formation with subsequent cycling indicate a deterioration of its durability. However, initial porosity at the Mg/Ti interface promotes Mg nucleation during desorption. In order to validate our findings, we combine both in-situ and ex-situ studies at high spatial resolution in STEM, enabling us to compare our results and interpret the effect of the e-beam dose rate on the analysis.
Conclusion
We demonstrate that STEM imaging, low-loss EELS, and ED allow us to track the phase transformation from metal-to-metal hydride in Mg thin films along with its structural and

morphological changes. The nucleation and growth of Mg are influenced by the stress/strain generated during the hydride transformation, distinct from the desorption process.

Optimizing Backscattered Electron Detection in SEM: Diode Layout and Collection Efficiency

Dr. Mozhdeh Abbasi[1], Dr. Maximilian Schmid[1], Dr. Alessia Mafodda[1], Dr. Stefan Aschauer[1]
[1]PNDetector GmbH, Munich, Germany

Poster Group 1

Scanning electron microscopes (SEMs) with their variety of attachments designed for surface observation and analysis stand as a key instrument in research institutes and quality testing facilities worldwide. The essence of the SEM is to induce the emission of various electron products from the specimen, among which backscattered electrons (BSEs) play a pivotal role. These BSEs emerging from the specimen carry information of composition and structure and play an important role in material and life science. Therefore, while most SEMs are equipped with a standard BSE detector, optimizing the measurement process of BSEs becomes crucial when considering the wide range of measurements into account and pushing the limits for aiming the maximum performance. In addition to the detection efficiency of the detector, the geometry of the set-up also plays a decisive role. We therefore address the question of how the layout of the detector affects the specific geometries present in SEM setups [1].
In SEM in general, ensuring clear visualization of specimen features relies on several factors, including beam current, pixel dwell time, working distance, and detector efficiency. Below a certain minimum contrast threshold, specimen details may become indistinguishable. However, for certain specimens or setups it may not always be feasible to increase beam currents, adjust beam energy, or change the working distance to enhance contrast. In such cases, maximizing the collection of electrons (here BSEs), becomes essential for obtaining satisfactory results. Achieving this involves optimizing the diode layout, thus emphasizing the importance of selecting suitable detectors aligned with specific measurement requirements for effectively optimizing SEM imaging parameters [2]. But despite the important role of BSE collection efficiency across scientific and industrial domains, the literature addressing this aspect remains relatively sparse, posing a significant challenge for comprehensive research in this field.
We conduct experiments measuring the backscattered electron collection at various working distances to determine the optimal conditions for each type of diode. To provide a quantitative assessment, we introduce the Geometric Collection Efficiency (GCE), defined as the ratio of BSE impinging on the active area of the diode to the total number of BSE leaving the sample. We present GCE values for different diode layouts across varying working distances. These results are supported by simulations of GCE based on the cosine distribution of BSE and the setup geometry.
Our study aims to illuminate a crucial aspect influencing the performance and accuracy of Back-scattered electron Detector (BSD). We seek to quantitatively understand the collection efficiency of backscattered electrons across a diverse range of BSD. Employing BSD with varying active areas ranging from 40 to 420 mm^2 and hole diameters ranging from 1 to 5.6 mm. Moreover, these findings enable the identification of the most suitable diode layout for specific measuring geometries.
Typically, the diode aperture should be sufficiently small to minimize backscattered electron (BSE) loss at shorter working distances, while the outer diameter of the diode must be large enough to capture a greater proportion of BSE at larger working distances. However, this general approach must be adapted to fit within an existing setup, where the hole size additionally impacts the field of view, and the outer diameter may obscure or interfere with other detectors within the SEM. Therefore, it is imperative to determine the optimal diode layout considering both geometric

collection efficiency and mechanical constraints of the setup. Subsequently, we will showcase images from various applications, spanning from low working distance (WD) and low keV scenarios to high-current applications accompanied by parallel energy-dispersive X-ray spectroscopy (EDX) measurements at higher WDs.

In conclusion, our investigation utilizes various BSD with distinct geometries to assess their suitability for diverse applications in SEM. Through systematic evaluation of detector performance under varying experimental parameters, we aim to offer insights into selecting the most appropriate detector for specific imaging tasks or analytical objectives.

Fig. 1. Comparing simulated and experimental Geometric Collection Efficiency (GCE) values for diverse Backscattered Electron (BSE) chips with different geometrical configurations. The analysis reveals a close agreement, providing insights into the performance and accuracy of each chip.

Empowering STEM in SEM: Integrative Approaches for Enhanced Detection

Dr. Maximilian Schmid[1], Mozhdeh Abbasi[1], Adam Meisel[1], Yassine Elamri[1], Dr. Alessia Mafodda, Dr. Stefan Aschauer[1]
[1]PNDetector GmbH, Munich, Germany

Poster Group 1

In parallel to finding new records in resolution in high energy Transmission Electron Microscopes (TEM) applications - somehow a little behind the scenes - the Scanning Electron Microscopes (SEMs) and TEM machines reach out for each other. Scanning Transmission Electron Microscopy (STEM) in SEM becomes a more and more versatile tool for economical STEM examinations. This may be as a pre-study for further STEM measurements in high end machines or as the final inspection tool. Even though this is an ongoing trend, there is still a gap between the detection capabilities of transmitted electrons in SEM and TEM machines. In SEM, STEM detectors mostly range from passive detection - via generated secondary electrons - to diode arrays and simple segmented diodes. In contrast, in TEM machines the varieties span from single cell detectors over multi segmented ring diodes to fully pixelated electron cameras. Nevertheless, there is a strong demand of expanding the detection possibilities in the SEM closer to TEM machines in order to increase the overlap in detection variability. Here, we introduce a versatile multi-channel STEM setup which can be used in SEM as well as TEM sharing the same platform but addressing the specialties of both worlds.

To perform STEM in SEM with the versatility of the TEM system one needs to address the differences in SEM in relation to TEM :

1. In SEMs the electron energies with <30keV are vastly lower than in TEMs. Therefore, the detector diodes are optimized to support electron energies from below 2 keV to 300keV.
2. SEMs in general offer higher scanning rates than TEM machines. Therefore, the pixel dwell times of down to few tens ns are supported.
3. While all diodes can be used in TEM and SEM, new diode geometries are added to address the different setup geometry in SEM. As seen in figure 1. the range starts with 4 channel segmented diodes and goes up to multi-segmented ring structures with and without BF cell.
4. Two mechanical concepts are chosen to fit most microscope chambers as well as addressing the radiation safety in SEM and TEM. Figure 2(a) shows the manual insertion mechanism for SEM systems. It is optimized for x-y-z positioning in SEM chambers. Figure 2(b) shows the pneumatic insertion mechanism mainly for TEM systems with y-z positioning. While the SEM mechanics cannot be adapted to TEM systems, the pneumatic mechanics can also be used for SEM and is therefore mentioned here.

Besides these differences the system shares the same platform. This includes the amplification chain, the acquisition system, and the ability to support up to 13 individual channels. The platform is divided into two configurations. For the use of the image acquisition system of the microscope there is the possibility to use a 4-channel amplification system. This outputs a user specified combination of the 4 signals (4 to 1) to be digitized by an auxiliary input of the SEM. This system also offers minimal pixel dwell times of few tens of ns but is limited in displaying information in parallel.
To utilize the capability of acquiring up to 13 channels in parallel the second configuration comes with a separate imaging acquisition system. Each of the signals is amplified and digitized separately

and the signals can then be digitally combined if needed. Here the minimum pixel dwell time is below 200 ns and there is no limitation in parallel acquisition, displaying or mixing of the individual signals.

In our contribution we will show the results of both configurations with different diode layouts. These examples show how these systems enlarge the STEM in SEM capabilities by sharing more information from the specimen and thus help to close the gap between transmitted electron detection in SEM and TEM.

Seeking peak precision in atomic EELS mapping with counting mode direct electron detection

Dr Duncan Alexander[1], Dr Chih-Ying Hsu[1,2], Dr Pau Torruella[1], Sebastian Cozma[1], Lucia Varbaro[2], Prof. Jean-Marc Triscone[2], Prof. Cécile Hébert[1]
[1]Electron Spectrometry and Microscopy Laboratory (LSME), Institute of Physics (IPHYS), École Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland, [2]Department of Quantum Matter Physics (DQMP), University of Geneva, Geneva, Switzerland

IM-05 (1), Lecture Theater 3, august 26, 2024, 10:30 - 12:30

Since the advent of aberration-corrected scanning transmission electron microscopy (STEM) with electron energy-loss spectroscopy (EELS) spectrum imaging capabilities, atomic resolution STEM-EELS has become a vital technique for probing both elemental compositions and bonding states across epitaxial thin films.[1] Nevertheless, data quality are often limited in terms of spatial and spectral precision. In large part, these limitations have derived from the charge-coupled devices (CCD) that, until recently, have been the primary sensors used for EELS, which are associated with a host of deficits: poor detective quantum efficiency (DQE) and point spread function (PSF); slow read out time and poor duty cycle; and correlated channel noise. Typical consequences for atomic resolution mapping include: spatial distortions from scan drift; strong trade-offs regarding the measurement of sharp spectral features versus large spectral range for measuring many elements; high beam currents and/or long dwell times for obtaining sufficient signal-to-noise; and a noise structure ill-suited to denoising using machine learning algorithms. In comparison, direct electron detection promises to address all of these deficiencies, at the same time. Here, we explore the benefits brought by direct electron detection using a large array monolithic active pixel sensor having ~3.4 k energy channels, coupled to a state-of-the-art EEL spectrometer, with the goal of seeking maximum precision for both spectral peaks (EELS fine structures) and spatial peaks (atomic columns).
As test objects, we take superlattices of perovskite rare-earth nickelates, which constitute both pure and alloyed layers.[2] Not only is it paramount to characterize their chemical nature for correctly interpreting their physical properties, these samples also provide interesting challenges for testing atomic-resolution STEM-EELS, such as the overlap of the rare-earth M edges with each other and with the Ni L edge. The STEM-EELS measurements are made using a Gatan Continuum ERS spectrometer equipped with a K3 detector operated in counting mode, installed on a double-aberration corrected and monochromated FEI Titan Themis 60-300, run at 200 (or 300) kV. Different acquisition strategies are tested: single-EELS, dual-EELS, single frame, multi-frame with on-line drift correction, multi-frame with off-line rigid and non-rigid registration.
The figure shows example results from a superlattice of layers with target compositions of alloy $(0.7Nd,0.3La)NiO_3$ and pure $SmNiO_3$, grown on $LaAlO_3$. The spectrum image was acquired using the detector's maximum speed of 0.34 ms per pixel, with 0.25 Å pixel size, a beam current of 100 pA, 20 and 47 mrad convergence and collection semi-angles, for a total of 5 integrated frames, with frame-by-frame drift correction. The right-hand side of the figure shows background-subtracted raw spectra integrated from regions of $SmNiO_3$ (top), $(Nd,La)NiO_3$ (middle) and $LaAlO_3$ (bottom). Despite the broad spectral range covering all major elemental edges of O K (532 eV), Al K (1560 eV), Ni L (855 eV), La M (832 eV), Nd M (978 eV) and Sm M (1080 eV) from the 0.45 eV/channel dispersion, because of the good PSF, the L and M edge white lines are remarkably sharp. This can be seen in the right-hand insets showing zooms of the La M–Ni L overlap region, where the shapes of both edges can be seen in the $(Nd,La)NiO_3$ alloy. The left-hand insets show the O K-edge onset. Both nickelate layers show a

prepeak at ~528 eV, that derives from hybridization of the O 2p with the Ni 3d, rare earth 5d, and Ni 4sp electronic states. The narrow prepeak is distinctly visible. Further, it acts a sensitive marker of electron flux-induced damage.[3] Its undiminished magnitude in the data show that, because of the detector speed, sensitivity and 100% duty cycle, we were able to stay below the flux damage threshold even with the small 0.25 Å pixel size; an order of magnitude improvement compared to the previous results taken with a CCD-based spectrometer. After denoising the spectrum image using principal component analysis (PCA), a standards-based approach was used to generate the displayed elemental maps, where the O K edge is fitted as either nickelate (O_nick) or $LaAlO_3$ (O_LAO). A clear atomic resolution is attained in all maps; even for Al whose K edge shows very small signal intensity. Fourier transform analysis indicates that the summed denoised spectrum image signal attains a spatial resolution of 1.2 Å. In the single-element Sm map of an $SmNiO_3$ layer, displayed at the bottom right, a resolution of 1.7 Å is achieved. More impressively, the spatial precision is such that this map clearly shows the characteristic ± 20 pm up-down antipolar displacements of the Sm cations in this orthorhombic phase.

In conclusion, a latest-generation counting mode detector shows a step-change improvement for atomic resolution mapping of perovskite oxide heterostructures. While ideal acquisition strategies are still being refined, current results already demonstrate the potential for high precision mapping, both spectrally and spatially. Although PCA-denoised maps are superficially correct, we note that this processing systematically generates spectral artefacts, as shown in the pixel-by-pixel sequence of 3 reconstructed spectra across a Sm column in the bottom right of the figure. Potentially this can be understood as the decomposition identifying the spectral structure of a phase, which however does not properly represent the sharp spatial modulations of the chemically-different atomic columns. Work is in progress to identify other denoising approaches that leverage the Poisson noise structure of the counting mode EELS data while generating a physically-correct output.

WhatEELS upgrade: the software tool based in Python for EELS analysis

Vanessa Costa-Ledesma[1], Daniel del-Pozo-Bueno[1], Francesca Peiró[1], Sònia Estradé[1]
[1]LENS-MIND, Dept. d'Enginyeria Electrònica i Biomèdica and Institute of Nanoscience and Nanotechnology (IN2UB), Universitat de Barcelona, Barcelona, Spain

Poster Group 1

BACKGROUND INCLUDING AIMS
Electron Energy Loss Spectroscopy (EELS) employing a Scanning Transmission Electron Microscope (STEM) offers precise elemental characterization with exceptional spatial resolution. Multiple Linear Least Squares fits are one of the approaches with short convergence times that are typically favoured for spectral unmixing in the quantitative analysis due to the complexity and sizes of the EELS spectrum pictures datasets collected by the state-of-the-art instruments. However, Non-Linear Least Squares (NLLS) fitting could be a better option for analysis in some circumstances, since it does not need calibrated reference spectra and yields information for each of the constituent parts of the fitted model. For efficient analysis of complex datasets, combining clustering segmentation with Non-Linear Least Squares fitting enhances parameter control and accommodates mixed-composition samples. To facilitate this approach, integrating clustering, and NLLS, a modular software solution implemented in Python by J. Blanco-Portals was developed and open for the public in 2022, WhatEELS [1]. In the present work, we update the WhatEELS software with elemental quantification tools [2] using full relativistic cross-sections [3].
METHODS
The interactive shell of WhatEELS is based on Python and, in particular, in the following modules: Panel and Holoviews, and the graphical backend on Bokeh. Below the surface, the NLLS fitting, and background removal are based on a library called lmfit, which expands the SciPy fitting capabilities. The machine learning analysis is based on Hierarchical Density-Based Spatial Clustering of Applications with Noise, Uniform Manifold Approximation and Projection and Support Vector Machines, which the first and the last one are packages from the Scikit-learn library. The full relativistic cross-sections are calculated from Quantum Mechanics following Salvat [3].
RESULTS
We successfully implemented the relativistic elemental quantification in WhatEELS, This testing was applied to iron oxide core-shell nanocubes and iron and manganese oxide core-shell nanoparticles, obtaining the expected results for the quantification.
CONCLUSIONS
WhatEELS is a software tool designed to analyze multiple-pixel EELS datasets by combining clustering algorithms for image segmentation and NLLS fitting routines for improved workflow efficiency. WhatEELS is advantageous for scientists and students who are just starting in EELS data analysis for materials science because of its open-source nature and low programming requirements.

IM-05 (3), Lecture Theater 3, august 27, 2024, 10:30 - 12:30

While modern analytical transmission electron microscopes fitted with an energy-dispersive X-ray (EDX) detector can acquire a huge amount of data at an ever-increasing speed, there is still a need to improve processing tools. Machine learning algorithms based on multivariate statistical analysis are widely used to reduce the dimensionality of datasets and perform denoising. On the other hand, to perform quantification, one needs to fit the EDX spectrum with Gaussians for the X-ray lines and a mathematical model taking into account the Bremsstrahlung background. Usually, those two steps are performed independently: first the statistical decomposition and denoising; and then the fitting and quantification.

With a new Python package named espm, that provides a new algorithm entitled ESpM-NMF, we propose to perform the two steps jointly, where the machine learning algorithm directly learns the parameter characterizing the model of the spectrum. We have, in addition, implemented an advanced regularization procedure to take into account the relatively smooth nature of the spatial distribution of components.
Our method has many advantages:
- It is much more resilient to noise and enables analysis and quantification of datasets with much lower signal than conventional methods.
- It allows prior knowledge to be easily taken into account, such as the fact that some regions of the image may contain only one phase or that some of the phases do/do not contain certain chemical elements. With this, we drastically improve the chances that the results of the decomposition have an actual physical meaning.
- The results of the decomposition naturally contain the information needed for quantification, as we directly learn the height of the Gaussian peaks modelling the X-ray lines. There is therefore no need for a further step of fitting the spectra to obtain relative abundances of elements.

In the following paper, we will demonstrate how we can easily use reasonable a priori knowledge on a sample to guide a decomposition. The sample is a synthetic mineral assemblage used to study Earth's mantle. It has a homogenous starting composition with major elements Si and Mg (besides O), minor elements Fe, Ca & Al, and some dopants. The sample is synthesized in a diamond anvil cell at pressure of 55 GPa, and heated with a laser to around 3200-3500 K, resulting in a complex microstructure of a matrix phase (bridgemanite) containing inclusions (ferropericlase and calcium perovkites). The overall composition of the main phases has, in addition, a gradient towards the center of the heated spot, that is of particular scientific interest. Small regions of the datasets are excluded from the analysis via a mask because they contain an iron-rich core which is not of interest (top right) and a hole due to the FIB preparation (bottom).

An unguided decomposition with two components leads to a nearly realistic result with two phases: a matrix (a), with inclusions (b). However, a close analysis shows that the intensity of the image of the component #2 never goes to 0, indicating an imperfect unmixing. Moreover, the Si content obtained in the matrix phase (panel (a)) is 52 at. %, which is above the expected maximum of 50%. Using a Mask (c), it is possible to force the inclusion component to be 0 in the yellow areas. This is a very reasonable constraint based on evidence from the general structure of the specimen. By doing so, we obtain a more realistic composition of the matrix phase with 48 at. % Si. This finding further supports the supposition that the mask selects a pure phase region containing only the matrix.

A further investigation can be performed using a decomposition with 4 components, of which 2 are forced to represent the matrix by setting the same mask on the other 2 components. This will allow for variations inside each of the 2 main phases. Indeed, as seen in the lower 4 panels of the figure, with this 4-component decomposition, one sees a compositional gradient from top right (close to the central laser spot) to bottom left. In general, both the matrix phase and the inclusions contain more iron as they approach the iron-enriched core.

While not shown in the figure, with our algorithm, it is also possible to constrain the chemical composition of some of the components. The use of well-chosen constraints can be both a way to reach a more realistic segmentation in the actual phases composing the specimen, but is also a powerful method to explore and better understand a complex specimen. As such, ESpM-NMF both redefines the standard pipeline for EDX dataset processing, and offers strong versatility for tailoring the analysis to the specific nature and characteristics of a sample.

3D ED for accurate structure analysis of nanoparticles

Erica Cordero Oyonarte[1], Philippe Boullay[1], Valerie Pralong[1], Luca Rebecchi[2,3], Ilka Kriegel[2]
[1]Normandie Université, ENSICAEN, UNICAEN, CNRS, CRISMAT, Caen, France, [2]Functional Nanosystems, IIT, Genova, Italy, [3]Department of Applied Science and Technology, Politecnico di Torino, Torino, Italy

PS-05 (3), Lecture Theater 3, august 30, 2024, 10:30 - 12:30

Background incl. aims
When it comes to characterizing nanomaterials, electron microscopy offers an unrivalled range of tools. This contribution focuses on the accurate structure analysis of individual nanoparticles (NP) through electron diffraction, particularly on 3D electron diffraction (3D ED) approaches1. In recent years, 3D ED has emerged as a valuable method for accurate structure analysis, specifically in cases where sample size limitations prevented structure analysis by X-ray diffraction. Nevertheless, very few experimental studies have investigated the applicability of 3D ED to small particles (10 nm and less), in particular by examining whether this approach can provide relevant quantitative information concerning the presence of elements in the structure and their localization.

Methods
In 3D ED, diffraction patterns of individual particles are captured at different goniometer tilt positions, using continuous or stepwise acquisition methods. Then, a 3D reconstruction of the reciprocal space of the NPs can be obtained and used for subsequent crystallographic analyses, including determination of cell parameters, space group and overall structure (atomic positions and occupancies). We tested several data acquisition protocols, including continuous rotation 3D ED, precession-assisted 3D ED and serial ED, using different instruments and parallel beam sizes. For small NPs (10 nm or less), the capability to generate parallel beams matching the size of the particles enables the acquisition of high-quality data. With a diffraction volume considerably reduced, lower diffracted intensities are expected, and the use of hybrid pixel detectors is an asset to investigate the size limit of NPs for 3D ED by improving the diffraction signal-to-noise ratio. To meet these requirements, we used a JEOL F200 electron microscope equipped with an ASI Cheetah M3 hybrid pixel detector as our main experimental setup. Beam precession motion, when applied, was achieved using a Nanomegas DigiStar unit. We also found advantages in employing a Gatan Elsa cryogenic and tomographic holder.

Results
The model materials used in this methodological study were nanoparticles of TiO2 (brookite), In2-xSnxO3 (ITO), and MgTi2O5. To assess the capability to localize light elements, lithium was incorporated into the brookite TiO2 structure, resulting in the compound LixTiO2. The feasibility and efficiency of various data acquisition protocols are first established for different particle sizes. For larger NPs, around 100 nm in size, rapid automated data acquisition is possible for different beam sizes. However, for NPs around 10 nm in size, only precession-assisted 3D ED with a small parallel beam has proven effective for subsequent accurate structure refinement (see Graphic rectangle 1). In this case, it becomes possible to achieve atomic position precision on the order of 0.01 Å or 0.03 Å depending on whether we consider dynamical effects in refinement2 or not.
Another approach, similar to serial ED, was also successfully tested in cases where the NPs are subjected to uncontrolled movement induced by an external stimulus. In our example, where NPs are

set in motion by beam energy that modifies the amorphous support (see Graphic rectangle 1), the induced rotation of NPs can be used advantageously to collect hundreds of diffraction patterns from different NPs. Here again, an atomic position accuracy of about 0.03 Å was achieved, considering only kinematical approximation refinement.
In the final part of this contribution, we successfully applied the established 3D ED data acquisition protocol and analysis (i.e. precession-assisted 3D ED and 'dynamical refinement') to two case studies. Firstly, we explored the feasibility of localizing lithium atoms in LixTiO2 (x=0.4) brookite nanorods, which have a maximum width of approximately 100 nm (see Graphic rectangle 2). Second, we addressed the challenge of determining the ratio of magnesium to titanium atoms sharing the same atomic positions within a MgTi2O5 NP of about 30 nm in size (see Graphic rectangle 3).

Conclusion
Our research highlights the ability of 3D ED to perform accurate structural analysis of NPs as small as 10 nm. Although still not widely used, 3D ED is an advanced EM technique offering complementary information to that obtained through imaging or spectroscopy. As examples, we demonstrate the localization of light elements, such as lithium, and the determination of element ratios in atomic positions with a mixed occupancy (in this case Mg/Ti). We are confident that these findings will capture the interest of the community and enhance the understanding of crystallographic structures of new nanoparticles, which are vital for applications in energy materials and catalysis.

These results were obtained as part of the European project NanED (Electron Nanocrystallography – H2020-MSCA-ITN GA956099).

Unsupervised Quantification of large EELS datasets

Prof. Dr. Jo Verbeeck[1,2], Dr. Daen Jannis[1,2], Dr. Wouter Van den Broek[3], Arno Annys[1,2], Dr. Zezhong Zhang[1,2,4], Prof. Dr. Sandra Van Aert[1,2]

IM-02, Lecture Theater 3, august 27, 2024, 14:00 - 16:00

Background incl. aims
Electron energy loss spectroscopy (EELS) has experienced substantial steps forward over the last decades in terms of energy resolution from monochromators, signal to noise and speed from improved detectors, vastly improved optics and stability in spectrometers and advances in the statistical treatment of the recorded data.
Yet, despite these efforts, EELS relies heavily on the interpretation skills of expert operators. This limits the widespread adoption of EELS and leaves room for experimenters' bias posing a significant reproducibility risk.
In this talk, I will give an overview of recent efforts towards the goal of an entirely autonomous data processing workflow, which could significantly improve the quantification of EELS spectra in terms of ease of use, precision and accuracy.
Methods
The method relies on model-based quantification as was e.g. implemented in EELSMODEL [1] but improves on several important aspects:

- The physical model is made entirely linear. This results in a single solution without the need for user provided initial parameter estimates.
- The background modelling process is significantly improved through a combination of a linearized model and constrained quadratic programming methods [2].
- The fine structure is described with a piecewise linear function with a nonlinear energy sampling to express that most significant ELNES features occur near the edge onset
- A complete Dirac-based database of open generalized oscillator strengths significantly improves the fit with experiments and provides a way to improve accuracy and precision. [3]

We investigate automatic identification of all EELS edges present in a dataset making use of neural network approach [4]. This allows building a complete model without any user input thereby completely removing the experimenter's preferences and opinions from the process. We discuss achieved precision approaching the statistical limit and show attempts to evaluate the accuracy with reference samples.

Results
The result provides a reliable quantification with highest possible precision and excellent accuracy and seamlessly provides background subtracted and deconvolved ELNES features without any user intervention. This is particularly interesting for high energy K-edges as they provide a direct lab-based alternative for XAS measurements even for edges that are traditionally considered to be far outside the achievable EELS energy range.

Conclusion
In summary, we believe that the days of manual processing of EELS data are over and fast and fully unsupervised data interpretation is available. Together with advances in EELS spectrometers, this widens the scope of EELS significantly and confirms its position as an indispensable analytical tool, also for non-expert users. It also satisfies the need for high reproducibility, essential in particular for industry applications.

PS-04 (1), Plenary, august 26, 2024, 10:30 - 12:30

Background incl. aims
In a landscape where the global demand for clean and reliable energy sources, and the need to mitigate the environmental impacts of fossil fuels, are constantly growing, lithium-ion batteries (LIBs) represent the most widespread energy storage technology, due to their reliability and excellent electrochemical performance. Nonetheless, the drawbacks of graphite, the most used negative electrode in LIBs, pose the need to study materials that present better outputs. In the limited landscape of alternative anodic materials, one of the most interesting is the family of MXenes: 2D materials with Mn+1XnTx stoichiometry (M represents a transition metal, X carbon or nitrogen, T the functionalization of the layers). However, these materials are obtained by etching the corresponding MAX phase precursor with HF, a seriously hazardous operation. To overcome the issue, we changed the paradigm and thermally treated Sn-doped MAX phases with different levels of Sn doping, obtaining peculiar MAX nanocomposites, and employing them as anodic materials in LIBs. [1] Since the key to understanding their electrochemical behavior lies in the morphology, crystal structure, and formation mechanism of the nanostructures, a multi-approach Transmission Electron Microscopy (TEM) analysis has been the main character in the investigation of the materials, consisting of static High-Resolution TEM (HRTEM), Operando TEM upon electrochemical materials lithiation [2] and pump-probe dynamic Ultrafast TEM (UTEM). [3]
Methods
The Ti3Al(1-x)SnxC2 MAX phase samples with nominal x = 0, 0.4, and 0.7 were synthesized through Spark Plasma Sintering (SPS). They were heated in air at 600°C and studied as anodic materials in LIBs by galvanostatic cycling with potential limitation (GCPL) in two-electrode coin cells. The sample were characterized by neutron and X-ray diffraction, CHNS, thermal gravimetric analysis, Scanning Electron Microscopy and Raman spectroscopy. Static HRTEM was executed with a JEOL JEM 2100 Plus operated at 200 kV at UNIMIB; Operando electrochemical TEM measurements were obtained with a JEOL JEM 2100 Plus at 200 kV at UNIST coupled to a Nanofactory Instruments in-situ Dual-Probe sample-holder used to apply bias and execute the lithiation. The pump-probe UTEM measurements are going to be acquired with a JEOL JEM 2100 coupled with a fs PHAROS laser in stroboscopic mode: the 1030 nm IR laser is both used as the pump and upconverted into UV light used to generate the photoelectron pulses used as the probe.
Results
The electrochemical performances show a very large improvement for the oxidized samples; moreover, the cells show a remarkably increasing capacity for a higher Sn content: it reaches 200 mAh g-1 for Sn0.4_Ox and 250 mAh g-1 for Sn0.7_Ox at 1 C, more than double to the non-Sn-doped material. Moreover, the samples showed an excellent value of Coulombic Efficiency (99.6%) and good stability upon cycling. The structural analysis evidenced the appearance of rutile and SnyTi(1-

y)O2 mixed oxides in the thermally treated samples, and the HRTEM imaging highlighted the morphology of such nanometric crystallites on the MAX phase surface as shown in Figure 1. Since the MAX phase is inert, the potential profiles from the GCPL suggest that for the LIBs the measured capacity is due to mixed mechanisms of intercalation, conversion, and alloying in the nanostructured oxide composite. The main contribution of SnO2 conversion and alloying has been confirmed thanks to the operando electrochemical TEM analysis, which shows the enlargement of the surface structures (clearly depicted in Figure 2), typical of the mentioned mechanisms.
According to our analysis, the presence of Sn lowers the MAX phase resistance to oxidation, giving a lower oxidation temperature and a higher percentage of oxides, which is confirmed also by CHNS; for a complete understanding of the process, as sketched in Figure 3, pump-probe dynamic UTEM measurements will be crucial to unveil the onset of the transient structural modification upon laser heating which leads to oxidation in the presence of oxygen.
Conclusions
Our study has highlighted that the unaltered conductive MAX phase cores show a beneficial role to the surrounding oxide nanoparticles since they can ensure sufficient electrical contact. In addition, as testified by the good stability of the samples, the SnyTi(1-y)O2 solid solution prevents the huge volume changes that pure SnO2 particles typically show, which cause an important loss of capacity after a few cycles due to active material shattering. Our investigation underscores the indispensable role of a diverse TEM analysis in elucidating the electrochemical behavior and structural transformations of the Ti/Sn oxides and Sn-doped MAX phase composite, paving the way for the rational design and optimization of such nanocomposites for next-generation LIBs.

Many-body effects in the electron-atom ionization cross section in Quantum Electrodynamics

Dr. Ioannis Iatrakis[1], Dr. Valerii Brudanin[2]
[1]Thermo Fisher Scientific, Eindhoven, Netherlands, [2]Delft University of Technology, Delft, Netherlands

Poster Group 1

The elemental composition of materials in the Transmission Electron Microscope is probed by inner shell ionization of atoms from highly energetic impact electrons. The ionization process is localized and can be well described by the electron-atom ionization cross section for the purpose of elemental quantification of TEM samples. The inelastic differential cross section is calculated in the context of Quantum Electrodynamics (QED) for a target of a neutral free atom, which is coupled to the QED Lagrangian as an external source. The beam-atom interaction factorizes and is treated perturbatively in QED, where the contributions of the transverse photons along with the Coulomb interaction are explicitly included. The multi-electron atomic transition currents are calculated in the context of the self-consistent Dirac-Hartree-Fock method. Hence, the relativistic effects on the atomic structure are explicitly included in this derivation. Higher order relativistic corrections of the electron-electron interaction within the atom are also assessed. The nuclear charge density which is used in the Dirac-Hartree-Fock calculation is modeled as a Fermi distribution. The many body effects are known to be particularly important for excitation processes in atoms, and they are shown to have significant impact on the shape of the cross section near the ionization threshold in Electron Energy Loss Spectra. The ionization energies are also calculated in this context and are shown to agree with experimental results.

Poster Group 2

Background incl. aims
Neumann's principle states that symmetries of physical properties (e.g., dielectric / piezoelectric / elastic tensor) derive from structural point (space) symmetry groups of the crystal lattice. The same can be applied for magnetism: the symmetry of magnetic properties (e.g., anomalous Hall effect, multiferroicity, altermagnetism) is determined by the magnetic point (space) group symmetry of the magnetic crystal. Consequently, the ability to determine such symmetries is crucial for the prediction of physical properties of new materials. Currently, the only probe for magnetic point and space group symmetries was neutron diffraction, requiring rather large samples and scarce beam time to be carried out.
It is well known, on the other hand, that convergent beam electron-beam diffraction methods can be used to determine spatial symmetries of crystalline samples, due to the direct relationship between the diffraction groups (symmetry group of convergent electron diffraction patterns) and the point (space) group of the sample [1]. In this work we employ group theory and electron scattering simulations to demonstrate an extension of CBED toward capable to determine magnetic point groups. The method would be applicable in Transmission Electron Microscopes with spatial resolution in the range of 10 nanometers.
Methods
Magnetic electron diffraction groups are composed of standard electron diffraction groups [1] plus time (magnetization) reversal symmetry. We used group theory to obtain and classify all 125 possible magnetic electron diffraction groups obtained by this procedure. The cornerstones for such a theory are the commutation of time-reversal with all other symmetry transformations and its antiunitary character. In a second step we establish the relations between the 122 crystallographic magnetic point groups and the electron diffraction groups for different zone axis orientations of the sample in the electron diffraction experiment.
The verify the theory, dynamic electron scattering simulations for samples with different magnetic point group symmetries and crystal orientations were conducted to obtain convergent beam electron diffraction patterns with magnetic Bragg discs.
Results
We provide the group theory for convergent beam electron diffraction of magnetic crystals and give a complete mapping of magnetic point groups to corresponding diffraction groups for all possible crystal orientations. We conduct electron scattering simulations for selected antiferromagnetic samples (NiO, etc.) in order to verify the group theoretical considerations. It is shown that obtained symmetries from simulated electron diffraction images correspond to the expected magnetic point groups of the samples.
Conclusion
This work proposes convergent beam electron diffraction as an alternative of neutron diffraction for unambiguous determination of magnetic point group symmetry. With a given map of magnetic point

groups to corresponding electron diffraction groups one can determine the latter from a finite series of diffraction experiments at different crystal orientations. Simplicity, accuracy and relatively small spatial resolution of a proposed method makes it an intriguing candidate for magnetic symmetry detection and investigation.

PS-10, Lecture Theater 5, august 26, 2024, 15:00 - 16:00

Background incl. aims
In conventional metals, the conduction electrons show Fermi-liquid behavior with a characteristic quadratic dependence of the resistance on temperature. In contrast, in so-called “strange” metals the Fermi-liquid behavior breaks down due to strong correlation of the charge carriers, which has various consequences, e.g. a linear dependence of the resistance on the temperature. On the other hand, “strange” metals show unconventional and partially also high temperature superconductivity. Since the latter is supposed to be related to the non-Fermi-liquid behavior, the electronic structures of “strange” metals are of great interest in the field of solid state physics. Here we study the charge density-density response connected with plasmon excitations in the layered material Sr_2RuO_4, a representative of the class of “strange” metals [1]. We also wanted to test a theoretical prediction based on holography calculations [2] that plasmons in “strange” metals are overdamped.
Methods
Focused ion beam milling was used to prepare a lamella in which the layers are oriented perpendicular to the surface. This lamella was investigated using momentum resolved electron energy-loss spectroscopy (M-EELS) in a monochromized transmission electron microscope. Plasmon excitation in dependence on the momentum parallel and perpendicular to the layers was measured almost over the whole Brillouin zone [see Fig. 1 (a)] with a spectral and momentum resolution of 120 meV and 0.04 1/Å, respectively. The experimental data was compared to theoretical predictions of the Fetter model [3] and with the susceptibility χ_0 calculated from a tight binding band structure, all derived in terms of mean-field random-phase approximation.
Results
The M-EELS data show dispersing plasmon excitations below 1.8 eV with a continuous transition between the optical plasmon at qc=0 [purple squares in Fig. 1 (b)] and the acoustic plasmon at qc=0.4 1/Å [red squares in Fig. 1 (b)] close to the edge of the Brillouin zone at qc=0.49 1/Å. All curves are generally in good agreement with the theoretical calculations within the Fetter model taking into account a coupled system of 2D plasmons in the layered crystal structure. However, for qa ≥ qcrit there are differences between the theoretical curves and the experimental data, which can be explained by Landau damping [see open symbols in Fig. 1 (b)]. Here, qcrit is the momentum at which the dispersion curves merge into the single-particle-particle continuum χ_0 [see gray shaded regions in Fig. 1 (b)].
As predicted by the Fetter model, the measured dispersion at qc=0.4 1/Å extrapolates approximately to zero energy, which is characteristic for an acoustical plasmon. A fit of the experimental plasmon data to the Fetter model reveals that the dispersion is determined by the spacing of the layers and is only weakly influenced by many-body interactions.
Conclusion
The long wavelength qa dispersion of the qc dependent plasmons, including the optical and the acoustic collective excitations, resembles the data of the Fetter model, i.e., that of coupled 2D

plasmons. Moreover, the critical momentum qcrit, at which the experimental data starts to deviate from the theoretical curves, agrees well with the calculated susceptibility χ0. In summary, all data can be well explained within the framework of a mean-field random-phase approximation model. On the other hand, we found no evidence supporting theories predicting an overdamped plasmon, i.e., a transition of the plasmon into a featureless, momentum-independent continuum already at very small momentum [2].

PS-11, Lecture Theater 2, august 28, 2024, 14:00 - 16:00

Background and aims.
Nanomaterials with chiroptical properties absorb differently left- and right-handed light, an asymmetry that is reinforced by the local surface plasmon resonance of metallic nanoparticles. The synthesis of such chiral particles with controlled shapes and optical properties is of major interest for a host of potential applications including bio-sensing, therapeutics or catalysis, and can be realized by transferring chirality from an organic inducer to the inorganic material in seed-mediated colloidal synthesis [1,2]. Usually, the handedness of the inducer is thought to be transferred to the product [1]. However, recent studies showed that the geometry of the achiral seeds can also influence handedness, even if the same inducer is used [3], and it remains unclear if such effect is related to morphological or structural (surface facets, twin boundaries, defects, …) properties.
Here, we aimed to understand the effect of the seeds on the growth of chiral features. Specifically, we investigated the growth starting on well-defined single-crystal (SC) or penta-twinned (PT) gold nanorod (NR) seeds. To uncover the complex morphological changes at the nanoscale, we used electron tomography (ET), a method that enables three-dimensional (3D) reconstructions down to the atomic scale. In two different synthesis protocols, micelle-templated or chemically induced, 3D reconstructions and nanoscale morphological analysis showed that the final products had reverse handedness and strong morphological differences when using PT or SC seeds [4].
Methods.
We studied the growth of chiral features on well-controlled achiral gold seeds synthesized by wet chemistry. The two systems investigated here were PT NRs featuring five {100} lateral facets and caped by {111} facets at the tips, and SC NRs with an octagonal cross-section, {520} lateral facets and {110} and {100} tips. Chiral features were grown by two protocols. The chemically induced pathway used the chiral L-cystine (L-cys) amino-acid, which was previously reported to yield highly twisted structures on SC seeds [2]. The micelle-templated protocol used chiral, worm-like micelles formed by (S)-1,1’-binaphthyl-2,2-diamine (S-BINAMINE) and cetyltrimethylammonium chloride (CTAC), that are known to yield wrinkled, helical, NRs [1]. The optical properties of the seeds and of the products were characterized by extinction spectroscopy and circular dichroism (CD) measurements.
To characterize the morphology and structure of the final products, we used ET, whereby projection images acquired at incremental tilt-angles are used to compute a 3D reconstruction of the object. Tilt-series were acquired in 2-3° increments and in scanning transmission electron microscopy (STEM) high angle annular dark field (HAADF) mode to provide mass-thickness contrast and meet the requirements for accurate reconstructions. The reconstructions were computed using an expected maximization (EM) algorithm or a constraint SIRT approach developed in-house and implemented in

Matlab with the ASTRA toolbox. Morphological analyses included helicity measurements and orientation tracking. Helicity uses a surface mesh extracted from reconstructions to compute a pseudoscalar metric indicating how close to a perfect helix the shape is and its handedness (positive helicity means right-handed, negative means left-handed) [5]. Orientation tracking reveals the dominant orientation of features around a NR to study the local variations of chirality and was implemented using a combination of the ImageJ OrientationJ plugin and in-house code.
Results.
Regardless of the synthetic pathway, starting from PT or SC seeds resulted in products with opposite signs in CD spectra, indicating a reverse handedness. Strong discrepancies were further seen in the morphology of the particles, as reconstructed in ET. With the L-Cys protocol, SC seeds resulted in strongly twisted NRs with clear right-handed morphology (Figure, a). This observation was supported by helicity measurements, showing strongly positive values. On the other hand, PT seeds resulted in poorly defined, highly complex shapes with no obvious handedness (Figure, b). Helicity measurements were typically weak, with a complex combination of right and left-handed features in each particle leading to some NRs exhibiting a dominantly left handedness and others with right handedness (Figure, b). This observation suggests that optical handedness is not limited to helical features. Overall, a strong influence from the seed crystal structure was expected in this growth protocol, as chirality emerges through the preferential growth of chiral facets stabilized by the chiral inducer. More surprisingly, micelle-templated NRs grown from PT seeds also had an opposite sign in CD spectra as compared to their SC counterpart. ET reconstructions showed closely resembling wrinkled morphologies in both cases, with a major difference in the orientation of the wrinkles (Figure, c, d). PT NRs showed left-handed wrinkles, coherently with positive g-factor plots, while SC NRs showed right-handed features. Helicity measurements confirmed this observation by showing close absolute values but opposite signs.
To further probe how the morphology of the seeds was impacting the final micelle-templated products, we assessed if the presence of corners and lateral facets influenced the wrinkle morphology beyond the global particle handedness. Notably, the tips featured better aligned wrinkles on SC NRs, and wrinkles on the lateral facets grew at different angles. Tracking the dominant orientation of wrinkles around the particles also revealed that PT NRs retained a 5-fold symmetry with alternating areas of flat and oriented wrinkles (Figure, c, d). In contrast, SC NRs had a 4-fold symmetry with similarly alternating flat and oriented wrinkles, coherent with an intermediate with square cross-section we previously identified. These observations confirm that the way micelles adsorb on the seeds' surface is influenced by geometrical (angles, number of facets) or crystallographic (facet index) consideration, in turn impacting the orientation of wrinkle growth and, likely, the handedness of the particle.
Conclusion.
We used ET and detailed nanoscale morphological analyses to show that the nature of the achiral seed in chiral seeded growth has a major influence on the handedness of the products and on their chiroptical properties. Furthermore, this observation in micelle-templated growth shows that wrinkle growth is not random but influenced by geometrical or crystallographic factors. This work enhances the toolbox for controlling chirality at the nanoscale and demonstrates the benefits of ET in linking morphology and optical properties, supporting the development of novel optical nanomaterials.

Poster Group 1

Lorentz microscopy is one of the powerful observation methods without the influence of magnetic field from the objective lens (OL) of a transmission electron microscope (TEM). Normally, the magnetic field around the TEM specimen is about 2T. This field could affect the observation of magnetic material. To avoid the influence, OL is turned off and the lens under the OL is used as focus lens, where it is called an objective mini-lens (OM) in JEOL instrument. We can use the OL to apply some amount of magnetic field to samples in Lorentz microscopy [1]. Recently, the spherical aberration correction was applied to Lorentz microscopy, the resolution was improved [2]. In addition, the applied magnetic field with OL is possible with spherical aberration correction. In this research, we characterized the detailed capabilities of spherical aberration-corrected Lorentz TEM while applying magnetic field by the OL.

In this time, JEM-ARM300F2 with TEM spherical aberration corrector was used. The pole-piece was wide gap pole-piece. The TEM resolutions with / without spherical aberration correction were investigated in 300kV. The varied resolution with applying the magnetic field and the field of view were also measured at that time. The aberration measurement was done by diffractogram tableau method. The correction area was about 4mrad and the third order spherical aberration coefficient of OM was under 10mm.

The Young's fringe test was performed to check the TEM resolution. The resolution without spherical aberration correction was 1.83nm without applying the magnetic field, 1.75nm with 0.5T and 1.61nm with 1T. On the other hand, they were improved with spherical aberration correction. 0.76nm, 0.67nm and 0.58nm with 0T, 0.5T and 1T were achieved. The effective field of view (FOV) was changed as applying magnetic field with objective lens. FOV was decreased as a function of the applied magnetic field. They were measured to be 200µm with 0.3T, and 20µm with 1T. This limitation was occurred by replicating of electron beam. The replicating was caused by the aberration of imaging system. On the other hand, the ratios of magnification were increased 6% with 0.5T and 45% with 1T.

The principal plane of complex lens was getting closer to the sample plane as applying magnetic field. The complex lens was formed by OM and OL. This lens improved the spatial resolution, and this result showed the resolution was limited by the chromatic aberration.

We have addressed making a setting of aberration-corrected Lorentz TEM imaging mode. The TEM resolution was improved by spherical aberration correction of OM. Additionally, applying the magnetic field by the OL, the resolution was also slightly improved. The magnification and FOV were changed as a function of applied magnetic field. In the presentation, which condition could be the better for imaging a magnetic sample will be discussed.

Background and aims.
Some optical nanomaterials exhibit the intriguing property of absorbing differently left- and right-handed polarized light. This optical handedness often arises from morphological chirality, the fact that mirrored shapes do not superimpose, but the quantitative relationships between morphology and optical properties are poorly understood. Establishing this knowledge requires accurate characterization the nanomaterials' morphology, as well as the calculation of chirality descriptors relevant to the optical properties of interest [1]. A prime example of such combination is the quantification of helicity from electron tomography (ET) three-dimensional (3D) reconstructions, which we previously presented [2]. Applied to wrinkled or twisted geometries such as those of chiral Au nanorods (NRs), this method informs about the helical character of the NRs and their handedness and is an excellent predictor of the sign of their circular dichroism (CD) spectra. However, helicity is a radially averaged measure, which limits its local interpretation, and entails strong geometrical assumptions, which limits its value for non-helical shapes even as they may still be chiral and exhibit clear optical handedness.
Here, we explored how different descriptors of chirality obtained from ET reconstructions can complement each other to link nanoscale morphology and optical handedness. To understand how local chiral features were varying, we first implemented a measure of their orientation, providing insights into both global and local handedness [3]. To overcome geometrical assumption, we then studied methods quantifying asymmetry on the basis of the difference between a geometry and its mirror image, including the Hausdorff chirality measure [1,4]. We finally tested if, beyond individual metrics, chiroptical performance could be statistically linked with a learned combination of morphological and chirality descriptors.
Methods.
As a prerequisite to study and establish chiral descriptors, a large dataset of ET reconstructions of chiral Au NRs was assembled. The particles in this dataset were typically 50-150 nm-long and were synthesized by seed-mediated growth. Two synthesis pathways were included: micelle-templating, whereby chiral micelles coil around achiral Au NR seeds, resulting in the growth of wrinkled particles whose helical morphology is characterized by a narrow pitch and a small helical orientation; chemical-inducing whereby chiral molecules such as amino-acids induce the preferential growth of high order, chiral surface facets. This latter approach yields highly helical, twisted structures with long pitches and high helical orientations when starting from single-crystalline seeds, but also strongly deformed, asymmetrical structures without clear geometrical handedness nor helical

character but a handed optical signal when starting from pentatwinned seeds. In addition, the dataset includes the optical properties of all batches from which the particles are sampled, including absorption and CD spectra.
ET tilt-series were obtained in high angle annular dark field (HAADF) scanning transmission electron microscopy (STEM) and typically span 130-140° in 2 or 3° increments. 3D reconstructions were performed using the SIRT, expected maximization (EM) or constrained SIRT algorithms with in-house code or the ASTRA toolbox.
Surface orientation was computed using the ImageJ plugin OrientationJ while other computations and the statistical analyses were performed in python or Matlab with in-house code.
Results.
We first investigated how to obtain local analysis of the orientation of chiral features. Typically, chirality measures provide summary data, with a single metric indicating the degree of chirality and/or the handedness. Here, the orientation of chiral features on Au NRs was tracked and analyzed with spatial accuracy around the NR, evidencing local variations that were not visible when analyzing helicity (Figure, a-d).
To further quantify the chirality of non-helical structures, we investigated methods based on the calculation of the difference between a reconstruction and its mirror image. Such a descriptor effectively quantifies asymmetry, without considerations of handedness, and the difference is typically evaluated on the basis the Hausdorff distance, yielding the Hausdorff chirality measure. We found that optimizing for the minimum Hausdorff distance as required to calculate the measure requires long computation times if the full surface is used, limiting the applicability to simple shapes. As an alternative, we used a shape overlap measure (Figure, e-g), which can be calculated at a fraction of the cost. This method provided results similar to the Hausdorff chirality measure for classifying particles on the basis of their asymmetry and demonstrated that the morphology of non-helical structures could still be highly chiral (Figure, g-h), thus complementing helicity and orientation-based analyses.
Although powerful because of their simple interpretation, orientation, helicity and chiral distances are descriptors that provide part of the information only. We finally investigated if a combination, rather than a single descriptor, can predict optical properties from morphological data. Given the vast amount of data accumulated by our lab in the recent years, we will present how such combination could be learned statistically from ET reconstructions and the corresponding optical spectra.
Conclusion.
Beyond helicity, orientation tracking and asymmetry quantification provide insights into different aspects of morphological chirality. The key towards fully characterizing chirality might be in their adequate combination. Focusing on interpretable descriptors, this work expands the toolbox for microscopists to quantify chirality from ET reconstructions and paves the way towards establishing quantitative relationships between the morphology of chiral nanomaterials and their optical properties.

Femtosecond electron beam probe of ultrafast electronics

Maximilian Mattes[1], Dr Mikhail Volkov[1], Prof Dr Peter Baum[1]
[1]Universität Konstanz, Konstanz, Germany

IM-08, Lecture Theater 2, august 28, 2024, 10:30 - 12:30

Background and Experiment

The need for ever-faster information processing requires exceptionally small devices that operate at frequencies approaching the terahertz and petahertz regimes. However, electronics itself is too slow to characterize a record-breaking device. Here we show how ultrafast electron beam probe with terahertz-compressed electron pulses can directly sense local electro-magnetic fields in electronic devices with femtosecond, micrometre and millivolt resolution under normal operation conditions [1].

Figure 1 shows the concept of our experiment. We use a femtosecond laser (red) that creates femtosecond electron pulses (grey) with only one electron per pulse. This electron pulse is then further shortened in time to less than 100 fs by using all optical terahertz compression [2]. These ultrashort electron pulses probe the local electromagnetic fields in our device under test (DUT), which is shown in Figure 1. We create a short voltage pulse by exciting a photoconductive switch. The generated femtosecond voltage pulses (magenta) travel through our device under test and the device response deflects the electron beam as a function of space and time. From the resulting electron beam deflections, we then obtain the strength and direction of the local electromagnetic fields [1]. The electron beam does not distort the dynamics under investigation and the measurement is therefore contact-less and impedance-free.

Results and outlook

In a proof of principle experiment, we investigate a coplanar waveguide which is the standard transmission line in high-frequency electronics. We fabricate the structure by lithography and drill two holes into the substrate for investigation. We observe the impulse response, signal reflections, attenuation and waveguide dispersion directly in the time domain. We find that the experiment has a sensitivity to electric potentials down to tens of millivolt or -20 dBm. With our 100-fs electron pulses, the bandwidth exceeds 10 THz which is well sufficient for almost any modern or near-future circuitry. In order to eventually obtain a full movie in space and time, we also report the design of an ultrafast transmission electron microscope with terahertz compression [3]. The use of an optical cavity with magnetic or electric nodes at the point of electron-terahertz interaction provides an almost aberration-free control. In this way, we can reach nanometer spatial resolution and reach even shorter electron pulse lengths down to 19 fs [3].

Our femtosecond time resolution and the capability to directly integrate our technique into existing electron-beam inspection devices in semiconductor industry make our femtosecond electron beam probe a promising tool for research and development of next-generation electronics at unprecedented speed and size.

Fig. 1. A laser pump pulse (red) creates a voltage pulse (magenta) by closing a photoconductive switch. This pulse then travels into the device under test and triggers its operation. Femtosecond electron pulses (grey) probe the local electric and magnetic field (magenta) [1].

Poster Group 1

Background: Array tomography is a flexible volume electron microscopy (vEM) workflow due to its non-destructive nature, multi-scale imaging (mm to nm sized imaging regions) and well-established correlative light and electron microscopy (CLEM) compatibility. Sections are collected on a solid, conductive support, and can be imaged multiple times at different resolutions.
There is a constant evolution and improvement of protocols/techniques for array tomography. Acquisition bottlenecks have pushed the development of workflows to tackle imaging efficiency. However, establishing standards for reproducible specimen preparation remains unsolved. There are a wide variety of preparation methods, contrasting techniques, and individual heterogeneity that affect uptake of stains and the visualisation of ultrastructure. This makes it difficult to directly compare experiments and different types of specimens, which can have repercussions on the reconstruction of vEM data. Quantitative compositional analysis, such as energy dispersive x-ray spectrometry (EDS), can help to identify common baselines and standards, positively impacting comparative data analysis and potentially facilitating automated segmentation of volume data.
We present Backscattered Electron and X-ray (BEX) imaging for the simultaneous and combined acquisition of backscattered electron (BSE) and x-ray data in a scanning electron microscope. BEX acquires ultrastructural and composition data simultaneously, providing fast and automated mapping across a large area of sample.

Methods: We used Unity (a BEX detector, Oxford Instruments, UK) combined with an Ultim 100 (Oxford Instruments, UK) to image array tomography slices of mouse brain tissue prepared with an adapted ROTO protocol. Large areas were collected automatically, using cartography mode, in a Zeiss 460 (Carl Zeiss Microscopy GmbH, Germany) operated at 8kV, 1-2nA probe current, at 7.5mm WD, 10µs dwell time.

Results: BEX cartography data achieved high resolution and fast mapping of array tomography brain slices. Large areas were imaged with a relatively short beam dwell time (10µs), which reduces beam damage, drift, and resin charging (Figure 1). Elemental information was acquired simultaneously and provided chemical differentiation that can be used to further distinguish between sample features, opening the possibility of improving subsequent segmentation of data. BEX also provided information about strain distribution, which EDS quantified. Being able to measure the amount of stain taken up by the sample improves our ability to make direct comparisons between samples and also enables us to optimise our sample preparation techniques.

Figure 1. Large area 7x8 tiles acquired using cartography mode. Top inset displayed at 50% zoom allows to easily distinguish different cell borders. Bottom inset at 100% zoom with a 10nm pixel size with detailed membranes in mitochondria and small vesicles (15-30nm range).
Conclusions: Creating reference specimens for the vEM community has been previously proposed, as benchmarks to compare microscopes, imaging conditions and image segmentation tools. As a high speed and sensitive imaging technique, BEX opens the way towards controlled reproducibility by complementing array tomography ultrastructural images with chemical information.

Conclusions: Creating reference specimens for the vEM community has been previously proposed, as benchmarks to compare microscopes, imaging conditions and image segmentation tools. Poster Group 2

Background incl. aims
Interaction of electromagnetic waves, such as electron beams or light, with conductive material can lead to localized surface plasmon resonances (LSPRs) where the incoming energy can be deposited in a collective excitation of electrons of the conduction band, which in turn can result in coherent localized plasmon oscillations. LSPR in metallic nanostructures, such as nanoparticles (NPs), which are sensitive to geometry, material composition and environment, are currently utilized in a wide range of applications, such as surface-enhanced Raman spectroscopy, plasmonic wave guides, improved solar cells, on-chip particle accelerators and nanoantennas. A host of studies that focus on plasmonic NPs ranging from single NPs with several shapes (cubic, spherical, tetrahedral) over 1D assemblies of NPs such as chains [1], to ordered 2D assemblies of NPs [2] show an increase of the complexity regarding the hybridization behavior of LSPRs eventually lead to delocalized Surface Plasmons. Furthermore, Anderson predicted in 1977 [3] the absence of diffusion or delocalization of waves in disordered systems, which has been discussed as the underlying mechanism for LSPRs localization in disordered metallic thin films and ultrathin 2D networks [4]. Our aim is to further develop these studies on the surface plasmon localization in disordered structures by (1) developing a novel NPs assembly fabrication method that allows fabricating disordered assemblies of NPs of a wide range of NPs sizes, and (2) probing the LSPR with high-resolution electron energy-loss spectroscopy (EELS). Moreover, the dominant dipolar interaction between the NPs, also facilitates an efficient numerical modeling of these systems, which in comparison with the experiments allows for an in-depth study of the impact of various geometric parameters as well as retardation and life-time damping on the observed localization behavior.

Methods
To synthesize 2D disordered assemblies of gold NPs on a TEM transparent silicon oxide substrate, a new synthesis routine was developed. This procedure is based on sublimation and redeposition of a gold microparticle precursor induced by an electron beam in a scanning electron microscope (SEM) operated at 30 kV. To characterize the assembly of synthesized NPs in terms of size, shape and spreading over the substrate, TEM measurements were conducted subsequently. To study LSPRs experimentally, EELS in scanning transmission electron microscopy (STEM) mode was carried out. The numerical modelling of LSPRs was performed using a self-consistent dipole model.

Results
The synthesized 2D disordered gold NPs assemblies (see Fig. 1a) exhibit a gradient in the NPs mean size, which ranges from 100 nm close to the precursor location down to 2 nm at a distance of more than 20 µm from the precursor location. Additionally, the interparticle distance between the gold NPs increases with increasing distance to the precursor location.

The experimental investigation (see Fig. 1b) as well as the numerical simulation (see Fig. 1c) of the LSPRs demonstrate a localization behavior that decreases toward larger energies, which is driven by the disorder of the NPs assembly (mainly the random particle distance). That localization behavior stays in contrast to what was found in ultrathin 2D gold networks showing increasing of localization towards higher LSPRs energies. By varying the geometric parameters of the NPs assembly in the simulation, we could identify the NPs thickness as the parameter, that determines the energy-dependence of the localization. Specifically, a critical thickness of approx. 10 nm separates the two localization regimes, which correlates to the energy of the dipole mode resonance crucially depending on the thickness of the NPs.

Conclusion

2D disordered assemblies of gold NPs of a wide range of NPs sizes and distances can be synthesized directly on thin substrates facilitating structural characterization and EELS measurements in a TEM. It could be shown that such assemblies exhibit LSPRs with a localization behavior that may be tuned by the NPs sizes (including thickness) and interparticle distances. The proposed synthesis of random NPs assemblies opens new avenues for fundamental studies on Anderson localization in disordered plasmonic structures as well as its applications such as surface-enhanced Raman spectroscopy where localization behavior must be tuned to specific wave lengths.

Exploring the infection cycle of Vaccinia virus using 3D EM with the FIB-SEM

Sandra Sara[1]
[1]Université Paris-Saclay, CEA, CNRS, Institute for Integrative Biology of the Cell (I2BC), Gif-Sur-Yvette, France

LS-07 (1), Lecture Theater 4, august 28, 2024, 11:30 - 12:30

Background incl. aims
Since its successful use as a live vaccine to eradicate Variola virus, the etiologic agent of smallpox, Vaccinia virus (VACV) has become a model to study the mechanisms underlying key processes of infection by poxviruses. At early stages of infection, viral genome replication takes place in the replication compartments, also known as viral factories. Following early viral genome replication, these viral factories subsequently seem to dissociate concomitant with VACV assembly that rely on a unique membrane acquisition mechanism. In brief, assembly of new virions involves the recruitment of vesicles from the endoplasmic reticulum, which are then ruptured-open and associate as crescents with open membrane ends. After packaging of the viral genome, the crescents are closed, forming the spherical immature virions. We aim to decipher the remodeling of VACV-infected cells during the stages of virion assembly by 3D reconstruction using the FIB-SEM technology.

Methods
Cells are cultured and infected with VACV Western Reserve strain on glass coverslips, followed by fixation using aldehyde. Subsequent steps involve post-fixation and staining with osmium tetroxide and uranyl acetate. After dehydration with an ethanol gradient, the cells are embedded in araldite resin and polymerized for 48 hours at 60°C. The resin blocks are then mounted on the FIB-SEM stub using argent lacquer, with cells protected by a platinum layer. To acquire a 3D volume, the slice-and-view approach is employed, starting with acquisition of an image stack. Subsequently, the raw images are pre-aligned using the SIFT algorithm through translation to create a template. Then, the raw data is aligned with the template created using affine transformations. Once the volume is obtained, segmentation can be performed using various software tools for subsequent data analysis.

Results
Spatial reorganization of VACV-infected HeLa cells was investigated through the acquisition of slices from a 3D volume at 8 hours post-infection, employing a FIB-SEM Cross-beam 550 system. The images, captured using electrons backscattered by the EsB detector, exhibited a pixel resolution and slice thickness of 15 nm each. Within the acquired volume, discernible changes in the organization of the endoplasmic reticulum (ER) were observed, indicative of the VACV viral replication compartment. Additionally, crescent-shaped membranes were evident in the assembly compartment, suggesting ongoing viral assembly processes. . These findings are presented in 3D format following segmentation of the various compartments and VACV virions.

Conclusion
We successfully optimized the sample preparation protocols for 3D EM analysis by FIB-SEM of VACV-infected HeLa cells. Additionally, we established an imaging workflow and implemented data acquisition of large volumes using the FIB-SEM slice and view approach. Through these efforts, we elucidated the virus-induced cellular reorganization, revealing the presence of the viral replication compartment, along with assembly involving both immature and mature virions.

The geometry of STEM tomography

Matthew Weyland[1]
[1]Monash Centre for Electron Microscopy, Monash University, , Australia, [2]Department of Materials Science and Engineering, Monash University, , Australia

IM-01, Lecture Theater 1, august 26, 2024, 14:00 - 16:00

Electron tomography (ET) by scanning transmission electron microscopy (STEM) [1], is a mature technique which has become part of the standard repository of tools available to electron microscopists in the physical sciences [2]. The acquisition of datasets is often carried out using commercially purchased automated acquisition tools, available from a number of microscope [3], accessory manufacturers or freeware solutions [4]. These automated tools save time, minimise dose, reduce the potential for error and prevent the operator dying from boredom. Whichever package is used for the acquisition they tend to follow a set approach, codified during the development of STEM tomography in the early 2000's [1]. This, while it works, has a number of problematic characteristics that have never been addressed in subsequent studies. One of these problems is the mismatch between the relative geometries of the STEM acquisition and that which is ideal for tomographic reconstruction. This is a consequence of choosing the scan rotation to place the fast scan direction parallel to the tilt axis; usually to allow the use of dynamic focussing. This choice just happens to maximise the degradation of the quality of the data due to specimen drift. The nature of this mismatch will be explored and demonstrated using both theory and experiment. The theory will be demonstrated with phantoms and the experiments will apply "forced" drift to accentuate the issues. A number of different solutions will be suggested and demonstrated. The potential for improved quality in reconstructions will be explored and discussed.

Poster Group 2

Background: We have developed a new method, named 4D-STEM/PNBD (i.e., four-dimensional scanning transmission electron microscopy/powder nanobeam diffraction), which can convert a modern SEM microscope to a simple, fast, and user-friendly powder electron diffractometer [1, 2]. The only hardware requirement is that the SEM microscope must be equipped with a 2D-array detector of transmitted electrons (also referred to as 2D-array STEM detector or pixelated STEM). In 4D-STEM/PNBD, we reduce a huge and complex 4D-STEM-in-SEM dataset to a single 2D powder diffraction pattern (as shown in the attached figure). The final powder diffraction patterns are equivalent to those from TEM/SAED as documented in our previous studies [1-3]. They can be compared to theoretically calculated powder X-ray diffraction patterns (PXRD) in order to identify the investigated nanocrystals [2, 3]. This contribution deals with the recent improvements of our method, which should make it even more user-friendly and robust [3, 4].

Materials and methods: We performed TEM/SAED (selected area electron diffraction) and 4D-STEM/PNBD measurements on three types of nanocrystalline samples on an electron-transparent carbon film. The samples differed by signal-to-noise ratio (SNR), where signal and noise are represented by the intensity of diffraction peaks and the amorphous background, respectively. The samples could be grouped as follows: (i) Au nanoislands with high SNR, (ii) GdF3 and TbF3 nanocrystals with good SNR, and (iii) magnetic iron oxide nanoclusters with or without amorphous silica shell with intermediate SNR. The 4D-STEM/PNBD calculations were performed with recent version of our open-source Python libraries STEMDIFF (conversion of 4D datasets to 2D powder diffraction patterns; https://pypi.org/project/stemdiff) and EDIFF (conversion of 2D-diffraction patterns to 1D radially averaged diffraction profiles and their comparison with theoretically calculated PXRD; https://pypi.org/project/ediff).

Results and discussion: Our initial studies [1-3] showed that the 4D-STEM/PNBD works very well for reasonably small, highly diffracting crystals with low absorption. If the crystals are thicker and/or surrounded by amorphous matrix, the extraction of 2D powder diffractogram can become difficult or impossible. This results from the lower-energy electrons in SEM (E < 30 keV), which suffer from higher absorption and inelastic scattering than the higher-energy electrons in TEM (E > 100 keV). The better 4D-STEM-in-SEM datasets and, subsequently, the higher-quality 2D powder diffractograms can be obtained with better hardware (i.e. better SEM microscope and/or pixelated STEM detector), better experimental parameters (optimized scanning speed, dwell time etc.), and better software (i.e. data processing). For given hardware and optimized experimental conditions, the decisive factor is the data processing. Consequently, we made several improvements of our STEMDIFF software. At first, we introduced better, multi-criteria filtering of the raw 4D-STEM-in-SEM dataset. The better filtering allows us to select the highly-diffracting locations and ignore the rest, which contain high noise. Moreover, it enables us to get the better estimate of the point-spread-function (PSF) of the

primary beam, which can improve the quality of the individual diffractograms by means of 2D-PSF deconvolution. At second, we increased the speed of the above-mentioned time-consuming 2D-PSF deconvolution step ca 5x by introducing multicore processing. Last but not the least, we improved the user interface and extended the original software package STEMDIFF (the conversion of 4D-datasets to 2D diffractograms) with a sister package EDIFF (the conversion of 2D diffractograms to 1D profiles and their comparison with theoretically calculated PXRD patterns). The recent versions of STEMDIFF and EDIFF employ the well-established Jupyter notebooks as interactive templates for complete data processing (4D → 2D → 1D) without any third-party software. The notebooks are written and documented in such a way that the data could be processed in step-by-step way by any SEM user without detailed knowledge of diffraction theory. The above-listed improvements enabled us to process not only the 4D-STEM-in-SEM datasets of strongly diffracting samples with high SNR (such as Au nanoislands), but also samples with intermediate SNR (such as iron oxide nanoclusters enveloped with amorphous silica). The samples with low and poor SNR remain as a challenge for our ongoing work, which comprises advanced 2D-PSF deconvolution methods and automated, machine learning-based noise reduction.

Conclusion: The 4D-STEM/PNBD method brings a simple, fast, and easy-to-use electron diffraction technique to SEM users. The classical SEM microscopes offer imaging modes (such as SE or BSE) and spectroscopy modes (such as EDX). The modern SEM microscopes equipped with pixelated STEM detectors add also the third mode – the electron diffraction. The pixelated detectors can be installed in a common SEM port like any other detector. The 4D-STEM datasets are easy-to-collect, but difficult-to-process – at least for non-crystallographers. Our STEMDIFF package reduces a complex 4D-STEM dataset to a simple 2D diffractogram. The sister EDIFF package enables a fast conversion of 2D diffractogram to radially averaged 1D diffraction profile and its comparison with theoretically calculated PXRD diffraction pattern. Both packages aim to be as user-friendly as possible, so that the new 4D-STEM/PNBD method could be employed by all users of SEM microscopes.

Poster Group 1

Background
The size-dependent properties of gold (Au) nanoparticles (NPs) have unique applications in various fields including science and technology ranging from environmental sensing and catalysis to drug delivery and biomedical imaging due to their excellent catalytic, electronic and optical properties. The practical applications of AuNPs in all fields usually require external stimuli, such as electron beam irradiation, temperature variations and mechanical compressions, which provide a further understanding of dynamics including the influence of kinetics of nanoparticle transformations and thermodynamic stability. However, such external stimuli induce structural transformations in AuNPs depending upon their intensity. In recent years, several studies have been conducted to understand the dynamic behavior of AuNPs under the control conditions to exploit their full potential and broaden their applicability in diverse fields. For this purpose, the comprehensive use of transmission electron microscopy (TEM) has already been implemented to study real-time in situ dynamic changes in NPs. The most common coalescence phenomenon is well documented in the literature, nonetheless, the nanoparticle size dynamic and repulsion phenomenon are considered here as a background for the knowledge gap.
The use of high-intensity electron beam irradiation in TEM outcomes in a beam-induced phase transition, surface charging, ionization and defects, providing insights to observe structural changes in individual metal NPs and interactions between a pair of coupled metal NPs at the nanoscale [1,2]. This study aims to investigate the dynamic behavior of AuNPs under the influence of electron beam irradiation including the interaction between closely placed a pair of AuNPs resulting in coalescence or repulsive behavior between them. The study made use of different surface substrates, such as carbon and silicon nitride (SiN) to additionally explore the effect of substrate-nanoparticle interactions. Furthermore, we target our focus on the interaction between different coupled NPs induced by surface charges, electrostatic forces, interparticle distance and size dynamics. By accomplishing these objectives, we aim to contribute to a deeper understanding of NPs manipulation for their applications in advanced photonic and plasmonic nanodevices.

Methods
Different-sized AuNPs on carbon and SiN substrates were irradiated under a controlled dose of an electron beam using TEM. In situ imaging was acquired using the OneView Gatan camera system to monitor dynamic changes in AuNPs.

Results
Several intriguing phenomena were observed upon the irradiation of the electron beam. Firstly, the individual spherical NPs showed remarkable structural transition, involving the structure transformation, for example, from face-centered cube (fcc) to a decahedral facet structure. The structural changes observed with atomic diffusion and structure reconstruction across the substrate are due to the transferred energy from the electron beam, during the electron-matter interactions.

Furthermore, two more phenomena were observed in the case of coupled AuNPs, such as coalescence and repulsion between a pair of coupled AuNPs under an electron beam depending on the electron dose, interparticle distance and size dynamics. Coalescence is a favorable phenomenon which is initiated with the formation of a neck-like structure with the lattice reorientation between two NPs in order to transform to a more stable structure by minimizing the overall surface energy and generating more localized plasmon at the particle-particle interface [3,4]. On the other hand, the repulsion phenomenon is also affirmative under the electron beam interactions governed by surface charge dynamics and electrostatic forces on a carbon substrate, which play a pivotal role in stability and dispersion under electron beam irradiation.

Conclusions

This study provides valuable insights into nanodynamic behavior of AuNPs under the influence of electron beam interaction to explore different nanoscale phenomena on carbon and SiN substrates. The dynamic behavior of AuNPs showed the structural transformation, coalescence and repulsion phenomena on carbon substrate under the electron beam irradiation. Contrarily, strong adhesive interaction between AuNPs and SiN substrate restricted the NPs diffusion across the surface leading to the melting of NPs under electron beam irradiation due to the transferred energy, consequently confining the coalescence and repulsion phenomena. Whereas heating treatment favored the coalescence phenomenon on SiN substrate. Furthermore, the dynamic behavior of AuNPs was recorded as perturbation and rotation of NPs on both substrates under electron beam effects. These outcomes contribute to a deeper understanding of AuNPs size and surface dynamics to manipulate for various applications, such as in material science including nanodevices, and nanotechnology. Future research directions may consider the substrate-nanoparticle interaction in depth using controlled experimental and computational methods.

LS-09, Lecture Theater 4, august 27, 2024, 14:00 - 16:00

Background incl. aims:
Retrons are reverse transcriptase-carrying prokaryotic immune systems that protect bacteria against phages. Retrons are formed of three components: A reverse transcriptase (RT), a non-coding RNA (ncRNA), and one or several effector proteins with diverse enzymatic activities. Typically, the RT synthesizes a multi-copy single-stranded DNA (msDNA) from the ncRNA template, a feature that has been exploited for gene editing and synthetic biology applications. Upon phage infection, the effectors induce cell dormancy or death, preventing the phage from spreading throughout the population – a phenomenon known as abortive infection (Abi). To avoid cellular toxicity in the absence of infection, Retron effectors are frequently kept in low-activity states, and RT and ncRNA/msDNA are believed to play a neutralizing role in this process. This work aims to elucidate the molecular events underlying the immune response by a Retron.
Methods:
We combine structural biology (CryoEM), biochemistry, mass spectrometry, and bacterial genetics to address the research question.
Results:
Here, we reveal the molecular mechanism of a Retron. First, we characterized the activity of the effector in vitro and during phage infection. CryoEM structures of the Retron complex illustrate that the msDNA stabilizes the effector in a low-activity state. Interestingly, msDNA's mutations induce the release of the effector from the complex and cause toxicity, underscoring the msDNA role in immunity. In addition, we identified and characterized a phage-encoded Retron inhibitor that suffices to offset the immune response.
Conclusion:
Collectively, our work outlines the structural basis of the Retron defense system and highlights the intricate interplay between bacterial defense systems and phages.

Data Augmentation and Innovative Machine Learning Approaches for Classifying EEL Spectra of Transition Metals Oxides

Daniel Del Pozo Bueno[1], Dr. Demie Kepaptsoglou[2], Prof. Quentin M. Ramasse[3], Prof. Francesca Peiró[1], Prof. Sònia Estradé[1]
[1]LENS-MIND, Dept. d'Enginyeria Electrònica i Biomèdica and Institute of Nanoscience and Nanotechnology (IN2UB), Universitat de Barcelona, Barcelona, , [2]School of Physics, Engineering and Technology, University of York & SuperSTEM Laboratory, Heslington - Daresbury, North Yorkshire - Cheshire, [3]Schools of Chemical and Process Engineering & Physics and Astronomy, University of Leeds & SuperSTEM Laboratory, Leeds - Daresbury, West Yorkshire - Cheshire

IM-10 (3), Lecture Theater 5, august 30, 2024, 14:00 - 16:00

Background including Aims:
The field of Scanning Transmission Electron Microscopy (STEM), especially through the application of Electron Energy Loss Spectroscopy (EELS), has experienced significant advancements due to technical innovations such as aberration correctors, direct detectors, and increased computing power. These advancements have facilitated the collection of large and complex datasets, highlighting the need for effective data management and analysis solutions in the STEM community. Machine Learning (ML), with its two main categories of supervised and unsupervised learning, has emerged as a crucial tool for addressing challenges in EELS, including classification, clustering of spectrum images, and denoising tasks [1,2].
However, the effective application of supervised ML is often hindered by the requirement for large, labeled datasets, which are difficult to acquire due to the susceptibility of samples to electron beam damage. Addressing this drawback, this study aims to compare the effectiveness of two supervised ML techniques: soft-margin Support Vector Machines (SVM) and Artificial Neural Networks (ANN) in classifying EEL spectra for the determination of oxidation states in transition metal oxides, particularly focusing on iron and manganese oxides. Additionally, we present a novel unsupervised learning approach that employs Generative Adversarial Networks (GANs) for data augmentation to address the problem of labeled data scarcity and improve the precision and effectiveness of oxidation state detection using EELS.
Methods:
This research presents a comparative analysis of soft-margin SVMs and ANNs, adapted to the specific challenges in EELS data classification [3]. We evaluate these classifiers based on their ability to accurately identify features indicative of oxidation states, such as white lines and the oxygen K edge, and the effect of energy shifts or noisy spectra. To enhance the classifiers' robustness and adaptability, we investigate the impact of incorporating energy-shifted spectra into the training process and explore various normalization methods, including maximum and L2 norms. The latter is analyzed by dimensionality reduction techniques, particularly Uniform Manifold Approximation and Projection. Additionally, we undertake a systematic exploration of ANN architectures through Random Search and Tree-structured Parzen Estimator (TPE) algorithms, aiming to pinpoint the most effective combinations of architecture and parameters for EELS data classification. Finally, we include the innovative use of GANs for data augmentation, which enables the generation of synthetic EEL spectra from a reduced set of experimental data. This approach not only amplifies the diversity and volume of available training data but also reduces the dependency on extensive, experimentally acquired datasets.
Results:

Based on white lines as particularly reliable indicators for oxidation state classification, SVMs are very robust against energy shifts for the EEL features under investigation, and they perform even better when trained on energy-shifted spectra. In comparison, ANNs, especially those employing convolutional layers, demonstrate a superior ability to adapt to the complexities of EEL spectra, achieving a level of precision comparable to the best SVMs. The analysis of normalization techniques and the strategic use of the cosine kernel in SVMs emerge as effective strategies for avoiding normalization while keeping classification accuracy. Finally, the use of GANs for data augmentation marks a pivotal advancement, since this approach generates synthetic data that closely mirrors the variability and complexity of large experimental data collections, facilitating the training of these classifiers to be both more accurate and more generalized, capable of adapting to the diverse spectra encountered in EELS analysis.

Conclusions:

This work not only elucidates the comparative advantages of SVMs and ANNs in the classification of EEL spectra but also introduces a groundbreaking strategy for overcoming the challenges imposed by the limited availability of labeled datasets. SVMs are particularly recommended for simpler classification tasks where data volume is limited, offering an efficient solution that does not compromise performance. On the other hand, ANNs are more suited to tackling complex classification problems that involve larger datasets, benefiting from their enhanced capacity for learning and adaptation. The successful integration of GANs for data augmentation represents a significant advance, substantially reducing the reliance on extensive labeled datasets and paving the way for more efficient and effective classifier training.

Three-dimensional imaging to study early bone mineralization

Dr Elena Macías-Sánchez[1], Dr Emeline Raguin[2], Dr Nadezda Tarakina[3], Prof Peter Fratzl[2]
[1]Department of Stratigraphy and Paleontology, University of Granada, Granada, Spain, [2]Department of Biomaterials, Max Planck Institute of Colloids and Interfaces, Potsdam, Germany, [3]Department of Colloid Chemistry, Max Planck Institute of Colloids and Interfaces, Potsdam, Germany

LS-07 (2), Lecture Theater 5, august 28, 2024, 14:00 - 16:00

Background incl. aims
Two-dimensional imaging represents a serious limitation when studying the structure of complex hierarchical materials such as bone. Three-dimensional visualization is essential for understanding the interactions that occur between the cellular network, collagen fibrils, and mineral precursors during the formation process. Over the last decade, FIB-SEM has revolutionized the study of mineralized tissues, providing not only three dimensional information in the nanometer range, but also the possibility to nanofabricate mineralized lamellae avoiding the mechanical stress caused by standard sectioning techniques.
These technical advances helped elucidate the mineral deposition in collagen-based materials, driven by a spherulitic-like crystal growth [1]. Initially, disordered mineral aggregates form in the interfibrillar spaces, and subsequently the mineral infiltrates adjacent collagen fibrils, which provide the structural framework for the formation of layered spherulites. These spherulites (also called mineral ellipsoids) imbricate forming a new hierarchical level of organization in bone termed tessellation [2]. Although the mechanism has been described in several systems [1, 2, 3], detailed data on the interaction of the organic and the mineral phases remain insufficient.
Methods
The present study combines electron tomography (FIB-SEM serial surface imaging) which provides 3D information, with the fabrication of lamellae for scanning/transmission electron microscopy (S/TEM), selected area electron diffraction (SAED) and energy dispersive spectroscopy (EDS) chemical mapping to elucidate crystal distribution and orientation throughout the collagen matrix.
Results
The study reveals the internal structure of the forming fibrolamellar bone at nanometer resolution. A connective tissue with dispersed and non-preferentially oriented collagen fibrils seems to be deposited first, serving as a scaffold for the deposition of more aligned collagen. During embryonic development, these osteocytes initiate the mineralization process and become buried in the mineral matrix, which expands both vertically and laterally to form the nascent fibrolamellar units. At the collagen-mineral interface, a multitude of mineral spherulites proliferate and grow to confluence. Their profiles are still recognizable in the consolidated mineral layer.
Conclusions
Our study confirms that the formation of mineral spherulites also drives the mineral deposition in embryonic fibrolamellar bone. This fact demonstrates that this protein-mediated crystal growth mechanism occurs in different types of bone tissue and in different species, indicating that it is a common and homologous mineralization mechanism in type I collagen-based materials [4].

Unraveling the original dissolution mechanism of LiFePO4 when treated for recycling

Dr. Adrien Boulineau[1], Julie Poulizac[1,2], Dr. Emmanuel Billy[1], Pr. Karien Masenelli-Varlot[2]
[1]Univ. Grenoble Alpes, CEA, LITEN, Grenoble, France, [2]Univ. Lyon, INSA Lyon, UCBL, CNRS, MATEIS, Villeurbanne, France

PS-04 (3), Plenary, august 27, 2024, 10:30 - 12:30

Background incl. aims
This presentation aims at demonstrating the original mechanism involved during the acid leaching treatment of the very common material used in Li-ion batteries, LiFePO4. Such treatment is the basis of the hydrometallurgical process used for recycling the material and the understanding of the chemical reactions involved is critical to optimize the recycling process. To date and to our knowledge, such a mechanism established thanks to advanced TEM experiments among which operando liquid TEM and STEM EELS for phase mappings has never been highlighted.

Methods
We first carried out operando liquid TEM experiments to follow the evolution of the shape of the particules and to see if the dissolution process was monotonous or composed of severals growth and dissolution steps. Ex situ characterisations on materials residues recovered from partial dissolutions, including HRTEM imaging and STEM-EELS experiments, were then performed. They enabled the identification of the phases and their localisation. All the results are finally correlated and confronted to global chemical and structural analyses by the means of ICP-MS and XRD experiments.

Results
Operando liquid TEM experiments are demonstrating a monotonous dissolution process without any reprecipitation or growth of particles. Moreover as already reported by us [1], it was possible to show the kinetic observed operando was comparable with the one deduced from ex-situ dissolution experiments. Ex-situ XRD analyses are evidencing a rather quick formation of crystallites composed by the FePO4 phase with still the presence of the pristine LiFePO4 one. Discriminating both phases is a challenge but STEM-EELS and HRTEM analyses enabled to prove the coexistence of both phases into the same particles and they demonstrate that a core-shell type or shricking-core mechanism does not occur as it is usually observed during such reactions.

Conclusion
During this talk we are presenting the original dissolution mechanism that is based on the tranformation from monocristalline LiFePO4 particles toward polycrstalline FePO4 ones separated by LiFePO4 residues. We demonstrate the evolution occurs into the same particules without any nucleation of new particules. Then, this is the level of pH that is governing the continuous dissolution process or its interruption. This study is of importance since it allows process optimization. It is also of great interest on a fundamental aspect since we demonstrate the generation of particles where the LiFePO4 and FePO4 phases coexist. Such phenomenon is not really expected when we know the bahavior of the material that is always presenting monophased particles when used in a li-ion battery [2,3].

Background
Biopolymers are electron beam-sensitive materials with low scattering power, which poses a significant challenge for nanoscale characterization. One promising technique to overcome these issues is scanning electron diffraction (SED), utilizing the strong interaction between electrons and matter. In SED, the sample is raster scanned using a near-parallel electron probe while simultaneously capturing a diffraction pattern at each beam position. These patterns provide highly localized crystalline information from the sample, including strain, phase, and orientation, later characterized through post-acquisition data analysis.
Cellulose, with its unique properties and crystalline structure, has emerged as a promising resource for sustainable composite materials. Controlling its hierarchical organization is an essential consideration in cellulose utilization. The aligned orientation of the highly anisotropic cellulose nanofibers is vital to macroscale mechanical properties. Fundamental insights into the intrinsic arrangement of cellulose enhance its exploitation in composites with new and improved properties.

Methods
The wood-based composite material was sectioned using ultramicrotomy in two orthogonal directions, longitudinally and transversely, relative to the elongated wood cell structure. The microscope was configured with a convergence angle of 0.1 mrad, resulting in a probe diameter of less than 10 nm. SED data was acquired using a beam current of 2 pA with a dwell time of 5 ms to minimize beam damage. Cellulose orientation and degree of alignment in each beam position were determined through post-acquisition data processing. 360 virtual detectors were arranged in an annular pattern around the unscattered beam, with a radius corresponding to the scattering angle of the most prominent 200-reflection of cellulose to optimize the signal-to-noise ratio.

Results
In this study, we employed SED to unveil the hierarchical assembly of cellulose nanofibers in transparent wood, a composite material prepared by infiltrating wood with polymerized methyl methacrylate (PMMA)[1]. Our results reveal a well-ordered hierarchical arrangement of nanofibers in the secondary cell wall with a spatial resolution of 15 nm[2]. In the inner regions, the nanofibers are aligned parallel to the cell elongation, including the innermost part closest to the lumen. In the outer part, the nanofibers transition to a tangential orientation. Based on the quantitative SED data, we can conclude that this reorientation occurs smoothly over 1.5 µm. Despite the change in direction, cellulose nanofibers stay well-aligned. Uniform cellulose orientation in the inner part and a plateau in the outermost part support a layered cell wall structure.
Furthermore, wood cells sectioned longitudinally exhibit clockwise or counterclockwise nanofiber rotation towards the outer part. This rotation difference is caused by sectioning the cells at different depths and is consistent with a helical arrangement of nanofibers with a gradually changing pitch.

Peak width analysis of transversely sectioned transparent wood discloses a higher degree of nanofiber alignment in the outer part of the cell wall than in the inner part.
Preserving the anisotropic organization of cellulose in this new biocomposite retains the mechanical properties of wood.

Conclusions
This work demonstrates the potential of Scanning Electron Diffraction in characterizing biobased composite materials. Combining sensitive detectors and innovative data analysis enables the detection of very subtle signals from the sample. SED provides quantitative crystal information with exceptionally high spatial resolution from a relatively large field of view (20x20 µm).

PS-03 (2), Lecture Theater 2, august 30, 2024, 10:30 - 12:30

The drive for miniaturization in the ever evolving field of semiconductor technology has pushed the ability to provide in depth material and device characterization to its limit. This is particularly strongly felt in the characterization of the opto-electronic properties, as the established techniques (such as photoluminescence) are inherently limited in their achievable spatial resolution. Nevertheless, being able to characterize not only the steady state optical properties on the nanoscale but also time dependent properties is paramount for further scientific and engineering progress. Especially as nanoscale features such as point and extended defects can significantly influence material and device properties.
While cathodoluminescence spectroscopy for characterization of steady state properties on the nanoscale has been available for quite some time, reports on (hyperspectral) time-resolved characterization with picosecond resolution have been much more limited (1), (2), (3). This work demonstrates hyperspectral time-resolved cathodoluminescence (TR-CL) spectroscopy for the analysis of the interplay between extended defect and point defects in UV-C light emitting AlGaN quantum wells (QWs), single nonradiative point defects in an InGaN/GaN QW and extended defects in InAs QDs on Si substrates.

We are using an Attolight Chronos dedicated TR-CL scanning electron microscope with laser pulsing system. We have achieved time-resolved measurements with 7 ps resolution in point and shoot mode, and 100 ps time resolution when recording hyperspectral TR-CL maps. All investigated samples were grown by MOVPE. Sample analysis has been performed using the open source Python packages Hyperspy and Lumispy.

We have successfully measured the carrier lifetime in AlGaN-based, UV-C light emitting, QWs with emission wavelengths ranging from 260 nm to 220 nm (with QW composition varying from 56% to 82%) at temperatures from 80 K to 300 K. We found, that the carrier lifetime decreases strongly with increasing QW Al mole fraction, indicating a significant increase in the point defect density. Further, spatially resolved, investigation of the interplay between threading dislocations and point defects show no evidence for a significant influence of the local threading dislocation density on the carrier lifetime, indicating that the optoelectronic properties of these materials are being controlled by their point defect density.
Observation of decay dynamics in InAs QD systems using hyperspectral TR-CL reveals changes in the carrier lifetime in and around misfit dislocations. In contrast to our observations in AlGaN we can observe a significant decrease in carrier lifetime, when compared to the surrounding material, at the extended defect. This does highlight both the strong effect extended defects can have on carrier

dynamics and that differences in the point defect density and carrier localization can significantly impact local recombination channels. We also observed a lack of impact of the misfit dislocation on the lifetime on the material immediately surrounding the dislocation which we attributed to a short carrier diffusion length, preventing carriers from reaching the non-radiative recombination centre. This in turn causes the observed high tolerance of the internal quantum efficiency for defects in this system (4).
Lastly, hyperspectral TR-CL has been carried out on a carefully designed InGaN/GaN QW system for the investigation of isolated point defects. The system contains an ultrathin QW (3 ~bilayers thick) on a low dislocation density template (~106 cm-2) with a point defect filtering layer, resulting in a point defect density of about 109 cm-2 . The low density allowed us to first find isolated point defects and then measure hyperspectral TR-CL maps containing these isolated point defects. Extracting spatially resolved carrier lifetimes from the hyperspectral dataset then allowed us to not only compare and analyse decay times across the mapped area but also to visualize carrier diffusion within the system. Our findings in this system reveal the direct influence of isolated nonradiative point defects on carrier recombination dynamics and open the pathway for indepth studies of the optoelectronic properties of point defects.

We have demonstrated the unparalleled ability of TR-CL to characterize the opto-electronic properties of defects in a wide range of materials systems on the nanoscale. Further development of TR-CL capabilities will only strengthen this research capability and provide future research on nanoscale devices and objects with an invaluable tool for the characterization of spatially resolved carrier dynamics.

Background
Understanding the details of oxygen exchange processes becomes key to understand the performance of catalysts used in redox processes as well as to fix the most convenient pretreatment conditions to activate the catalyst prior to reaction. At macroscopic level, hydrogen temperature programmed experiments (H_2-TPR) are the most commonly used tool to propose the different phases and processes resulting from this activation step. Nevertheless, the interpretation of these TPRs becomes cumbersome and most of the times rather speculative.
A reliable determination of the actual phases appearing during the different oxygen evolution processes involved in these TPRs requires a precise quantification of the oxygen content of the materials at different steps of the reduction process. Such information, combined with structural analysis at local level provides the necessary information to interpret the H_2-TPR trace at quantitative level on solid backgrounds.
Regarding the compositional aspects. STEM-XEDS stems as a possible technique to face the quantification of the oxygen content at nanoscale in oxides with interest in redox catalysis. However, such approach requires to overcome two major difficulties: (a) dealing with absorption effects in the quantification of the oxygen signal; (b) disentangling the influence of beam reduction effects, which are particularly relevant in the case of high surface area, beam sensitive oxide nanostructures.
This contribution illustrates how combining time-resolved STEM XEDS experiments recorded during the in-situ reduction under the electron-beam performed on an aberration-corrected microscope equipped with large area detectors; an O-quantification scheme based on the use of the so-called ζ-factors method [1] and modeling of the kinetics of oxygen evolution, it is possible to determine with high accuracy the composition of the intermediate phases involved in the oxygen exchange processes of oxide nanostructures. In particular, the methodology is applied to the quite challenging case of nanorods of a complex, extremely beam sensitive, multicationic K-modified manganese oxide with hollandite type structure highly active in CO oxidation.

Methods
The starting K0.11MnO2-δ nanoxide was prepared from Mn(SO4)2, HNO3 and KMnO4 solutions under reflux over 24 h. This oxide was characterized at microscopic and macroscopic levels by Electron Probe Microanalysis (EPMA) and Neutron Diffraction (ND). The implementation of the ζ-factors method was done starting from Electron Tomography experiments performed in a Titan Themis 60-300 microscope operated at 80 kV. For reconstruction, a methodology based on TVM3D algorithms was employed to ensure high accuracy in the determination of local thickness values the oxide nanostructures [2]. XEDS maps were acquired with a Super-X G2 detector, using a beam current ranging between 135 and 145 pA. Maps were recorded in both single and multiple frames

modes setting a pixel dwell time between 0.128 and 5.000 ms respectively. These conditions result in a frame acquisition time of approximately 3-100s, after which the drift was corrected using cross correlation. XEDS line profiles were extracted using Velox 3.1 and the quantification was carried out using home-made scripts coded in Matlab.
Hydrogen temperature-programmed reduction (H_2-TPR) experiments were performed in an AutoChem II 2920 automated characterization system, equipped with a calibrated thermal conductivity detector (TCD).

Results
The quantitative analysis of XEDS spectra recorded at different irradiation times under the electron beam allowed us tracking the evolution of the O/Mn molar ratio of different oxide nanostructures, Figure 1 (left). Extrapolation to t=0 of the O/Mn ratio vs t plot provided an estimate of K0.13MnO1.98 stoichiometry for the pristine material. Full agreement with the K/Mn ratio determined by EPMA (K/Mn=0.125) and with the composition obtained by ND (K0.11MnO1.96) and H_2-TPR (K0.13MnO1.99) validated the oxygen quantification procedure proposed by us.
Formation of K0.13MnO1.61 as steady-state product of the electron-beam reduction process, which could be perfectly fitted to a contracting-volume kinetics, suggested that oxygen evolution proceeds in steps of 1/3 of the oxygen located at the O1 or O2 positions of the unit cell.
Taking this experimental observation into account and analysing in quantitative terms the deconvolution of the H_2-TPR experiments, Figure 1 (middle), all the steps involved in the reduction under hydrogen of this type of oxides could be perfectly interpreted and the corresponding intermediate phases proposed (Figure 1, right).
Combination of these results with those coming from DFT calculations allowed us confirming that the usual pre-reduction procedures used to activate these oxides lead to the elimination of all the oxygen residing at the O2 sites of the hollandite structure, rather than just all the oxygen sites (O1 and O2) at the surface of the oxide nanorods, as it has been proposed on speculative basis in the existing literature.
Likewise, it was possible to determine that the formation of MnO concludes at 553°C after the so-called δ step, rather than after the γ one, just at 423°, as it has also been proposed in literature.
Moreover, it has been possible to clarify that the intensity of this δ step is totally determined by the initial K content of the hollandite, this suggesting that oxygen evolution in this peak is related to O at the interface between Mn and K.

Conclusions
A novel methodology to implement the ζ-factors scheme to quantify with high accuracy the oxygen content in multi-cationic, beam sensitive, materials has been developed [3]. This methodology has been fruitfully applied to analyse in full quantitative terms time-resolved STEM-XEDS experiments recorded during the in-situ e-beam irradiation of nanorods of a potassium-modified manganese oxide with hollandite-type structure.
The quantitative results obtained at nanoscopic level fully agree with reference data obtained at macroscopic level by EPMA, ND and H_2-TPR, which supports the reliability of the developed approach. Moreover, from the nanoscopic results and the deconvolution of the TPR diagram on the basis of α step processes, it has been possible to determine the composition of the different intermediate phases involved in the reduction of the oxide under hydrogen, avoiding erroneous assignments in the literature.

Background incl. aims

The standard method for detecting macromolecules in cryo-electron tomography (cryo-ET) images is template matching (TM), which suffers from high computational complexity and difficulties in identifying particles with similar structures. In TM, one uses template density maps of a specific macromolecular particle and computes the cross-correlation score at every voxel across the whole tomogram. The highest-ranked cross-correlation scores correspond to possible particle locations. In addition to the particle location, one also obtains an estimation of the particle orientation. As a final step, sub-volumes are extracted at those locations which can be used in turn for other tasks like classification and segmentation.

Recently, the investigation of crowded cell environments using cryo-ET has been attempted with deep learning (DL) methods. Models like DeepFinder [1] improve particle picking by being much faster while at the same time providing a reasonable accuracy. Prediction of the particle orientation using DL methods, however, has, to the best of our knowledge, not yet been achieved. This, we believe, is mainly because learning based on representations like Euler angles or quaternions fails due to discontinuities of the representation space [2].

Here, we investigate DL-based particle orientation estimation using a continuous representation with six degrees of freedom (6DoF) that empowers neural networks for the optimal estimation. Input to the neural network is a 3D image patch containing the particle. Since for experimental data, usually no ground truth is available, we generate test data using the PolNet software that was recently published [3]. We evaluate the accuracy of the orientation estimation using an end-to-end model on this test data. Our promising results suggest that particle orientation using DL methods is indeed feasible.

Methods

Different rotation representations may be used to train a machine learning model for orientation estimation. Inspired by the work of Zhou et al. [2] , we address the problem of orientation estimation as a regression problem. We use M =[a1, …, an] and SO(n) to denote a rotation matrix and the space of n-dimensional rotations, respectively, and ai represents a column vector. In consequence, having a set of 3D rotations, one can define the original space X=SO(3). Zhou et al. [2] showed that representations for 3D rotations are discontinuous in four or lower dimensions; hence, representation spaces for rotations based on Euler angles and quaternions are discontinuous.

Let R and X be the representation space and the original space of rotations; then the neural network should predict an intermediary representation in R that can be mapped into the original space X. In other words, we are looking for a representation (f, g) such that f:R→X maps from the representation space to the original space and g:X→R maps back to R, preserving the continuity. Figure 1 illustrates these definitions. However, the problem is that the limit of g is undefined for zero rotation, i.e. limit of g in one direction gives 0 and in the other 2π.

One possible solution is to employ identity mapping. Although this guarantees that the network output is back in SO(3), it results in matrices of size 3 × 3 which can be computationally exhaustive due to orthogonalization. As a result, we perform the orthogonalization in the representation space. Having the original space X=SO(3), a representation space $R=R^{3\times2}\backslash D$, and a rotation matrix M, the mapping g is simply defined as dropping the last column of the rotation matrix, resulting in [a1, a2], as suggested by Zhou et al. Here, the set D represents that part of the space that f cannot map to SO(3) [2].

In addition to these challenges, designing a network structure that can reduce the computational cost while accurately estimating the orientation is a profound task. One such structure is a multi-layer perceptron (MLP). We use a four-layer fully connected network with 32 nodes per layer and a regression layer with tanh activation function. The number of output nodes in the regression layer equals the dimension of the orientation representation, i.e. 3, 4, and 6 for Euler angles, quaternions, and 6DoF, respectively.

Results

We performed experiments on a synthetic dataset generated by PolNet [3] that for uniform random sampling of the rotations uses the Algorithm S2 in [4]. We generated 150 tomograms of resolution 10A° containing the ribosomal complex (4v4r) and Thermoplasma acidophilum 20S proteasome (3j9i). We extracted centred patches of size 40^3 for all 4v4r particles, leading to 26703 samples. 130 tomograms (23128 samples) were used for training and validation, and 20 tomograms (3575 samples) for testing. Note that the synthesized tomograms contain the missing-wedge artifact and noise.

We trained our network for 50 epochs using Adam optimization, batch size 32, learning rate 0.0001, and patch size of 40^3. We used Huber loss to calculate differences between ground truth and predicted orientation representation. Our experimental results suggest that the continuous representation performs much better in practice. Figure 2, left, shows the ground truth and predicted orientations on a test tomogram for the 6DoF representation. Green and red colors represent ground truth and prediction, respectively. Our model predicted 81% of the test samples correctly using the Crowther criterion [5] with an angle difference threshold of 20 degrees. Visual analysis shows that most incorrect predictions occur in regions where the particles form a cluster. While training time was about 1 hour, inference time was only approximately 25 seconds on a single GPU. We achieved an R2 score of 0.96 on training data and 0.87 on test data for the 6DoF representation. These values downgrade to 0.76, -0.07 on training and -0.47, -0.07 on test data for the quaternion and Euler representations, respectively. Figure 2, right, shows a histogram chart of the angle differences for all three representations.

Conclusion

We studied the use of MLP to estimate macromolecule orientation using various representation spaces, namely Euler angles, quaternions, and a 6DoF-continuous. The continuous representation space shows a huge advantage over the others. Our future work includes developing more complex models to perform multiple downstream tasks along rotation estimation.

Direct observation of Ni nanoparticle growth in carbon supported nickel under carbon dioxide hydrogenation atmosphere

Nienke Visser[1], Savannah Turner[1], Joseph Stewart[2], Bart Vandegehuchte[2], Dr. Jessi Van Der Hoeven[1], Petra de Jongh[1]
[1]Utrecht University, Utrecht, Netherlands, [2]TotalEnergies OneTech Belgium, Seneffe, Belgium
PS-05 (2), Lecture Theater 1, august 28, 2024, 14:00 - 16:00

Background:
Understanding nanoparticle growth is crucial to increase the lifetime of supported metal catalysts. The recent advances in in situ transmission electron microscopy (TEM) using closed cell nanoreactors, in which samples can be exposed to gas or liquid phase environments, allow the visualization of nanoparticle catalysts under 1 bar gas. This enables the analysis of changes in nanoparticle morphology, size, composition and shape of metal nanoparticles under reaction conditions, which is highly relevant to the field of catalysis.[1]
Nickel-based catalysts are of interest for the conversion of CO2 and renewable H2 into synthetic natural gas (Power-to-Gas process). The catalytic performance in terms of activity is controlled by the available surface area of the metal nanoparticles. The exposure of nanoparticles to reaction atmospheres and elevated temperatures can result in nickel particle growth and activity loss. In this study,[2] in situ gas phase TEM is employed to visualize the movement and growth of ensembles of tens of nickel nanoparticles supported on carbon for CO2 hydrogenation at atmospheric pressure in real time.

Methods:
Carbon supported nickel catalysts were prepared via incipient wetness impregnation using an aqueous Ni(NO3)2 precursor solution, followed by a heat treatment under H2 atmosphere. In situ gas phase TEM was performed at 450 °C under 1 bar H2:CO2 (4:1) atmosphere using a Protochips Atmosphere holder. The results were compared to ex situ experiments, amongst others in a catalytic setup, to study the influence of beam dose, which was kept at a maximum of 20 e- A-2 s-1.

Results:
Various movement and growth mechanisms of a supported Ni catalyst were directly observed in real time under CO2 hydrogenation conditions, using in situ gas cell TEM at 1 bar and 450 °C. During 50 min under reaction conditions, the average Ni particle diameter grew from d = 5.7 ± 1.4 nm to d = 7.7 ± 1.9 nm, while the number of particles decreased from 72 at t = 2 min to 34 at t = 50 min. This correlated to a decrease in specific Ni active surface area from 105 to 78 m2 gNi-1. Comparison of the averaged particle growth within a nickel on carbon catalyst in situ and ex situ validated the relevance of the in situ obtained results.
Furthermore, the in situ TEM experiments enabled the analysis of individual nanoparticles in real time. We observed two modes of particle movement with an order of magnitude difference in velocity: fast, intermittent movement (vmax = 0.7 nm s-1) and slow, gradual movement (vaverage = 0.05 nm s-1). Two distinct particle growth mechanisms were visualized: diffusion and coalescence, and Ostwald ripening. Figure 1A shows the electron microscopy images of particles at selected times with the projected areas of the four particles highlighted in Figure 1B. Figures 1C-F show the evolution of the projected areas of the four particles over time. Particle 2 and particle 3 disappeared due to coalescence with particle 1, highlighted in the purple regions. Interestingly, particle 4 showed

different growth behavior. After the first 20 minutes in which particle 1 had grown to ~60 nm2, particle 4 started shrinking, until it completely disappeared after 50 minutes. Hence a striking interplay between the two mechanisms was observed: first coalescence took place, followed by Ostwald ripening, caused by the increased difference in particle size.

Conclusions:
Our direct visualization of the complex nanoparticle growth mechanisms highlights the relevance of studying nanoparticle growth in supported nanoparticle ensembles under reaction conditions, and contributes to the fundamental understanding of the stability in supported metal catalysts.

Figure 1 - Direct observation of particle growth via coalescence (purple) and Ostwald ripening (green). Background incl. aims
In-situ transmission electron microscopy (in-situ TEM) has become an essential tool for studying dynamic phenomena at the nanoscale [1]. Observing nanoscale phenomena with in-situ TEM allows us to understand the mechanism in more detail, which leads to improving material properties or increasing the process efficiency. However, most of the information is available only after a long time of analysis, which ends up as a passive approach. To actively investigate the phenomena, more information should be extracted during the in-situ experiment to manage the stimuli in real time. Live processing during the in-situ TEM experiment can allow to overcome this limitation by actively controlling the stimulus conditions according to the observed features, thus allowing dynamic adjustments during the experiments. Achieving live processing requires two critical components: 1) establishing real-time communication channels between the TEM, the in-situ stimuli, and the processing server, and 2) developing fast and efficient image processing algorithms capable of handling the high throughput of data generated during in-situ TEM experiments. Until now, artificial intelligence (AI) has not been able to help with live processing due to the large amount of computing power and time required. While the establishment of real-time communication channels requires cooperation with TEM manufacturers, this paper focused on the development of image processing algorithms suitable for live processing.
In this work, we present the development of simple but effective image processing techniques suitable for live processing in in-situ TEM. Three cases of segmentation from electrochemical in-situ TEM experiments were shown as: (Case 1) plating and stripping of Zinc (Zn), (Case 2) dendritic growth of Zn, and (Case 3) particle-like plating and stripping of Copper (Cu) [2, 3]. Through these case studies, we demonstrate the ability of simple image processing to understand electrochemical phenomena and its potential for applications.

Methods
a) Performing in-situ electrochemical TEM experiments
In-situ Liquid TEM holder (Stream, DENSsolution) assembled with 3-electrode Micro-Electro-Mechanical System (MEMS) chips was used for experiments. In case 1, Pt electrode MEMS chip and 0.1 M ZnSO4 solution (flowing) were used and cyclic voltammetry (CV, -1.5 V ~ +0.8 V for 0.01 V/s scan rate) was applied. In case 2, Pt electrode MEMS chip and 0.1 M ZnSO4 solution (non-flowing) were used and chronopotentiommetry (CP, 5 µA for 10 seconds) was applied. In case 3, TiNx electrode MEMS chip and 0.02M CuSO4/0.01M KH2PO4 solution (flowing) were used and chronoamperometry (CA) with 4 cycles (one cycle: +1.5 V for 15 seconds and –1.5 V for 15 seconds) was applied. Case 1 and 2 were monitored at STEM mode and case 3 was monitored at TEM mode.

b) Developing simple image processing methods dedicated to in-situ TEM
All the image processing methods are developed as python codes. To reduce the noise level, a gaussian filter was applied as pre-processing. Key strategies are 1) subtraction of the reference image (pure electrode) from target image (during experiment) to extract the information changes and 2) thresholding the subtracted image to binary-segmenting as feature and background. Especially case 2, the subtraction was performed between images with 1 second difference, in order to emphasize the fast growth of dendrite within 1 second. After the segmentations, the deposition information such as deposited area was numerically extracted and plotted.

Results
In case 1 (Figure 1a), Zn plating and stripping phenomena were recorded with CV stimuli. On the recorded STEM images, the plated Zn is well visible, but the brightness of the plated Zn looks similar to the rectangular Pt electrode on the right side. After the simple image processing as described in methods, the plated Zn is clearly visible without Pt electrode and the area of plated Zn can be measured easily. After measuring the area throughout the whole CV process, the plated Zn area can be synchronized with the CV stimulus data, which leads to a quantitative understanding of the phenomena.
In case 2 (Figure 1b), Zn dendritic growth was recorded with CP stimuli. From the video, a dendritic growth took only a few seconds, so the information related to the growth rate is more important than the amount of growth. By subtracting the 1-second difference between frames, the grown dendrite is visualized in 1 second, which can directly show not only how fast the dendritic growth is, but also which direction is preferred. In this case, Zn dendrite growth occurred to the left where the counter electrode is located.
In case 3 (Figure 1c), Cu particle-like plating and stripping was recorded with cyclic CA stimuli. On the recorded TEM images, plated Cu particles are well visible on the top of the electrode (round shape with hole), but small dots are also visible at the outside of electrode. Large Cu particles on the top of the electrode are formed based on electrochemical deposition and small Cu particles outside of electrode are electron beam induced deposition. To focus on electrochemical deposition, the only electrode area was selected to further particle segmentation. After the image processing, each individual Cu particle was segmented and could be tracked during the plating and stripping process. The area and number of particles were plotted with a time scale to study the plating and stripping phenomena.

Conclusions
In-situ TEM has been enabled to observe countless phenomena in nanoscale, but quantitative information was very limited due to huge amount of dataset which cannot be handled by human. This paper showed that the bunch of quantitative information can be extracted from recorded in-situ TEM video by simple image processing. We believe that simple image processing will allow to actively investigate the phenomena at nanoscale by correlating the observed feature and applied stimuli in real time.

Figure 1. Examples of image processing from in-situ TEM dataset. (a) STEM image and segmented image of metal deposit. (b) STEM image and reconstructed image of metal dendrite growth within 1 second. (c) STEM image, segmented image of particle shape deposits and graphs about deposit area and number of particles vs. time. [2, 3]

PS-04 (2), Plenary, august 26, 2024, 14:00 - 16:00

Background
Increasing the durability of solid oxide cells is one of the main goals for achieving wider industrial application. The quality of the electrode plays a major role in the performance and durability of a fuel and electrolysis cells. Ni/YSZ or Ni/BZCY (BZCY stays for the state-of-the-art proton conducting ceramic material BaZr1-x(Ce,Y)xO3-d) electrodes of solid oxide cells are commonly reduced from NiO/YSZ or NiO/BZCY under hydrogen atmosphere at high temperatures, prior to operation. It is known from commissioning that e.g. reduction temperature and H2 pressure influence the initial performance of the fuel electrode by governing Ni particle size and shape. The reduction results in a significant change in microstructure. As specific microstructural properties are crucial to achieve high performance and durability of the cell, a comprehensive understanding of the reduction process is required.
Methods
With in-situ TEM we are able to observe the reduction of NiO in real time while exposing the sample to hydrogen gas and heat [1]. Using in-situ TEM atmosphere system from Protochips we studied the electrode reduction at the H2 pressures up to 1 atmosphere and temperatures up to 850 °C which fit the real working condition of a conventional solid oxide cell based on oxygen ion conductor as an electrolyte.
Results and conclusions
With this set-up we can observe the initial steps of NiO reduction, local change in oxidation state of Ni and formation of defects in Ni grains. Grain boundaries and triple junctions between NiO and YSZ or BZCY are determined as the starting points of the reduction process at lower temperatures. Closely reproducing the reduction conditions of the real cell, we demonstrate that NiO reduction mechanism is different from the previous findings. We also showed that the initial temperature of the reduction is crucial to achieve a high number of electrochemically active triple phase boundaries between e.g. Ni/YSZ and gas. In-situ results go in good agreement with ex-situ results obtained from a bulk cell reduced in a test bench described in Ref. [2].
Figure 1. Step-by-step reduction of NiO/YSZ material for fuel electrode. Ni becomes porous and nanocrystalline after the reduction. The grain size grows with temperature and pores disappear due to the Ni coarsening.

Poster Group 2

For beam sensitive materials, the dose that can be applied and the dose efficiency of the imaging method often sets the achievable resolution, rather than just the capabilities of the optical system. This is crucial in biology but also for many materials science samples such as metal organic frameworks (MOFs), zeolites, and organic perovskites. While scanning transmission electron microscopy (STEM) has come to dominate high resolution materials science, for the most beam sensitive materials TEM [1] has remained predominant due to the dose efficiency of its phase contrast imaging. Recent technological advances have, however, started to challenge this status quo for low dose imaging, through the combination of fast 4D STEM and ptychography. Ptychography can exceed the dose efficiency of TEM but has been limited until very recently by the relatively slow speed of cameras, which makes 4D STEM exceedingly slow for high probe position count datasets. This bottleneck has recently been overcome using event driven camera technology [2], and conventional framing cameras are also increasingly closing the gap between 4D STEM scan speeds and high-speed conventional STEM, greatly facilitating drift-free and low dose 4D data acquisition.

However, there are many forms of ptychography and so far, sufficient broad comparison of the low dose performance of the various ptychographic methods has been lacking. Ptychographic methods can be grouped into iterative and direct algorithms. Iterative methods are most often performed with a defocused probe, as the higher signal per diffraction pattern facilitates convergence, but with a careful choice of reconstruction parameters they can also produce useful phase images in a low dose focused probe configuration. Here, we present a comparison of a broad spectrum of these algorithms, both iterative and direct, for reconstructing low dose data sets.

Figure 1 compares ptychographic reconstructions of 2.5 nm thick Methylammonium lead iodide (MAPbI3) at a dose of 50 e-/A², using a convergence angle of 13 mrad, with a focused probe. The iterative gradient descent (GD) algorithm converges, but to a relatively poor quality image showing very little atomic structure. The rPIE, ePIE [3], ER and WASP [4] iterative and direct SSB algorithms, all perform better under these conditions, revealing relatively similar atomic structures from which the iodide and the Pb sites can be located. On the heavy Pb atomic sites, contrast reversals are present. These reversals can be easily corrected using our new phase offset method [5], which can greatly improve the interpretability of ptychographic data.

Switching to a defocus of 20 nm, as shown in Figure 2, improves the GD result significantly, however it remains dominated by low frequency features of limited utility, with high resolution information still less clear than the other iterative methods. Although the SSB becomes blurred when the probe is defocused, as expected due to the optical sectioning effect, this can be corrected post collection as we show in the figure.

In addition to the choice of algorithm, the parameters used are critical to obtaining the best solutions. For iterative schemes, probe step size and defocus are linked in their importance to the amount of overlap of adjacent illuminated regions. The convergence angle determines which frequencies will be transferred most strongly and sets the upper limit on conventional image resolution. Although ptychography can provide super-resolution and exceed this limit, at very low doses there is insufficient scattering to higher angles for super-resolution to provide significant benefits; rather, at low doses, correction of residual aberrations is expected to play a greater role.

Poster Group 2

Background incl. aims
Multi-photon 3D laser printing of polymers can be used to create complex structures on the micro- and nanoscale [1,2]. This technique involves focusing a laser into a liquid ink, initiating a reaction that solidifies the material at the laser focus. While this technology has primarily been employed with polymers, recent developments aim to extend its capabilities to inorganic materials. However, these materials often need post-processing at elevated temperatures, facing challenges for multi-material architectures due to the potential impact on polymer structure [3]. Recent advances in the direct printing of semiconducting ZnO through hydrothermal synthesis offer a promising alternative since no post-processing step is needed [3]. This enables the direct laser printing of functional microelectronic devices, possibly combined with polymers. Using electron microscopy, we demonstrate that single crystalline ZnO can be printed on amorphous substrates, opening the possibility of new applications, e.g., non-linear properties for devices in optics. However, a deeper understanding of the growth of the ZnO crystals and the crystal rotation is necessary for further applications in microelectronic devices.

Methods
The ZnO structures are photothermally printed from a liquid ink (zinc formate and sodium citrate in dimethyl sulfoxide) onto a glass substrate using a focused continuous-wave laser (532 nm wavelength).
An FEI Helios G4 FX combined focused ion beam (FIB) and scanning electron microscopy (SEM) dual-beam system was used to characterize the crystallinity and crystal orientation of the printed ZnO with electron backscatter diffraction (EBSD) with a Bruker eFlash detector. EBSD requires a polished sample surface, for which we used FIB milling since the ZnO structure sizes are in the µm range. First, a Pt protection layer is deposited using the FIB. Then, the sample is tilted so that the sample surface is aligned at an angle of 10° relative to the Ga+-ion incidence. After polishing, the sample is tilted to a 70° effective sample tilt relative to the electron beam incidence for EBSD data acquisition. The Bruker Esprit software was used for the collection of the EBSD patterns, data processing, and indexing using the Hough transformation of EBSD patterns to detect the Kikuchi lines . Subsequent orientation analysis was performed using the MTEX toolbox for MATLAB [4], providing, e.g., inverse pole figure (IPF) maps.

Cross-section samples for scanning transmission electron microscopy (STEM) were prepared using the in-situ lift-out technique in an FEI Strata 400S Ga+-ion FIB/SEM instrument. A Pt protection layer was deposited by FIB to protect the underlying material during FIB milling. High-resolution high-angle annular dark-field (HAADF-) STEM images were acquired on an FEI Titan³ 80-300 at 300 keV. An FEI Tecnai Osiris operated at 200 keV and equipped with ChemiSTEM technology was used for chemical analyses with energy-dispersive x-ray spectroscopy (EDXS). The EDXS data was processed using Bruker Esprit.

Results

The continuous laser is focused at the interface of ink and substrate, resulting in the deposition of crystalline ZnO. Residual ink is removed by a solvent and the ZnO line is left (Fig. 1g).
SEM -EBSD was applied to analyze the crystallinity of ZnO (Fig. 1a). Single crystalline ZnO with the wurtzite crystal structure (P63mc) grows on the amorphous substrate for a 1 µm/s printing speed and a laser power of approximately 0.8 mW. The initial ZnO orientation is likely random since different lines show different initial orientations (not shown). In the IPF maps, one large ZnO single-crystal can be identified due to one single general color in each IPF map (Fig. 1b-d). However, a gradient of the color in all IPF maps indicates that the orientation of the crystal varies along the printed line, which means the crystal rotates along the printing direction. The corresponding color legend is presented in a triangle color legend (Fig. 1e). The orientation of the hexagonal lattice of ZnO at the start and the end of the printing is schematically shown (Fig. 1f). Earlier works have reported rotating lattice crystals in Sb-S-I glass system, by using different materials and laser printing parameters [5]. A total misorientation of 20° over the entire printed line (7.9 µm) is observed, corresponding to a linearly changing rotation rate of 2.6°/µm.
STEM-EDXS is used for chemical analysis of a cross-section TEM sample, which shows porous ZnO formed on silica (Fig. 1h). Nanometer-sized pores in the ZnO layer are visible as dark regions in the HAADF-STEM image result from the printing process (marked with arrows) . The Pt layer on the ZnO is deposited by FIB and acts as a protection layer during TEM lamella preparation. Also chemical analysis shows that the substrate layer below ZnO consists of 20 nm SiO2 and the layer below is a 250 nm Si layer. The silica glass under the Si contains Ti. The atomic resolution image shows a small region of the single crystalline laser-printed ZnO, here viewed along the ZnO<2-1-10> zone axis orientation (Fig. 1i). The Zn atomic columns appear bright and the O columns are not visible due to the HAADF-STEM Z-contrast.

Conclusion

To conclude, we provide an extensive electron microscopic examination of ZnO single crystals produced by photothermal laser printing at relatively low printing speed and laser power on an amorphous substrate. EBSD confirms the single crystallinity of ZnO with a rotating lattice over a distance of 7.9 µm. We will explore different printed geometries for a better understanding of the rotating lattice ZnO single crystals and the growth process regarding laser printing parameters. The aim will be to use such laser-printed semiconductor devices in microelectronics applications [3].

Towards atom-counting from first-moment STEM images

Dr. Yansong Hao[1], Dr. Annick De Backer[1], Prof. Scott David Findlay[2], Prof. Sandra Van Aert[1]
[1]EMAT, University of Antwerp, Antwerp, Belgium, [2]School of Physics and Astronomy, Monash, Australia

Poster Group 2

Background incl. aims
Over the past few years, a model-based approach has been established to extract quantitative measurements from atomic resolution HAADF STEM images. In this approach, the image is modelled as a superposition of 2D Gaussian peaks from which unknown structure parameters, such as atomic column positions, peak intensities and scattering cross-sections, can be estimated. This approach has been used to achieve accurate and precise determination of the chemical composition of materials and to count the number of atoms with single atom sensitivity. Atomic column intensities in HAADF STEM scale with the square of the atomic number and so light columns are easily hidden by the stronger intensity from heavier columns, making simultaneously estimating structural parameters for both light and heavy atomic columns challenging. However, this limitation might be overcome by quantifying other types of STEM image via a model-based method.
Methods
Recent advances in pixelated detectors, along with the capability to collect 4D STEM datasets, offers significant flexibility in generating diverse STEM imaging modes. One example is first-moment STEM images, in which the center of mass (COM) of convergent beam electron diffraction (CBED) patterns is recorded at each scan position. Typically, the COM is determined in two perpendicular directions, generating COMX and COMY images. Within the phase object approximation, the COM is proportional to the gradient of the projected potential, which is expected to scale linearly with the number of atoms in atomic columns as well as atomic number. Therefore, COMX(Y) images are expected to narrow down the signal difference between light and heavy atomic columns. By means of simulations, our study has explored the possibilities to estimate structure parameters and to perform atom counting based on COMX(Y) images. The precision of counting atoms with COMX(Y) images is also evaluated and compared to that using the traditional HAADF regime.
Results
We have performed model-based quantification on simulated COMX(Y) images of aluminum crystals. The integrated-intensities of atomic columns have been determined as a function of thickness by fitting a parametric model of a superposition of X(Y) derivatives of 2D Lorentzian-functions. For aluminum, a monotonic increase is observed up to a thickness of 30 atoms (~12nm), suggesting these intensities can be used as a quantitative measure for atom counting. Based on repetitive noise realizations of both COMX(Y) and HAADF images, it is possible to estimate the precision with which intensities can be measured. Furthermore, examining the overlap of the integrated-intensity distribution between atomic columns with consecutive thickness offers a means to evaluate the atom counting precision. This overlap can be quantified in terms of its relative width. The reduction of the relative width suggests the possibility to attain more precise atom counts when using COMX(Y) images as compared to the use of HAADF STEM images. Finally, the integrated-intensities from an aluminum wedge, whose thickness ranges from 5 to 15 atoms, is compared to those values from the aluminum crystals. The excellent agreement demonstrates the robustness to use bulk crystal simulations as a library, where the atom counting for samples with different shapes can be achieved by comparing to those library values.

Conclusions
In this study, a model-based quantification approach for COMX(Y) images has been developed. Unknown structure parameters, especially the integrated intensities of atomic columns, can be estimated, which enables us to perform atom-counting. As a comparison to traditional HAADF STEM imaging, atom-counting based on COMX(Y) images shows better precision and has great potential for further use in materials where both light and heavy elements are present.

Poster Group 2

Background incl. aims
There is a growing need to quantify and characterize the varying components within cements and concretes in multiple dimensions and at the multi-scale. This is particularly true for cements and concretes developed for the nuclear industry, whether as vessels for nuclear reactors or for nuclear waste containment, and to understand their constituents more holistically in three dimensions. However, cements and concretes are generally challenging to image in 3D, particularly at high resolution; this is because of typically large core sizes and consequential limited X-ray penetration, as well as varying chemistries of the components, and differing grain sizes. Further, because most of the components are calcium based, it can be difficult to differentiate them using density-based greyscale data alone when using traditional reconstruction (FDK) techniques. Because of these difficulties, scans usually need to contain many projections and long exposure times, therefore leading to long scan times and limited throughput. Here, we apply a variety of machine learning and AI approaches in a new XRM > machine learning reconstruction > AI quantified phase classification workflow. This workflow vastly improves the resulting scan data and enhances the component quantification process.

Methods
Here, we use non-destructive 3D imaging via X-ray Microscopy (XRM), combined with a novel 3D automated quantitative phase classification technique to spatially characterize the mineralogical phases in a variety of cements and concretes. We collected multi-scale 3D scans on a ZEISS Xradia Versa 620 X-ray Microscope (XRM), the data being subsequently run through numerous reconstruction options belonging to the Advanced Reconstruction Toolbox (ART): this includes DeepRecon Pro, a machine learning based approach for advanced denoising, enhanced contrast, and faster scans, and DeepScout, which allows users to upscale higher resolution interior tomographies to larger fields of view without sacrificing resolution. Finally, we use Mineralogic 3D to spatially characterize and quantify the mineralogy/phases within the concretes and cements in 3D (Mitchell et al., 2024).

Results
We find that DeepRecon Pro is effective at reducing noise in the resulting scan data (Figure 1). We also find that by using DeepRecon Pro, we can collect fewer projections (801 rather than 2401), resulting in better quality data, and we are able to collect scans three times quicker (29 minutes instead of 1 hour 35), leading to greater throughput of samples. We also find that we can improve the size of the field of view for high resolution scans; we are able to upscale 5.8 um voxel size scans from 5.9 mm3 field of view to 23 mm3, resulting in a field of view increase, and resolution recovery, of roughly 4x. This consequently leads to more representative segmentations over larger sample areas and better-quality data. In the final step we have applied Mineralogic 3D to achieve

quantitative phase classification of the concrete components; we are able to distinguish components of similar chemical composition and contrast (in particular, those that are Ca-rich), segment, and quantify them, which is an improvement on standard thresholding which does not take into account the scan conditions and relative density of the material. The results presented here show how new software options (DeepRecon Pro, DeepScout, Mineralogic 3D) are valuable to improve the image quality, characterization, and quantification of cements and concretes in 3D.

Microstructure and thermal stability of ultrafine-grained CuZn5 processed by HPT

Yuting Dai[1]
[1]Institute of Nanotechnology, Karlsruhe Institute of Technology, Eggenstein-Leopoldshafen, Germany

Poster Group 2

Background and aims:
High-pressure torsion (HPT) is widely known as an effective method for severe plastic deformation (SPD). This intense shear strain, combined with high pressure, not only results in notable grain refinement but also introduces a substantial density of dislocations, thereby enhancing mechanical strength [1].
Concurrently, ensuring the stability of ultrafine-grained (UFG) microstructures is crucial for their reliable performance in practical applications. Grain growth can compromise the enhanced strength of UFG materials, highlighting the importance of investigating microstructural stability for their commercial feasibility [2].
This concern is particularly notable in certain pure metals with low stacking fault energy such as fcc metals. In order to avoid grain growth, the grain boundary (GB) migration has to be limited. This can be done through the segregation of solute elements, which depends on the GB character. In this work, we use copper (Cu) as bulk material and add different amounts of Zn to examine the impact of varying Zn content on microstructural changes and thermal stability of GBs after HPT processing at room temperature.

Methods:
CuZn5 solid solutions were processed using HPT with a pressure of 4.5 GPa. The thermal behaviors of these materials were studied using differential scanning calorimetry (DSC). Scanning transmission electron microscopy (TEM) in combination with energy dispersive X-ray spectroscopy (EDX) was used to investigate the microstructure and composition of Cu-5at.%Zn (CuZn5), with a focus on GB segregation before and after annealing at different temperatures. Additionally, 4D-STEM (ACOM) was utilized to extract information on grain size distribution, grain orientation, and grain boundary types.

Results:
Annealing of CuZn5 up to 300°C by DSC shows a single exothermic peak at about 275°C. it should be mentioned that no grain growth or changes in the grain orientations occurred up to 200°C. High-angle annular dark-field (HAADF)-STEM imaging helps to understand the effect of Zn on the microstructure and GBs. From the 4D-STEM orientation mapping, the GBs can be classified into low-angle GBs, special coincidence site lattice (CSL) boundaries as well as high-angle general GBs. Together with STEM-EDX, it was found out that low energy boundaries such as Σ3 twin boundary is not enriched by Zn. On the other hand, Zn general GBs are segregated with Zn. This observation agrees well with the theory that solute segregation depends strongly on the GB energy. While special Σ-boundaries have low energy, they are less affected by solute segregation.
Conclusion:

Both CuZn5 and CuZn30 maintain a single-phase structure even after annealing, suggesting that the improved thermal stability of the alloys compared to pure Cu is attributed to the presence of solute content. This is due to the solute-drag effect [3], hindering the diffusion of GBs and contributing to the enhanced thermal stability of the alloys

Evaluation of Conventional Adherent Cell Enumeration Methodologies alongside Image-Enhanced Flow Cytometry

Dr Matthew Bourn[1], Mrs Lauren Daly[1], Mr Scott Gregory[1], Mrs Jeanne Rivera[1]
[1]National Measurement Laboratory at LGC Ltd, Leeds, UK

Poster Group 2

Background incl. aims
Enumeration and characterisation of cell populations are vital processes in both clinical and industrial laboratories. Accurate, reproducible counts of viable and apoptotic cells are crucial to many biological assays and require the development of robust experimental protocols. Currently, interlaboratory comparability between cell measurements is limited due to the lack of alignment in cell analysis techniques and methodologies. In general, the enumeration of adherent cells poses a greater metrological challenge than suspension cells, due to morphological complexity and diversity these cells can present. The impact of cellular morphology and growth characteristics on cell counting is yet to be fully investigated for many conventional enumeration techniques. The use of DNA and membrane stains allowed for quantification of cell confluency as a function of cell count using microscopy, demonstrating the impact of cell type on limits of quantification and linearity. Overall, this study evaluated the efficacy of three common enumeration techniques: haemocytometry, microscopy and flow cytometry using five distinct adherent cell types. Finally, a novel counting technique, which uses combined brightfield imaging flow cytometry, was investigated as a means of overcoming the current limitations associated with conventional flow cytometry.

Methods
Five adherent cell types; MCF-7, HeLa, MRC-5, HUVEC, and CHO were selected to cover a range of morphologies and disease states. Cells were seeded at commonly used concentrations, recommended by the ATCC. Cells were analysed forty-eight hours after seeding, using six separate instruments across three different counting techniques: haemocytometry (automated Countess and manual), microscopy (confocal and widefield), and flow cytometry (Attune CytPix and Beckmann Coulter CytoFlex). Cells for haemocytometry and flow cytometry were detached for counting using TrypLE. Cells for microscopy were fixed using 4 % paraformaldehyde, then DNA and membranes stained using Hoechst 33342 (2 µg/ml) and Wheat Germ Agglutin 594 (2.5 µg/ml) respectively. Imaging was performed using a Zeiss LSM 880 confocal or a EVOS FL 2 Auto widefield microscope. Automated image analysis of nuclei counts, and membrane area was performed using CellProfiler 4.2.1.

Results
Cell counts measured using hemocytometry demonstrated that this technique is least impacted by cellular morphology and growth characteristics. Low sampling volumes and user bias are the primary sources of counting variations which result in a relatively high limit of detection when compared to other techniques. The efficacy of microscopy-based counting was the most influenced by cellular morphology. Cells which displayed densely populated growth characteristics, such as CHO and HeLa, proved challenging in the identification and segmentation of single cell nuclei. These limitations resulted in a loss of linearity in cell count v confluency plots, which showed cell counts continuing to rise despite having a 100 % confluency. Both conventional flow cytometers consistently underestimated cell counts when compared to the other four techniques. This was primarily due to

the presence of cell aggregates in the sample which were incorrectly counted as single cell events and was not resolved following single gating approach of scatter height against width. In particular, cells displaying clustered growth morphologies, such as MCF-7, were found to produce the lowest cell counts in flow cytometry. Using the Attune CytPix brightfield imaging and analysis capabilities, cell aggregates could be identified and the number of cells in each aggregate determined. Image enhanced cell counts (CytPix En.) displayed values significantly more in-line with alternative techniques, demonstrating the efficacy of this novel counting methodology (graphic).

Conclusion

Results throughout this cell counting study demonstrated the impact of cell morphology and growth characteristics on countability. Several key factors have been highlighted which must be considered when aiming to develop robust cell counting methodologies and standards. Microscopy has been shown to be a useful tool for cell counting, however, this study notes that its limit of linearity and quantification is dictated by cell type. The combined use of flow cytometry and imaging for cell counting presents a quantitative method of determining cell count without the use of reference materials. This method overcomes the limitations of both microscopy and flow cytometry, in particular, removing the uncertainties associated with user-based single-cell gating strategies.

Structure and Function of Fructose 6-phosphate aldolase

Prof Hans Hebert[1], Dr Eda Sönmez[2], Dr Pasi Purhonen[1], Prof Mikael Widersten[2]
[1]School of Engineering Sciences in Chemistry, Biotechnology and Health, Department of Biomedical Engineering and Health Systems, KTH Royal Institute of Technology, Huddinge, Sweden, [2]Department of Chemistry – BMC, Uppsala University, Uppsala, Sweden

Poster Group 1

Background
Fructose 6-phosphate aldolase (FSA) catalyzes formation of fructose 6-phosphate from dihydroxyacetone and D-glyceraldehyde 3-phosphate via an aldolization reaction (1).
Methods
Cryo-EM structures of FSA from E. coli were obtained of the wild type enzyme and a mutant, L107C/A129G/R134V/L163C/S166G (FSAm), that had been identified as having substantially improved activity(2).
Results
Both proteins form D5 symmetrical decamers and X-ray structures (pdb: 7qxf, 1l6w) could be used for model building(2,3). FSAm samples contained the substrate 2-hydroxyacetophenone and the map had density corresponding to the crucial iminium reaction intermediate captured in the active site. The refined model showed a modification of a lysine residue (Lys85), 2-imino-2-phenylethanol-lysine not previously described in the Chemical Component Dictionary of the pdb database. Moreover, the side chain of the critical residue Y131 was rotated 100 degrees shifting the position of the phenolic group 3 Å. A water molecule participating in a hydrogen bonding network at the active site and thought to be involved in proton relay was shifted similarly.
Conclusion
The new structure can guide identification of additional FSA variants that display improved carboligation activities with 2-hydroxyacetophenone and phenylacetaldehyde.

PS-02 (1), Lecture Theater 5, august 28, 2024, 10:30 - 12:30

Background incl. aims
To reduce CO2 emission and comply with European legislation, automotive market implements new electrical powertrain. It implies changes in the operating conditions of its bearings requiring new material development (grades and/or thermochemical treatments) for bearing manufacturers. A typical mode of failure for bearings operating in contaminated lubricant is surface-initiated spalling on a dent[1,2], such as in gearboxes. The denting process creates micrometer-scale shoulders, intensifying localized stress [3] and leading to plastic deformation over the operational lifespan (Figure 1,a). Therefore, cracks are often observed to be initiated at the vicinity of the shoulder. However, the life cycle of the bearing was observed to be dependent of its initial microstructure[4]. To guide the development of new materials, a better understanding of the link between microstructure of the material and its performance in contaminated conditions is needed. Understanding the influence of each microstructural constituent on microstructural evolution, fracture development, and propagation is paramount for the development of more durable materials.

Methods
This study presents a multi-scale characterization of martensitic 100Cr6 bearings before and after RCF under standard test conditions. Samples were collected from bearings before and after the tests. Observations were realized at different locations (outside the dent area, under the dent, under the shoulder) using techniques such as SEM, SEM/FIB, EBSD, TKD and TEM-ASTAR.

Results
Prior to RCF, finishing operations leads to the formation of a 0.5 µm thick surface layer consisting in refined martensite and spread primary carbides. After RCF, away from the dent, no further grain refinement was observed along the raceway; the refined surface layer being resistant enough to plastic deformation during fatigue. Surprisingly, at the bottom of the dent, were large plastic deformation occurred during the indentation phase, no significant additional alteration of the microstructure was observed.
The major microstructural evolutions were observed beneath the dent shoulder where plastic flow occurred during the indentation and running-in, and where the stress is localized during the rolling process. First a fibered region is observed below surface, with a thickness of around 1µm (Figure1b). In this region, martensite grains are refined so that nano-grains are observed, and primary carbides are sheared. Below and down to 3 µm deep, far from finished surface, an ultra-fine grain layer is observed, mixing coarse and fine martensite. The martensite morphology, size and disorientations maps suggest that martensite undergoes refinement through twinning and continuous Dynamic Recrystallisation (Figure 1,b).

Crack initiation was preferentially observed in the nano-grain layer, at carbides/matrix interfaces. Above the crack, another refined grain region is detected that was interpreted to be due to high deformation and stresses through crack propagation.
In all characterized areas, nanosized austenite islands were observed. The initial retained austenite does not completely transform during fatigue in this case while it is known to transform under surface-RCF [5]. The major microstructural evolution observed is related to the refinement/reorientation of martensite grains that occurs through twinning and/ cDRX depending on the initial orientation of the grains.

Conclusion
The multiscale characterization of such localized deformed area, in non homogenous pieces (indentation being a random process) is a complex and tedious task to achieve. However, it gave crucial information about the microstructural deformation mechanisms. We infer that a material producing dents with smaller shoulder and less primary carbides at its surface would improve its lifetime.

Fig. 1: (a) Schematic representation of a dent after RCF, (b) SEM-BSE image of a crack initiated under the dent shoulder, and c) ASTAR-ACOM map of the white square area.

Poster Group 2

Background incl. aims
Grain boundaries (GBs) are pivotal in determining the physical characteristics of materials. The presence of extended strain fields localized at GBs can significantly impact atomic transport within these boundaries. Our research focuses on understanding the atomic structure of GBs and its correlation with the strain state along these boundaries. To delve deeper into the influence of strain on GB diffusion, we are investigating the evolution of strain along GBs under mechanical treatment using two distinct methods across varying length scales to establish a connection between microstructure and atomic transport properties.
Methods
A Cu bi-crystal containing a Σ5(310) GB was fabricated using a modified Bridgman technique, followed by annealing at 800 °C. An electron-transparent sample was prepared using FIB lamella target preparation to observe the GB in a cross-sectional view. The elastic strain along and across the GB was measured at the nanometer scale using a stack of nano-beam diffraction patterns (NBDPs) acquired in STEM mode with a 1 nm probe size, while ensuring grains were oriented in zone axis conditions. A custom-written code was utilized to extract the strain maps [1]. On an atomic scale, strain was characterized using the geometrical phase analysis (GPA) applied to high-resolution STEM images, based on measuring small displacements of lattice fringes relative to a reference lattice in the HR(S)TEM images [2].
Results
In the reference state of the pure Cu GB structure, shear strain, dilation, and rotation were measured along and across the GB using the NBDP method. The strain in the vicinity of the GB was found to be negligible (<0.1%). The results were consistent with the GPA method, showing almost constant small values of strain (<0.5%) in both halves of the crystal. These measurements were compared with strain mapping on cobalt-deposited samples.
Conclusion
Strain analysis of the GB in the Cu bi-crystal was conducted using two methods, GPA and NBDP, both of which yielded consistent results for strain across and along the Gb. GPA provided localized information at the nanometer scale, while NBDP offered strain information over a larger area. The strain analysis using GPA was correlated with the high-resolution structure of the GB. The high-resolution image of the GB provided insights into the variation of motifs within the boundary, potentially influencing strain distribution across both crystal halves.

CEFID: A flexible platform for spectroscopic experiments

Dr. Giulio Guzzinati[1], Pirmin Kükelhan[1], Martin Linck[1], Angelika Leibscher[1], Dominique Lörks[1], Volker Gerheim[1], Heiko Müller[1]
[1]CEOS GmbH, Heidelberg, Germany

IM-02, Lecture Theater 3, august 27, 2024, 14:00 - 16:00

TEM-related instrumentation has been developing rapidly in the last few years and a state-of-the-art experiment often involves a variety of third-party components ranging from advanced in-situ specimen holders and new generation detectors to pulsed lasers and programmable phase plates. The CEOS Energy Filtering and Imaging Device (CEFID) is an energy filter and spectrometer offering state-of-the-art specifications and the flexibility to implement ambitious and unprecedented experiments.
Under a concept of separation of function that mirrors the design of a TEM itself, the filter design comprises highly optimised and stable optics up to the energy-selecting slit, and a flexible and minimalist projective stage [1]. This gives high performance and stability, while allowing to hop between modes (imaging, spectroscopic dispersions) with little to no re-tuning. The Python/Qt-based graphical software used for the filter operation, implements interactive and automated procedures for alignments, common workflows ranging from EFTEM to 4D-STEM, and tools for on-the-fly analysis such as live DFT, EELS maps computation/quantification, Center-of-Mass, etc.
The software is highly extendable and offers a scripting and plug-in API in python and a remote control interface for the integration into third-party software.
A wide range of detectors and scan generators from different manufacturers has already been integrated and can be used for both the tuning and data acquisition, and the filter can be installed on TEM columns from the three major manufacturers. The capability and versatility of the system make it well suited for rapidly acquiring and evaluating spectroscopic information on samples of interest [2], while its flexibility and compatibility make it a platform for complex experiments where different tools need to work in unison, such as the synchronization of acquisition with in-situ stimuli, or photon-induced near-field electron microscopy [3].
Recent developments on the CEFID will also be shown. This includes the recently introduced Dual Range EELS, a solution to rapidly switch energy range so that two different losses can be recorded concurrently, as well as methodological developments in energy-momentum mapping, and in the measurement of high-loss edges.

Improving Transmission Kikuchi Diffraction workflows

Dr. Mark Coleman[1], Mr Kim Larsen[1]
[1]Oxford Instruments NanoAnalysis, High Wycombe, United Kingdom

Poster Group 2

Transmission Kikuchi diffraction (TKD) is an increasingly popular technique in the scanning electron microscope (SEM) for the characterization of nanoscale structures in wide range of materials [1-3]. The convenience of being able to utilize a conventional commercial electron backscatter diffraction (EBSD) system in a field emission SEM or focused ion beam (FIB) SEM has made TKD a particularly attractive alternative to orientation mapping techniques in the transmission electron microscope (TEM).

Improvements to focused ion beam instruments and sample preparation methods [4], have added analysis capabilities but not significantly improved the overall workflow or data quality. Methods such as the large area preparation method have made it possible to apply many standard approaches used for EBSD, however there is scope for TKD specific improvements. related to data processing during data acquisition, offline reprocessing and the geometry in which data is being acquired.

We will discuss the latest improvements to TKD workflows, improving the acquisition of high-resolution data, making the end-to-end workflow easier, and improving data processing to obtain better data quality in relation to TKD analysis.

Poster Group 1

Recent developments of add-on equipment in transmission electron microscopy cause a demand for modular and flexible data acquisition software. Fully integrated commercial solutions exist, but these are typically tailored towards a certain combination of proprietary hardware components from one manufacturer. For off-line data analysis and very specific high-throughput workflows open source software packages became available during the last years. Nevertheless, a lack of highly interactive software, directly usable during the operation of the instrument with its different components, is obvious.
To close this gap, CEOS Panta Rhei is designed as an interactive platform for data acquisition, processing and visualization in electron microscopy written in Python using the Qt, ZMQ and numpy libraries.
The primary purpose of Panta Rhei is to enable simple steering and supervision of workflows combining the control of the microscope and its accessories with data acquisition, online data analysis, and direct visual feedback. The capabilities for online data evaluation are progressing. We currently concentrate on functionality for quick and meaningful assessment of data quality and online session planning like image filters, data statistics, diffractograms, live 4D-STEM evaluation, and elemental mapping and quantification for EELS as well as EFTEM. Recently, the fitting of EELS spectra (and maps) using a library of precomputed generalised oscillator strengths (GOS) was also added [1]. Data can be interchanged with other software using common file formats like npz, hspy, mrc, msa, and tiff.
Interactive dialogs are provided to control the supported hardware, and perform interactive data acquisition from the separate device (e.g. camera images or STEM images), or combining multiple hardware components (e.g. STEM-EELS mapping).
The acquisition (via cameras or scan detectors) can generate a high volume of data which has to be transferred and processed efficiently. Therefore, a central component of Panta Rhei is a separate server process called Repository providing access to a managed shared memory. As soon as an acquisition device stores data in the Repository other clients are notified and can directly access the data with minimal CPU load and memory consumption. Clients themselves may also use the Repository to store processed data.
The Panta Rhei GUI is an application to acquire, display and process data and control hardware components which connects as client to the Repository. It displays Views of data from the Repository via a multiple document interface (MDI). Views are used to live display certain aspects of the data and the numerous available DataTools continuously calculate dependent data from updated input. The name Panta Rhei (πάντα ῥεῖ -- everything flows) is motivated by these chains of transformations that may even run in separate processes.
For custom extensions, a scripting interface provides control of data processing and display tools as well as hardware devices. For easy external access to hardware control, an RPC-interface is available.

Currently, Panta Rhei has interfaces for the TEMs of 3 manufacturers, 5 families of detectors, 4 different scan generators, and the CEOS Imaging Energy Filter (CEFID [2]). We expect that the number of compatible devices will continuously grow over time.

Background incl. aims
The adoption of direct electron detectors (DEDs) has led to the "resolution revolution" in cryogenic electron microscopy (cryo-EM) [1]. In Cryo-EM the state-of-the-art is back-thinned Monolithic Active Pixel Sensors (MAPS) due to their small pixel size (< 15 µm) and high-quality imaging capabilities. However, back-thinned MAPS have several drawbacks in terms of radiation hardness, frame rate, and non-optimal performance for low-energy electrons (≤ 120 keV), which are of increasing interest for better image contrast for a given electron dose and lower operational costs [2].
An alternative type of direct electron detector, Hybrid Pixel Detectors (HPDs), have been widely adopted for diffraction-based modalities in electron microscopy on the account of their high frame rates (> 1 kHz) and large dynamic range. However, currently available HPDs are limited in their suitability for imaging by their large pixels (≥ 55 µm) and multiple scattering of electrons in their thick (≥ 300 µm) sensors, such that the signal produced by incident electrons is recorded by many pixels, despite the large pixel pitch. MÖNCH [3] is a general-purpose, charge integrating HPD under development which is notable for its small, 25 µm pixels. Therefore, to fully realize the potential benefits of fast, radiation hard HPDs across the widest range of electron energies and experimental modalities of electron microscopy, we are developing deep learning methods to reconstruct the impact points of incident electrons from their complex track in the sensor with sub-pixel resolution.
Methods
We generated training samples including detector responses and impact points of individual incident electrons from both simulation and measurements. The simulation configuration closely mirrors the design parameters of the MÖNCH. Whereas previous studies [4] have been entirely based on simulations, we have, uniquely, prepared training samples with precise labels from experimental measurements by developing two novel data acquisition approaches, which will be presented in detail. For this purpose, as well as for the measurement of the detector's performance as quantified by its modulation transfer function (MTF) and detective quantum efficiency (DQE), a MÖNCH 03 prototype was mounted on a JEOL JEM-ARM200F NEOARM at the Paul Scherrer Institute for data collection.
Based on the simulated and experimental datasets, deep learning models were developed for impact point reconstruction. We will show details of the deep learning model design, training scheme, and evaluation results.
Results
Sub-pixel resolution was attained at all tested energy levels (200, 120, 80, 60 keV). For example, at energy levels of 200 keV and 60 keV, the resolutions were 1.8 pixels and 0.4 pixels for the conventional charge centroid method, while via the deep learning approaches the resolutions were 0.6 pixels and 0.3 pixels, respectively. Images of a test sample consisting of continuous carbon with gold nanoparticles at 200 keV are shown in Figure 1, processed using the conventional charge

centroid method (left) and the deep learning approach (right). With the deep learning method, we were able to image the spacing of the {1 1 1} gold atomic planes, with a spacing of 2.35 Å. The MTF and DQE results at all energy levels, with and without the deep learning algorithms applied, will also be presented as a benchmark of the system's capabilities. Lastly, the data processing pipeline for the MÖNCH detector for its use in electron microscopy will be discussed.

Conclusion

In this work, we have successfully developed deep learning approaches for localizing electron impacts on MÖNCH. Using measurement-based training enabled by the novel acquisition setup we have developed, sub-pixel spatial resolution was achieved across all electron energies tested. The improvement relative to the results obtained with the charge centroid method increased with electron energy. The spatial resolution obtained for 200 keV electrons (0.6 pixels) represents a threefold enhancement compared to the charge centroid method. Our results show that MÖNCH, with its spatial resolution enhanced using deep learning, is a highly promising detector for electron microscopy studies using electrons up to 200 keV.

Background incl. aims
Among various candidates for the rare-earth free permanent magnets, the ferromagnetic τ-MnAl-C (L10, P4/mmm) shows great potential to replace ferrites and bonded Nd-Fe-B magnets for its attractive magnetic properties and the non-critical nature of the raw elements [1, 2]. Further magnetic properties enhancement will depend on understanding of the effect of various crystallographic defects in the magnet, e.g. twin boundaries, and on developing novel processing routes for microstructure optimization.
Twin boundaries are frequently observed in both the as-transformed and hot deformed τ-MnAl-C magnets [3]. Three different types of twin boundaries have been discovered in the τ-MnAl-C magnet and they are described as true twins, order twins and pseudo twins [4]. Considering the tetragonal structure of the chemically ordered τ-MnAl-C magnet, it is reasonable to assume that a different atomistic structure exists at these three types of twins, as well as its local magnetic properties.
Methods
In this study, aberration-corrected scanning transmission electron microscopy coupled with electron energy-loss spectroscopy (STEM-EELS) was used to investigate the atomistic structure and chemical composition at various twin boundaries in τ-MnAl-C [5].
Results
The results show differing levels of structural disorder at the various types of twin boundaries and EELS data reveal the presence of a Mn-enriched layer at the twin boundary surrounded by Al-enriched layers. The thickness of these layers and the magnitude of the chemical segregation vary with the level of structural disorder. Micromagnetic simulations based closely on the experimental results showed that the coercivity tends to increase with increasing structural and chemical disorder at the twin interface.
Conclusions
These results suggest that targeted doping of interfaces in τ-MnAl may be a promising strategy to increase the coercivity of the material for applications.

Background incl. aims

The invention of aberration correctors at the end of the 20th century has made modern Transmission Electron Microscopes (TEMs) one of the most sought-after scientific instruments in modern material science and life science laboratories since they now allow to image and characterize samples with the highest lateral (spatial) resolution. [1,2] The most important technological advancement which further increased the interest in TEMs was the invention of spherical aberration correctors. [3,4] Unfortunately, aberration correctors are quite costly and are reaching performance limitations: this has prompted some research groups to work on computational imaging methods to increase the lateral resolution in TEMs.
Here we present the results from a simulated computational ghost imaging (CGI) scheme for TEMs where we demonstrate numerically that it's possible to overcome the resolution limit imposed by aberrations using well-characterized structured probes and a bucket detector.

Methods

In computational ghost imaging the image of the sample (and its spatial information) is computationally recovered by illuminating the sample with a series of known structured beams and collecting the integrated transmitted intensity via a single-pixel bucket detector positioned after the sample. In fact, if the measurement is linear we can see that it can be described in matrix notation with the equation $I = P \hat{} T$ where I is the array containing the N signals recorded by the single pixel detector, P is the array containing the intensity pattern of the N probes and T is the sample transfer function. By knowing both P and I it is possible to recover T and many algorithms exist to this end [5]. We have developed a custom python-based algorithm that allows us to simulate the generation of structured patterns, provides us with the value of the signal measured by a virtual bucket detector (even in presence of noise and realistic coherence effects) and recovers T with three different reconstruction algorithms: the traditional one, the alternated projection algorithm and the conjugate gradient descent algorithm.

Results

For the generation of the simulated structured patterns we assumed a 300kV microscope with Cs=2.7mm, a 15.4 mrad probe convergence angle and as defocus four times the Scherzer STEM defocus. All other aberrations were neglected since we had such a large value of Cs. The electron modulator is assumed to be in the last condenser aperture, while the sample of choice (a twisted

bilayer of MoS2 – Figure1a) is conventionally positioned in the sample plane. As single pixel detector we used the annular dark field detector, but in principle we could use other single pixel detectors such the bright field detector or those used for energy dispersive X-Ray imaging, electron energy loss spectroscopy or cathodoluminescence.
As it is possible to appreciate from figure 1, our CGI scheme is able to overcome the aberration limit imposed by the instrument (figure 1e) with a two-fold increase in spatial resolution compared to an aberration-limited STEM image (figure 1c) as confirmed by the analysis of their FTTs (figure 1f and d, respectively).

Conclusion

Here we have demonstrated that, if the optical system is well characterized and the aberrations that act on the illumination are known and quantified, it is possible via a computational imaging technique to overcome the aberration-limit.
We are already working on an experimental implementation where the phase plate for structuring the beam has been realized using MEMS technology. As a next step for further improvements, we are working on the possibility to use machine learning (ML) to further optimize our electron modulator and the pattern that it can generate, with should enhance both our simulated results and more importantly the future experimental ones. Moreover, we are also working on a mixed scheme where we also control the scan coil of the TEM to optimize the illumination, increases reliability and acquisition speed, and should allow for the reconstruction of the probe.

Figure 1 Caption: a) schematic of the electron-optical setup, (b,d,f) comparison between the sample atomic potential, the aberration-limited STEM image, and CGI reconstruction and their corresponding FFT (c,e,g). For the CGI reconstruction reported here no noise and no realistic coherence effects (temporal or spatia) were considered, but we have also performed simulations in those scenarios. In the FFT images the yellow inner circle corresponds to 2α, while the red outer circle corresponds 4α, where α=7.3 mrad. Scalebar in b,d and f is 0.5nm. In h) is shown an example of a structured pattern utilized for the CGI reconstruction and in i) is shown complex image of its FFT.

Indium-Gallium-Zinc-Oxide (IGZO) compounds have been regarded as attractive material for the channel in transparent thin-film transistors (TFTs), with low leakage in the off-state and high mobility. IGZO-based materials belong to the class of high band-gap semiconductors and their crystallographic properties are the key characteristic determining the final performances of the electronic devices. Amorphous IGZO, for example, is easy to grow and has good electron mobility, in contrast to other semiconductors such as Si and Ge in the amorphous state. However, in the perspective of the fabrication of electronic devices, amorphous IGZO TFTs suffer from electrical instability. Crystalline IGZO mostly exists in two polytypes having spaces group R3̄m (160) and P63/mmc (194), and has showed improved electrical performances. There is also an intermediate crystal phase where the periodicity is kept only in the c-axis, while being structureless in the a and b-axis. This phase is called CAAC (c-axis aligned crystalline) IGZO and it is less prone to defect formation. More sophisticated configurations have been employed in TFTs: for example, a double layer design, constituted of amorphous and CAAC-IGZO, has shown good device stability [1]. To further enrich the family of IGZO compounds, a new a spinel polytype has been recently demonstrated, which can be grown via PVD using intermediate conditions derived from the growth of amorphous and CAAC-IGZO, and exploiting a Ga2ZnO4 (GZO) layer as a seed [2].
In such a complex panorama, there is a need for an appropriate technique to characterize the huge diversity of crystal phases in IGZO-based TFTs. To this end, we referred to Precession Electron Diffraction (PED) [3] executed via a Transmission Electron Microscope (TEM) in scanning (STEM) mode. In fact, standard electron diffraction, due to sample thickness, is significantly affected by multiple/dynamic scattering, which leads to diffracted intensities not easy to be interpreted. PED was introduced to solve this issue and analyze crystal structures with better sensitivity. In PED, the electron beam is rocked at a fixed angle to the optic axis above the sample, forming a hollow cone, and then it is de-rocked below the sample. It can be demonstrated that the final diffraction pattern has many more reflections than in the case of an unprecessed beam, having intensities unaffected by dynamic scattering. We applied scanning PED to the study of IGZO thin (about 20 nm) films having spinel structure and grown on GZO layers having different thickness (from 2 to 10 nm). We prove the possibility to correctly identify materials with similar electron diffraction patterns, such are IGZO and GZO, using PED and Phase & Orientation mapping of the scanned area (ASTAR, NanoMEGAS) [4]. We demonstrate that high sensitivity can be achieved to properly resolve even narrow GZO layers, as thin as 2 nm, from the above IGZO. This can be inferred from Figure 1, which shows the combination of phase map and indexation for two different IGZO samples, grown on GZO having thickness of 10 nm (a) and 2 nm (b), respectively. Moreover, phase and orientation mapping allowed us to study the grains structural properties in IGZO grown on GZO layer with different thickness. We show that, as expected, IGZO grows epitaxially on the GZO seed layer. Moreover, IGZO grain growth is related to the thickness of the underlying GZO layers: size of the IGZO grains is coarse when GZO has higher thickness, while columnar growth of narrower and IGZO grains is reached when thin GZO is used. For GZO having 2 nm thickness, IGZO and GZO present texture, with growth of IGZO/GZO along the

<111> direction. Finally, we study the case where thermal annealing in a hydrogen atmosphere reduces the IGZO film and induces the formation of In-rich grains dispersed in the IGZO matrix. In this context, we study the crystal structure of these grains and their matrix.
This study is preliminary to the characterization of TFTs devices employing complex design and based on IGZO compounds as channel material. In general, these results can open the way to the study of different devices, where the common feature relies in the close link between the crystallographic structure and the final performances.

Background incl. aims
Ultra-small atom precise metal nanoclusters (NCs) have emerged as (electro)catalysts due to their large surface area and abundant unsaturated active sites. However, surface ligands and strong agglomeration tendency limit NCs' catalytic activity [1]. Zeolitic imidazolate frameworks (ZIFs), a sub-set of metal-organic-frameworks (MOFs) emerge as excellent support to host NCs due to their well-controllable pore size of 11.6 Å, pore aperture 3.4 Å and high internal surface area. Understanding the state and the stability of these NCs inside the ZIF pores under operating condition is crucial for tuning the catalytic properties.
Generally, in high-resolution TEM (HRTEM) experiments few atom NCs appear to be more stable than ZIF when exposed to the electron beam. The atomicity of Pt NCs is measured using spectroscopy techniques as mentioned [2]. Therefore, HRTEM experiments to understand the structure, e.g. of Pt27@ZIF-8 nanocomposites (shown in fig. 1(a)), are very challenging because ZIF-8 tends to lose crystallinity already at a cumulative electron dose of ~ 25 e-Å-2, which is far below the required dose for standard high-resolution images [3]. So far, no quantitative measurement of a critical electron dose limit for real-time observations of ZIF-8 (and NCs@ZIF-8) under operating conditions (elevated temperature and various gaseous environments) has been reported. Hence, the structural and morphological integrity in such experiments as well as the mechanism of possible loss of crystallinity under the exposure of electron beam are still largely unexplored. However, we consider this to be a prerequisite before conducting an (in-situ) study of such a beam sensitive material.
Methods
To establish the critical electron dose for ZIF-8, we systematically investigated here the effect of the accumulated electron dose on the ZIF-8 crystallinity using selected area diffraction (SAD). Thereby we quantitatively measured 1. the fading of intensity of specific Bragg planes as well as 2. the relative displacement of Bragg planes, both as a function of accumulated total electron dose. We have varied the TEM sample support (graphene versus amorphous holey carbon) and we have applied different TEM imaging parameters such as accelerating voltage (200 vs 300 keV) as well as electron dose rates (0.33, 0.5, 1, and 2 e-Å-2s-1). The bright field (BF) image and the corresponding SAD pattern of single crystalline ZIF-8 particles are shown in fig. 1(b, c). The fading of the relative intensity of 431 Bragg ring in the SAD pattern as function of cumulative dose is shown in fig. 1(d).
Further, we investigated the stability of ZIF-8 at different sample temperatures, varying the temperature from -176°C to 550°C. Both the TEM cryo and heating experiments were performed in a ThermoFisher Titan microscope using a Gatan 626 and Inconel holder, respectively. In the heating experiment the temperature was varied from 200 to 550°C with a step of 50°C.
Under all experimental conditions, the critical accumulated dose was determined by measuring the fading of the respected Brag spots. In order to understand the mechanism of loss in crystallinity we further measure any crystal lattice expansion or shrinkage indicated by changes in the radius of the SAD rings (= Bragg planes).

At last, we investigated the stability of ZIF-8 under oxygen atmosphere and elevated temperatures, using a ThermoFisher Titan ETEM (300 keV) and a Gatan Inconel heating holder. The temperature was varied from 350°C to 550°C under constant O2 pressure of 2.7 mbar. Again, the transformation of ZIF-8 to ZnO nanoparticles was observed in BF images and SAD pattern, and the change in the crystal structure and morphology of the particles were studied.

Results

Based on our systematic study, we report the critical limit of cumulative dose of ~10 e-Å-2 to enable non-invasive structural characterization using HRTEM imaging. We thereby provide insights into the fundamental mechanisms of electron beam-induced damage in ZIF-8.

The influence of different imaging conditions, substrate materials and temperature on the critical dose will be discussed. Finally, the challenges and development of in-situ gas experiments on beam-sensitive materials will be discussed, taking ZIF-8 MOF to ZnO transformation as a reference.

Conclusion

This work provides a deeper understanding of the interaction of electrons with MOF (here: ZIF-8) under different HRTEM imaging conditions, an understanding of the underlying damage mechanism and the identification of optimal conditions for (in-situ) characterization experiments.

These findings have significant implications for the further development of NC@MOF nanocomposites in a wide range of applications, such as catalysis.

Background and Aims
4D Scanning Transmission Electron Microscopy (4D-STEM) has revolutionized the study of nanoscale materials by offering localized structural imaging capabilities through electron diffraction patterns [1]. However, the inherent noise within these patterns often impedes critical structural details, posing challenges to accurate analysis, particularly in orientation-based clustering [2]. In response, this paper presents a comprehensive approach to denoising 4D-STEM datasets, focusing on leveraging Pix2Pix Generative Adversarial Networks (GANs) to reduce noise and the influence of the artefacts [3].
Methods
The methodology is to focus on training a Pix2Pix GAN architecture using paired noisy-clean 4D-STEM image data. Adjusting the conditional GAN framework, the generator network learns to map noise from input images to their corresponding clean counterparts, guided by the discriminator network, which distinguishes between real-clean images and generated ones [3]. This approach effectively captures the intricate relationships between noisy and clean data, facilitating precise denoising. To address artifacts commonly encountered in GAN-generated images [4], we integrate additional regularization techniques and architectural modifications into the generator. Furthermore, architectural adjustments such as skip connections and multi-scale discriminators are implemented to enhance image fidelity and minimize artifact occurrence.
Results
Extensive experimentation was conducted on both synthetic and real-world 4D-STEM datasets to evaluate the effectiveness of our approach. Quantitative metrics, including peak signal-to-noise ratio (PSNR) and structural similarity index (SSIM), were employed to assess denoising performance, complemented by visual comparisons to highlight the clarity and fidelity of denoised images. Results demonstrate significant noise reduction and artifact suppression, enabling clearer visualization of nanoscale structures and more precise analysis. Importantly, our approach offers a substantial time-saving advantage compared to traditional methods, reducing processing time from 15 hours (using e-Pattern processing [5]) to just 0.2 hours.
Conclusion
In conclusion, our methodology provides a robust solution for denoising 4D-STEM datasets, leveraging Pix2Pix GANs while effectively addressing the challenge of artifact reduction. Significantly, this work contributes to advancing the field of materials science by enhancing the utility of 4D-STEM imaging techniques and emphasising the potential of GAN-based approaches in complex image-processing tasks.

IM-05 (1), Lecture Theater 3, august 26, 2024, 10:30 - 12:30

Background incl. aims
For systems with a complex morphology, 2D information can be insufficient, which requires tomographic approaches. Together, electron tomography and nanoscale X-ray CT cover the range from 3D sub-nanometer resolution for small sample volumes, up to samples sized several tens of micrometers, and in the electron microscope this information can be coupled with analytical information from associated spectroscopy techniques.
Among advanced modern materials, nanoporous metals (usually represented by nanoporous gold or other noble metals) can form the backbone for various applications, such as catalysis or supercapacitors. Copper is a promising alternative to rare and expensive noble metals due to its cost, redundancy and scalability. Nanoporous Cu materials can be made by electrochemical dealloying[1] where the size of resulting pores is tailored to fit the intended application. Due to its less noble nature, Cu is more prone to oxidation, and oxide chemistry on the pore surfaces plays a significant role for intended applications. It is therefore imperative to know the morphology and inner surface chemistry of the nanoporous material as well as to be able to assess pore parameters, such as size distribution or local curvatures for scalable pore sizes ranging from 20 to 500 nm, which requires adapting available characterization methods.
Methods
Nanoporous Cu structures, dealloyed from either Cu-Mn or Cu-Al alloys with different dealloying conditions and optional subsequent coarsening, were investigated with following methods: high-angle annular dark field scanning transmission electron tomography (electron tomography), energy-dispersive x-ray spectroscopy (EDXS), electron energy loss spectroscopy (EELS), Zernike phase contrast laboratory nanoscale x-ray computed tomography (nano-CT). Samples for electron tomography were prepared as 100-300 nm thin pillars via focused ion beam milling (FIB). Samples for nano-CT (60 µm thick) were formed by laser ablation with a finishing touch of FIB.
Results
We use electron tomography to capture in detail the nanoporous Cu network morphology from HAADF data, while also reconstructing 3D elemental distributions from EDXS. Implementing multimodal joint reconstruction of all channels (EDXS and HAADF) with total generalized variation regularization (TGV)[2] algorithm we can capture the surface oxidation of Cu in 3D, as well as local residuals of Mn after dealloying. We use EELS fine structure to self-reference multiple linear least squares fitting (MLLS) segmentation to classify and map present Cu and Mn oxide species. We further implement Zernike phase contrast laboratory nano-CT for statistical pore parameter analysis of coarsened samples.
Conclusion

In nanoporous copper samples dealloyed from Cu-Mn alloy we were able to identify and map Cu and Mn oxide species. Based on Mn oxides present we suppose a different reaction path on the dealloying stage to the one suggested in literature.[1] We have reconstructed and segmented 3D distributions of present elements and overall nanoporous Cu morphology to quantify porosity as well as pore size, distribution and connectivity. With statistically-rich nano-CT segmentation we show that at the testing stage coarsening procedure works differently on np-Cu dealloyed from Cu-Mn or Cu-Al alloys likely because of the complexity of phase diagram of Cu-Al. We report that pore coarsening on Cu-Al has good scalability but suffers from residual presence of unreacted mother alloy bubbles. [3]

Poster Group 1

Background incl. aims

Electron tomography is a technique that allows 3D data analysis at the nanometer scale. It has always been considered a difficult and time-consuming technique, from tilt series acquisition to volume reconstruction and data analysis. In the beginning, the tilt series acquisition was performed in several tens of minutes in bright field mode to several hours in scanning transmission mode (STEM). Huge technical developments have been made to make tilt series acquisition faster and faster, and to enable fast electron tomography compatible with environmental electron microscopy. [1,2] Environmental electron tomography in gas, and even more in liquid state, is very sensitive to the electron beam, therefore recording fast tilt series in STEM mode with a very low electron dose received by the sample is a real challenge even for the most experienced users. One solution to ensure the recording of fast tilt series with low electron dose at a constant rate is to automate the recording process.
This presentation will introduce the M-SIS software. Its purpose is to take advantage of the power and robustness of the computer code to assist the operator and improve his/her skills while acquiring a series of tilts in electron microscopy. The automation minimizes the electron dose received by the sample by reducing its exposure time to the electron beam.

Methods

The M-SIS code (Figure1) is written in Python and is compatible with different environments and machines. It can be installed on an Environmental Scanning Electron Microscope (ESEM), which is compatible with Thermo Scientific™ Autoscript, as well as on an Environmental Transmission Electron Microscope (ETEM), as a plug-in of DigitalMicrograph™. In addition, built-in libraries enable hardware control, such as the Smaract MCS-3D piezo-inertial stages used to control the stage and detector in the ESEM.

Results

The M-SIS software is compatible with ESEM and ETEM, enabling multi-scale electron tomography in environmental mode at very low electron dose in STEM (scanning transmission) imaging mode. It is able to automatically set the sample at the eucentric position. The brightness and contrast of the images are automatically adjusted, and then fast tilt series are acquired. One of the problems of fast tilting is that the sample drifts out of the field of view due to mechanical imperfections while tilting. The M-SIS software automatically corrects the drift of the specimen during image acquisition and keeps it in the field of view during the tilt. The code allows the acquisition of multiple imaging modes

simultaneously, i.e. SE, BF, DF and HAADF, all while protecting the sample from beam damage. During validation tests, the total electron dose received by the sample ranged from 1,042 e-/nm2 in ESEM at 30 keV to 16,000 e-/nm2 in ETEM at 300 keV both recorded in liquid mode, for the acquisition of more than 100 images per imaging mode, in about 10 min. Volumes have been reconstructed on very sensitive samples from materials science and biology, at different hydration states, and quantitative data could be reliably extracted.

Conclusion
We have developed a software based on Python language, which is compatible with ESEM and ETEM electron microscopes, allowing the recording of low electron dose tilt series in STEM mode in environmental mode at multi-scale. The software is user independent, automatically sets the sample to the eucentric position, corrects brightness and contrast, and records fast tilt series with controlled electron dose, while tracking the sample as it rotates. [3]

PS-02 (2), Lecture Theater 5, august 28, 2024, 14:00 - 16:00

Background incl. aims
In recent decades, bimetallic core-shell nanoparticles (NPs) have attracted great attention in materials science, primarily due to their unique optical properties based on surface plasmon resonances. However, the practical application of these materials, particularly under elevated temperature conditions, often leads to particle reshaping and redistribution of metals between the core and shell of the particle, gradually altering nanoplasmonic properties. Consequently, advancing nanoplasmonic-based technologies necessitates a comprehensive understanding of heat-induced transformations, considering factors like nanoparticle size, shape, and defect presence. Conventional two-dimensional Scanning Transmission Electron Microscopy (2D STEM) imaging falls short in reliably analysing diffusion, especially in asymmetric NPs. Thus, employing three-dimensional (3D) characterization techniques becomes paramount. Herein, electron tomography (ET) emerges as a pivotal tool. Moreover, achieving atomic resolution in the 3D investigation of elemental redistribution is crucial. This enables drawing conclusions regarding the structural parameters influencing diffusion kinetics in bimetallic NPs, such as core-shell Au@Ag NPs.
Methods
To conduct a thorough 3D investigation of heat-induced alloying in individual Au@Ag NPs, ET based on High-Angle Annular Dark Field (HAADF) STEM was combined with in situ heating holders.1 To reach ET reconstructions with atomic resolution, an aberration-corrected Themis Z transmission electron microscope offering a spatial resolution of 60 pm was used. The 3D reconstruction of each studied NP was performed after several heating steps using advanced reconstruction algorithms2 supported by convolutional neural network, allowing for compensation of scanning distortions during the acquisition of HAADF-STEM projections and missing wedge artifacts.3 Mass-thickness contrast (Z-contrast) of HAADF-STEM ET enabled us to distinguish between individual Au and Ag atoms, facilitating the determination of atom positions. Additionally, a set of selected slices through the obtained reconstructions were used as an input for StatSTEM analysis,4 to correlate the kinetics of atomic redistribution with the presence of lattice distortions.
Results
As reported in our previous work, we observed significantly faster alloying kinetics in pentatwinned (PT) Au@Ag NPs compared to their single-crystalline (SC) counterparts, which we attributed to lattice distortions near the twin boundaries, facilitating faster atomic transport.5 To support this hypothesis, heat-induced alloying in SC and PT Au@Ag nanorods (NRs) with similar sizes and compositions was studied using atomic resolution ET. To induce alloying, all particles were heated to 450°C using the specialized heating tomography holder until complete and uniform alloying was achieved. To investigate intermediate states of alloying, the heating process was interrupted, and atomic resolution ET series were acquired after several heating time intervals. The obtained tomography datasets were further utilized as input for advanced ET reconstruction algorithms, where prior knowledge is typically used to enhance the outcome of the reconstructed 3D volumes. Specifically,

the Sparse Spheres Reconstruction (SSR) algorithm2 was implemented, where parameters such as the sizes and intensity values of atoms within an NP can be parameterized, leading to the improved distinction between individual Au and Ag atoms. In this manner, we were able to study the atomic transport in different NPs in 3D and assess the diffusion kinetics in the SC regions of the studied NPs or in the vicinity of twin boundaries, where lattice distortions can be carefully determined from the positions of all atoms obtained from atomic resolution ET reconstructions.

Conclusion

In this work, we demonstrate the capability of advanced ET techniques to conduct in situ investigations and quantitative analyses of heat-induced processes in complex NPs, such as core-shell Au@Ag NRs, with atomic resolution in 3D. By employing these techniques, which involve the combination of state-of-the-art TEM instruments with dedicated heating tomography holders and specialized reconstruction algorithms, we show that diffusion kinetics are faster in regions where twin boundaries cause higher interatomic distances compared to the "perfect" crystal lattice of Au and Ag.

The project has received funding from European Research Council (ERC Consolidator Grant 815128, REALNANO) and European Commission (grant 731019, EUSMI).

Unveiling the three-dimensional ultrastructure of Poly Lactic Acid (PLA) spherulites by means of electron microscopy

Dr Paola Parlanti[1], Dr Giovanna Molinari[2], Prof Andrea Lazzeri[3,4], Dr Mauro Gemmi[1]
[1]Istituto Italiano di Tecnologia CMI-IIT, Pontedera, Italy, [2]National Research Council CNR-IPCF, Pisa, Italy, [3]University of Pisa, Pisa, Italy, [4]National Interuniversity Consortium of Materials Science and Technology, Florence, Italy

PS-07 (2), Plenary, august 30, 2024, 10:30 - 12:30

Background incl. aims
Among biobased polymers, Poly Lactic Acid (PLA) is widely used in a variety of daily-use products from packaging to biomedicine, thanks to its properties (high strength, lightweight, toughness, corrosion resistance, transparency) and its ability to be easily and economically processed from renewable resources via traditional manufacturing techniques, such as injection-moulding. It is therefore a good candidate for replacing conventional petrochemical-derived plastics [1]. To improve the fabrication of this promising material, and optimize its properties (mechanical, thermal, etc.), a deeper comprehension of PLA morphology is mandatory. During the injection-moulding fabrication process, molten PLA solidifies into semicrystalline structures called “spherulites” (figure A), which are constituted by fibrillar lamellae (with thickness ranging from 10 to 30 nm), radially growing from a nucleation center (figure B). Depending on the manufacturing process, spherulites vary their morphology leading to a great impact on the macroscopic (e.g. mechanical) properties of this material [2]. To date, few studies extensively describe PLA spherulites’ morphology [3], but generally their characterization is limited to two-dimensional observations. Here we report our work in the three-dimensional (3D) investigation of PLA spherulites, by means of electron microscopy, toward a better comprehension of the relation between micro- and macroscopic properties of this material.
Methods
Dog-bone semicrystalline PLA samples were obtained by injection-moulding technique. PLA blocks (approx. 5 mm each side) were retrieved from the central portion of the dog-bone specimens, while keeping track of the orientation of the material within the hot mould. Then, using an ultramicrotome, we sectioned PLA blocks for transmission electron microscopy (TEM) imaging, by carrying out two different sectioning approaches: 1) directional sectioning; 2) serial sectioning. The first requires that the sample was cut into three mutually orthogonal directions, to investigate the PLA spherulites respective 3D arrangements in the block. The latter was instead chosen for 3D reconstruction of a single spherulite, by collecting sequential PLA sections, and imaging the same structure across the entire series of sections. We also performed scanning electron microscopy (SEM) imaging of the PLA sections collected on silicon wafers and tested the capabilities of focused ion beam scanning electron microscopy (FIB-SEM) for the spherulite volume imaging. Finally, ultramicrotome sectioning and FIB-SEM were used for fabricating PLA blocks suitable for X-ray ptycho-tomography.
Results
TEM analysis of directionally sectioned PLA blocks revealed the 3D organization of spherulites within the samples (figure A), which appeared to have an elliptical shape, with lower ellipticity extent at the faces perpendicular to the hot polymer flow direction during the injection-moulding processing. This would be directly related to the shear flow generated at the hot mould walls, which favored the elongation of the spherulites in the direction of the hot polymer flow.

Concerning the 3D characterization of a single spherulite, TEM imaging of the same structure across the entire series of sections collected with the serial sectioning approach allowed to reconstruct the lamellar arrangement within the spherulite, for a total volume of about 1.1 um (figure C).
In order to reconstruct larger volumes of PLA spherulites, SEM analysis as well as FIB-SEM tomography were tested too, but spherulite's lamellae were not visible with the same resolution achieved with TEM.
For this reason, we are now approaching a new imaging technique (figure D): X-ray ptycho-tomography, pushed to the limit of spatial resolution (voxel side) down to tens of nanometers. This would give for the first time information along the third dimension about spherulites morphology and lamellar arrangements at the nanoscale.
Conclusion
PLA morphology and its mechanical/thermal characteristics are strictly related. Thus, the knowledge of PLA ultrastructure is particularly important for optimizing the fabrication process and finally obtaining a material with tailored macroscopic properties, such as thermal behavior, flexibility, strength. Our observations demonstrate the importance of microscopy in polymer science, through the application of cutting-edge (electron) microscopy techniques. Here we bring new insights of the PLA morphology, paving the route towards optimized industrial processing of this versatile and environmental friendly material.

PS-09, Lecture Theater 2, august 26, 2024, 14:00 - 16:00

Background
Throughout history, bright colours have contributed to the advancement of art and science through inspiring creativity, improving mental wellbeing, and enhancing the transfer of information. However, since many common pigments are produced using toxic materials, there has been a recent burst of interest in producing non-toxic, colourfast, long-lasting pigments for various colour treatment applications [1], led by the discovery of a durable, environmentally friendly inorganic blue pigment Y(Mn_{1-x}In_x)O_3 [2].
The two end compounds of this mixture, $YInO_3$ and $YMnO_3$, are white and black, respectively. Both compounds crystallize in a layered hexagonal lattice, while the intermediate compounds form a solid solution in which In and Mn occupy the same lattice sites. Mixing a small amount of Mn into the $YInO_3$ lattice results in a startling blue colour originating from absorption of other colours by electronic transitions from the Mn 3d states, including nominally forbidden d-d transitions. These transitions are made possible by the non-centrosymmetric trigonal biypramidal (TBP) environment of O around the Mn ions [2,3].
In this study, we present a thorough characterization of the structural and spectral characteristics of Y(Mn_{1-x}In_x)O_3 across the full compositional range. We discuss the origin of the strong blue colour and its correlation with the crystallographic properties of this oxide material.
Methods
We use a Nion HERMES100 STEM operated at 60 keV, with an average energy resolution of 5 meV, to acquire high resolution EEL spectra across a broad range of the electromagnetic spectrum: from the mid-IR to the UV and core-loss regions. We complement our EELS results with high resolution imaging of the crystal structure using STEM, EDS, and iDPC on a double-corrected ThermoFisher Spectra Ultra STEM operated at 200 keV. JEMS enables us to visualize the crystal structure and simulate HAADF images of the various orientations we find in the STEM.
Results
In our EEL spectra, we observe several trends in the mid-IR to UV regions of the spectrum. In the mid-IR, the phonon modes redshift with more In content due to the larger relative atomic mass and size of In compared to Mn. In the visible region of the spectrum, $YMnO_3$ has strong extinction peaks arising from Mn 3d transitions (Fig. 1A), resulting in broadband absorption across the visible spectrum and a black colour in the bulk material. $YInO_3$, on the other hand, has no peaks in this spectral regime until the bandgap onset in the near-UV, resulting in a material which reflects all colours of light and appears white. In the intermediate compounds, such as Y(Mn_{0.1}In_{0.9})O_3, we observe a small peak around 2.2 eV and a change in

the higher energy bandgap onset relative to the pure In compound. Further increasing the Mn fraction results in stronger intensity on the 2.2 eV peak, and a new peak at 1.9 eV which redshifts to 1.7 eV and dominates the lower energy part of this spectrum. Additional extinction signal also arises near the bandgap onset, which overall shifts to lower energy and results in absorption of purple and UV light. This combination of transitions leaves only blue light to be reflected.
Through HR-STEM-EDS, we are able to identify the lattice sites occupied by Mn even in samples with low In concentration, such as Y(Mn_{0.9}In_{0.1})O_3 (Fig. 1B). From our EDS results, we observe that the Mn and In occupy the same lattice sites, substituting for each other in a disordered fashion, for the most part. One notable exception that we have observed is in the Y(Mn_{0.5}In_{0.5})O_3 oxide, wherein the Mn ions are distinctly noted to occupy specific lattice sites in a unit cell larger than former studies suggest (Fig. 1C), whereas the In ions do not show the same behaviour in this lattice. The origins of this mysterious ordering remain to be understood.
Through further analysis of our HR-STEM images, we observe an anisotropic expansion of the crystal lattice as Mn ions are replaced with the larger In ions. The lattice exhibits more expansion along the apical than the basal directions, with the c lattice parameter increasing by 1 Å in $YInO_3$ compared to $YMnO_3$. We observe through selected area diffraction that in several of the intermediate compounds, the crystal lattice has a twist, likely due to the mismatch in size of the substitutional Mn and In ions. Further, using iDPC imaging, we are able to observe distinct structural features in alternating lattice planes, with a repetition matching the size of the system's unit cell (Fig. 1D).
Conclusion
In conclusion, we present a thorough characterization of the blue chromophoric oxide, hexagonal Y(Mn_{1-x}In_x)O_3. We examine the crystallographic and spectral characteristics of the material across the range of compositions to understand the origin of the optical properties that make this such an attractive pigment. We directly confirm the trends observed in x-ray based studies of this material and uncover evidence of Mn ions preferentially occupying unexpected sites in a larger supercell in Y(Mn_{0.5}In_{0.5})O_3.

Twinning in HfO2 nanocrystals

Hongchu Du[1], Prof. Dr. Joachim Mayer[1,2,3]
[1]Forschungszentrum Jülich GmbH, Jülich, Germany, [2]RWTH Aachen University, Aachen , Germany, [3]Jülich Aachen Research Alliance, Jülich, Germany

Poster Group 1

Background
Twinning, a phenomenon observed in a variety of crystalline solids, often arises during growth, deformation, and phase transformations [1]. The symmetry connecting adjacent crystal twins differs from the point group symmetries of the parent crystal. These additional symmetry operations, known as twin operations, typically include rotation, reflection, and inversion [1].
Materials with polar point group symmetries exhibit spontaneous polarization. An emergent polarization from twinning is anticipated when the additional symmetry coincides with a polar point group's symmetry. Nonetheless, the complex interplay between twinning and polarization has been scantily addressed in the literature.
The twinning associated with the tetragonal to monoclinic phase transformation in ZrO_2 and HfO_2 has undergone extensive study. Twin planes are commonly observed on the (100) plane and potentially on others, such as (001) and {110} [2]. A thorough understanding of twinning necessitates resolving both the heavier metal and lighter oxygen atoms.
The negative spherical aberration (Cs) imaging (NCSI) technique provides optimal negative phase contrast under conditions of negative Cs and overfocus in conventional transmission electron microscopy (TEM) mode [3]. Comparative studies have demonstrated the superiority of NCSI over positive Cs imaging in terms of image contrast, signal intensity, and noise robustness. Notably, NCSI excels in visualizing all atoms, including oxygen, in metal oxides.
This work aims to elucidate the atomic structure of twin boundaries in HfO_2nanocrystals using the NCSI technique [3].
Methods
In this study, NCSI TEM images were captured at 200 kV with a Gatan OneView phosphor-CMOS camera on an FEI Titan 50-300 PICO electron microscope, featuring a Schottky field emission electron gun and a CEOS Cc/Cs corrector. Additional NCSI images were obtained at 300 kV using a Thermo Fisher Scientific Spectra 300 microscope equipped with a high-brightness X-FEG source, a piezo-enhanced CompuStage, a CEOS CETCOR Cs corrector for the S-TWIN objective lens, and a fast Ceta CMOS camera. The monoclinic HfO_2 nanocrystals under study were synthesized via a sol-gel method [5].
Results
Using the NCSI TEM technique, we resolved both hafnium and oxygen atoms within individual HfO_2 nanocrystals (Fig. 1). The NCSI findings disclosed both individual and unit-cell-wise multiple consecutive twinning on the (200) plane of colloidal HfO2 nanocrystals. Each twinning event involves two-fold screw symmetry, leading to a unit-cell scale polar orthorhombic phase with a $Pbc2_1$ space group at the twin boundary. The unit-cell-wise multiple consecutive twinning gives rise to a novel antipolar phase with the Pbca space group. These interpretations were corroborated through an iterative two-step optimization process for image matching between experimental and simulated images.
Figure 1 Top: Atomic resolution TEM image of an HfO_2 nanocrystals recorded using the negative spherical aberration (Cs) imaging (NCSI) technique. Middle: Map of polarization vectors and structure

model (blue: Hf, orange: O, grey: bond) superimposed on the NCSI image of the region marked in the top. Bottom: Structural illustration of polarization resulting from twinning.

Conclusions

We have revealed the correlation between twinning and polarization in HfO_2 colloidal nanocrystals via the NCSI technique [3]. The polarization induced by twinning correlates with sub-nanometer ferroelectric and antiferroelectric phases. The discovery of twinning-induced polarization may offer a new avenue for identifying novel ferroelectric phases in ionic compounds beyond oxides.

Microscopy techniques show the assembly of nanovesicles around lipid droplets via the tumor protein TPD54

Doctor Sandra Lacas-Gervais[1], Maud Magdeleine[2], Christelle Boscagli[1], Doctor François Orange[1], Doctor Bruno Antonny[2]
[1]Université Côte d'Azur, Centre Commun de microscopie Appliquée, CCMA, Nice, France, [2]Université Côte d'Azur, Institut de Pharmacologie Moléculaire et Cellulaire, IPMC, Valbonne, France

LS-04 (2), Lecture Theater 4, august 29, 2024, 14:00 - 16:00

Background : TPD54 belongs to the TPD52-like family of tumor proteins which are of great interest because they are overexpressed in aggressive metastatic cancers with poor prognosis. Recently an article showed the membrane association of TPD54 with small vesicles of around 30 nm, half the size of conventional transport vesicles, and its involvement in cell migration (1). To determine the underlying mechanism, our collaborators showed that this protein has an ALPS motif (Amphipathic lipid packing sensor), which recognizes curved membranes, and binds nanovesicles via ALPS-dependent and -independent mechanisms (2). However, its functions remain unclear. To further understand the function of TPD54 in intracellular trafficking, we worked on cultures of epithelial cells (RPE1) overexpressing various forms of GFP-TPD54, including phospho-mimetic mutants.
Methods : By confocal microscopy, the localisation of the two mutants GFP-TPD54 S166E and S166A was analyzed. A cell ultrastructural analysis was realized by different transmission electron microscopy (TEM) methods and correlative light and electron microscopy (CLEM) techniques: a) classical chemical fixation and epon embedding, and tomography b) Tokuyasu immunogold TPD54-GFP localization, c)CLEM on HM20 resin sections on samples prepared with high pressure freezing, and freeze substitution in uranyl acetate 0,2%. Sections were observed with a JEOL 1400 TEM.
Results : Confocal microscopy shows that GFP-TPD54 phosphomimetic S166E is localized to Golgi apparatus, whereas GFP-TPD54 S166A is also found at big spherical structures at the periphery of the nucleus and colocalized with Rab11, a small G protein associated to recycling endosomes. The GFP fluorescence is also found around lipid droplets. When overexpressed in RPE1 cells, we observed by TEM that TPD54 induces the formation of huge assemblies of very small vesicles and tubular structures in close contact but still at a defined distance (10-20 nm) from lipid droplets. The diameter of the vesicles (38 +/- 8 nm) is about half the size of classical transport vesicles (e.g. COPI and COPII vesicles). These assemblies contain selective membrane markers including the autophagy transmembrane protein ATG9 and RAB11. The immunogold staining and CLEM confirm the localization of TPD54 to the vesicular aggregates.
Conclusion: Our EM observations validate the existence of the TPD54 nanovesicles without the artificial trick of mitochondrial attachment published previously by Larocque et al. Furthermore, they suggest an intimate link with lipid droplets. This process seems controlled by phophorylation.

Background:
Calcium phosphate (CaP) is a crucial biomineral essential for human health, primarily forming the foundation of bones and teeth [1]. The nucleation of CaP begins from amorphous calcium phosphate (ACP) phases and transitions to hydroxyapatite (HAP), a key process in the mineralization of bones and teeth [2]. The mechanisms behind this phase transformation are complex and, despite decades of research, remain a topic of ongoing debate, particularly regarding the influence of additives such as Mg2+ [3]. This study aims to delve into the effects of Mg2+ on the transformation of ACP to HAP, employing high-throughput transmission electron microscopy (TEM) [4]for detailed analysis.

Methods:
To assess the impact of additives on phase transformation, we designed an automated sample preparation platform. This system uses a standard 24-well plate, complemented by a picoliter-volume liquid dispenser and a motorized stage under precise control. Custom Python scripts automate the liquid dispensing and stage movements, facilitating the accurate placement of 30 samples on a single TEM grid for comprehensive TEM analysis. Chemical reactions were initiated with three base solutions: 20 mM calcium chloride (CaCl2), 10 mM magnesium chloride (MgCl2), and 12 mM sodium phosphate (NaH2PO4). CaCl2 and MgCl2 solutions were mixed in various Mg2+/Ca2+ ratios (0, 0.01, 0.06, 0.3, and 0.5), as shown in Figure 1a. The addition of sodium phosphate solution and extra water marked the start of the reaction. Samples were extracted 3 minutes after the reaction's initiation, with a 300 pL aliquot deposited onto a TEM grid. This sampling continued at 45, 90, 135, 180, and 225-minute intervals on the same grid. Each 300 pL sample dried in about 2 seconds, creating distinct areas roughly 130 µm in diameter as in Figure 1a. The dispenser was cleaned after each sampling. Results were analyzed using bright-field TEM and electron diffraction, revealing insights into the samples' morphological and structure as illustrated in Figure 1.

Results:
Samples 1, 2, and 3 showed similar morphological evolutions: spheroidal nanoparticles formed within 3 minutes, transitioning into sheet-like nanostructures characteristic of HAP, as evidenced in Figures 1b and c. Diffraction patterns at 45 minutes confirmed the crystalline structure of HAP, indicating the shift from ACP to HAP. Mg2+ addition was found to expedite this crystallization, as seen in sample 3's radial average diffraction pattern, where HAP's distinctive peaks were more pronounced compared to samples 1 and 2. However, excessive Mg2+ concentrations delayed or prevented the ACP to HAP conversion, as demonstrated in Figures 1c and d, where sample 4 showed a delayed HAP transformation at 225 minutes, and notably, sample 5 did not transition to HAP even after 225 minutes.

Conclusion:
The innovative automated sample preparation platform significantly enhances our capacity to deposit multiple samples on a single TEM grid, enabling thorough investigation of the ACP to HAP

phase transition with and without additives across various reaction times. This study highlights the advantages of applying high-throughput TEM for deep dives into chemical and biochemical reaction mechanisms. Our findings suggest that while Mg2+ does not affect the initial ACP formation, it does modify the crystallization rate. Crystallization accelerates up to a Mg2+/Ca2+ ratio of 0.06, after which it slows down or stops the ACP to HAP conversion. Future work will aim to refine TEM techniques, such as optimizing sampling rates and integrating data acquisition processes, including in-situ methods like liquid-phase TEM [5], to further elucidate the mechanisms in-situ.

Introduction
Direct band gap GeSn epilayers have great potential in high-performance Si-based electronics and optoelectronics. A transition to a direct band gap can be achieved in GeSn layers when the Sn concentration exceeds 6 at% [1], a value well above the solubility limit. Therefore, these non-equilibrium GeSn alloys with the desired materials concentrations are unstable at high temperatures, resulting in phase separation and decomposition processes [2]. Two main epitaxial methods used for the material synthesis are molecular beam epitaxy (MBE) and chemical vapor deposition (CVD). Depending on the method, the properties of the GeSn can vary strongly. For example, the CVD GeSn films exhibit better optical properties and, to the best of our knowledge, all GeSn-based lasers were grown via this technique. Thermal stability is another property that can vary. The excess of Sn and its possible segregation that, can occur during material growth, has a major influence on thermal stability. Understanding this is important for predicting the thermal budget that a Ge1-xSnx layer can be exposed to during device fabrication.
Methods
We use the powerful technique of in situ transmission electron microscopy (TEM) to study the dynamic process during thermal annealing experiments. We analyze how the Sn concentration and the presence of dislocations affect the thermal stability. In this regard, samples grown by CVD and MBE, 50 nm thick epilayers with 6-14 at% Sn on Ge substrate, were analyzed in cross-section and plan-view geometries. The cross-sectional lamellae were cut and installed on micro-electro-mechanical system (MEMS) heating chips with a Ga+ focused ion beam (FIB). In the case of the plan-view, first, the samples were prepared by wedge polishing technique, and then with FIB transferred to the MEMS chip and finally thinned [3]. The experiments were performed by heating-cooling-cycles with an increasing maximum temperature up to 750°C, investigating the sample via complementary HRTEM and STEM EDXS. In cross-section geometry, we can trace precipitation in relation to present interfaces and surfaces, while in plan-view geometry we can gain information about the morphological changes and particle size distribution on the surface of interest.
Results
For the MBE samples, two different concentrations of 10 and 14 at% Sn were investigated. The cross-section specimen with 10 at% Sn is stable up to 500°C. At 500°C, Sn-based precipitates are formed in the GeSn epilayer. HRTEM Fast Fourier transform (FFT) analysis of these inhomogeneities reveals a pattern well-fitted with the β-Sn crystal structure [4]. At the same temperature, we monitored the formation of Sn drops in the plan-view sample. In the case of a cross-section sample with 14 at% Sn, the start of the precipitation process is found at a lower temperature of 350°C. For a CVD GeSn layer with 11.5 at% Sn, the specimen shows stability up to 450°C where also β-Sn precipitates appeared. However, to achieve these results the cross-section specimen had to be prepared by the wedge

polishing technique, reducing the FIB processing and Ga contamination. Without this measure, the CVD-grown sample decomposes already at 200°C under the influence of Ga impurities implanted during FIB-assisted specimen preparation. To better understand the present Ga contamination effects and the relation with defects, we analyzed CVD samples with different growth and buffer qualities, which influence the density of threading dislocations. However, all samples were highly susceptible to Ga contamination during the standard lamella preparation. Applying our optimized wedge polishing technique, we analyzed additionally a CVD sample with 6 at% Sn, which demonstrated stability up to 650°C during the in situ TEM experiment.

Conclusion

The measured Sn segregation temperature for cross-sectional and plan-view geometries correlate well, however, there are differences in the precipitate densities which are attributed to the free surface diffusion of Sn for the plan-view specimen compared to the suppressed one for the capped cross-section. Regarding the two MBE specimens, since no formation of liquid phases was observed, a solid-state diffusion and precipitation mechanism is believed to occur. Ga contamination during preparation can lead to the formation of a GaSn liquid phase during annealing [4], leading to a fast decomposition of the GeSn layer. CVD GeSn layers are more susceptible to this effect, which we believe is due to the presence of point defects induced by the CVD method. Nevertheless, using the wedge polishing approach it was possible to overcome this challenge. The obtained results show the highest stability for the sample with 6 at% Sn and the lowest for the sample with 14 at% Sn. The gained results indicate a strong dependence of the decomposition temperature on the Sn content, which is summarized in the figure presented.

Background incl. aims
Correlative light and electron microscopy (CLEM) is a powerful imaging tool that combines the advantages of light/fluorescence (LM/FM) and electron microscopy(EM). In CLEM , FM images can be used to observe the localization of one or more molecules of interest indicating where the region of interest (ROI) the needle in the haystack is located whereas EM provides the ultrastructural information. Samples used for investigation of ultrastructure by EM are subjected to chemical fixation and are treated with heavy metal salts and contrasting agents such as osmium tetroxide and uranyl acetate to improve imaging contrast and later embedded in resin as it stabilizes the samples so that it withstands the vacuum condition of the EM and enables long storage. However, chemical fixation and resin embedding process which is essential for good quality of the ultrastructure is impaired by the contrasting agents or the florescence protein tag in the samples lose their ability to fluoresce due to protein denaturation which possess a major challenge for CLEM. The discovery that fluorescence can be retained in resin-embedded specimens following moderate heavy metal staining revolutionised CLEM. R221 (CryoCapCell) is a methacrylate based acrylic resin with promising results allowing florescence preservation facilitating CLEM approaches to identify the ROI and obtain high resolution ultrastructural images of the targeted ROI. We aim to use Resin R221 to identify the interface of plant microbe interaction which is ROI under florescence microscope with the help of florescent tags before thin sectioning for EM ultrastructural analysis. This immensely reduces the time required to locate the ROI in plant samples. For instance, symbiotic bacteria present in root cells can be easily identified if the bacteria are florescent tagged allowing efficient identification of the bacteria infected cells for EM analysis.
Method:
In the initial phase cyanobacterial and algal strains are subjected to high pressure freezing followed by freeze substitution(FS) in a cocktail containing uranyl acetate, glutaraldehyde, H2O and acetone(at – 90 to -30°C) followed by R221 resin infiltration and polymerization in low oxygen level and exposure to UV light to ensure proper polymerization. After polymerization the specimen blocks are stored at room temperature protected from light to preserve florescence. Thin sections of 0.7 µm70 nm are placed on copper grids coated with collodium which are then mounted on glass slides with cover slips sealed with paraffin wax for CLEM analysis.
Results :
Three different fluorescent tags could be detected in sections of samples prepared in the resin R221 so far. This facilitates the application of CLEM analysis to identify the cyanobacterial and algal strains as well as plants associated with microbes under the TEM. The R221 resin paves a way for multimodal analysis without having to follow different sample preparation for florescence and electron microscopy.
Conclusion:

While resin already gave us very promising results, there's still work to do in fine tuning the workflow for plant materials to facilitate the identification of ROI and target rare events. Additionally, it is also essential to explore chemical fixation methods as it is a more convenient method especially for plant materials. Subsequent steps will involve application of this optimized workflow to various This will be followed by applications of different plant material, plant-microbe associations and implementation of other plant material and with other fluorescent tags.

Background
The transformation of precursors with high carbon content into open-porous carbon foams and coatings via thermal processes is gaining traction as a promising and eco-friendly method for a range of applications including catalysis, energy utilization, and sensing [1]. In this investigation, we employ a one-step laser patterning technique to locally pyrolyze doctor-bladed ink coatings on flexible PET substrates. This process yields highly porous and intricate CO2 sensor architectures with a thickness of around 50 µm. The ink composition includes glucose as a pore-forming agent and adenine as a nitrogen source, contributing to the sensing capabilities. Laser treatment in an oxygen-rich environment results in flexible and highly porous sensor structures with distinct nitrogen and oxygen functionalities within different regions. The laser intensity varies with depth, leading to the creation of a well-defined highly porous graphitic surface layer (acting as the electric transducer layer) and a less porous nitrogen-rich lower sensor layer, interconnected by a thin transition zone [2].
Methods
To understand the formation of these structures and their relationship with functionality, we conducted a thorough TEM investigation on cross-sections (0.25 - 0.5 t/λ) of the entire device prepared by microtomic cross-sectioning.
Results & Conclusion
STEM-EELS elemental distribution maps reveal a clear distinction in chemical composition between the upper and lower layers of the sensor. Principal component analyses were utilized to unravel the complex sensor structures, comprising various crystalline and amorphous phases containing carbon and nitrogen. 4D-STEM analysis unveils the distribution of the crystalline graphitic phase and the alignment of graphite basal planes relative to the pore walls of the open-porous sensor. Understanding these parameters is crucial for deciphering the electrical performance of the sensor (refer to Figure 1) [3].

PS-05 (1), Lecture Theater 1, august 28, 2024, 10:30 - 12:30

The study of model catalyst systems with mass selected Pt, Pd and Pt-Pd clusters on nanostructured metal oxide supports like CeO2, Al2O3 in exhaust gas environments can be helpful to understand the fundamental processes in catalytic reactions of exhaust gases, to unravel the complex relationship between the structure and the catalytic properties. During a catalytic reaction, the active metal clusters/ particles dynamically change their structure due to the interaction with the gas environment at elevated temperatures. In-situ TEM can be of aid to track the dynamic transient stages involved such as structural or morphological changes of clusters under catalytic reaction conditions. In this work the behavior of size selected Pt clusters (50-200 atoms) deposited on CeO2 support are studied using advanced scanning transmission electron microscopy (STEM) techniques, under pure gas environments (H2, Ar, O2, CO, CO2) and during CO oxidation (with CO and O2 as input gases).

Size selected Pt clusters are deposited using an ultra high vacuum (UHV) cluster ion beam deposition (CIBD) system on top CeO2 thin films, which is deposited on in-situ TEM nanoreactors[1]. Pt clusters are characterized calculating the pair distribution function from 4D-STEM datasets. The morphology changes in the clusters, cluster-support interaction, cluster-gas interaction etc. are studied realtime in pretreatment and exhaust gas environments using in-situ STEM imaging & spectroscopy. The CO2 generation and the level of conversion at different temperatures can be qualitatively studied using high sensitivity residual gas analyzer (RGA).

Figure 1(a) shows the 4D-STEM image of Pt55 deposited directly onto Si3N4. In order to calculate the PDF, it is necessary to substract the background signal of Si3N4 in the reciprocal space. The PDF is calculated by averaging the signal from the whole particle and compared with one another. The integrated PDF of all Pt55 clusters is comapred to the neighbouring distances expected for Pt FCC (Fig. 1). Additionally PDFs are obtained from multislice simulations of Pt55 icosahedra for comparison with experimental PDFs from individual clusters[2].

In-situ (S)TEM on Pt200 supported on CeO2 at pretreatment conditions (oxidation and reduction cycles at 300-500°C) are done and the clusters are found stable at both reducing and oxidative atmospheres. The clusters dynamics under catalytic reaction conditions (in CO & O2 atmospheres) are tracked in-situ at different temperatures from 200-700°C. The RGA showed a constant CO2 partial pressure at all the reaction temperatures, over a conversion of 15%. With continuous imaging, the clusters are found hopping through CeO2, sintering only at 200-300°C. The movement is not identified at higher temperatures when tracked with the electron beam. Clusters in the areas which are not tracked with e- beam are found coalesced, moved to other locations at higher temperatures.

This shows that the effect of the electron beam on the reaction sites are inevitable and has to be taken into account during acquisition.

To summarize, the study concentrates on the structural characterization of Pt clusters using 4D-STEM PDF. The results show clear differences from bulk FCC-Pt but resemble towards isomeric shapes. Comparison of PDFs of Pt55 icosahedron at various orientations confirms shift of pair distances and intensity variations according to the changes in diffraction intensities with different orientation. Additionally, in-situ evaluation of the model catalyst system shows changes in the morphology as well as movement and sintering of the clusters on CeO2 under catalytic reaction conditions.

Poster Group 1

Hybrid organic-inorganic perovskites (HOIP), a class of materials with a cubic unit cell (ABX3) possess remarkable physical and chemical properties and have aroused growing interest in the scientific community in the last decade. The A-cation, at eight corners of the cube, is surrounded by twelve X-anions (mainly halides, Cl− , Br− , I−), while the B-cation (typically divalent metal ions such as Pb2+, Sn2+ or Cu2+) is located at the body center surrounded by six X-anions in an octahedral [BX6]4- cluster. When the A cation is replaced by methylammonium cations (MA=CH3NH3+), three-dimensional hybrid organic–inorganic structures are obtained, known as 3D hybrid perovskites, with potential applications in solar cell technologies. Their high power conversion efficiency (PCE), together with their low-cost and scalable, solution-based fabrication processes lead to intense research efforts towards their industrialization. Despite these advantages, 3D perovskite solar cells also face significant challenges. The long-term stability of these materials remains a major concern, as they can be sensitive to moisture and other environmental factors, leading to a premature degradation. In this context, there has been growing interest in 2D HOIPs. These materials include larger organic cations as hydrophobic spacers, isolating the inorganic metal halide octahedra and leading to improved stability compared to their 3D counterparts. A wide variety of structures can be obtained for these materials, depending on the organic or inorganic cations and the synthesis conditions. Indeed, their synthesis in solution implies complex chemistry, with pre-organization, nucleation, reorganization and precipitation. Controlling the properties of these materials need a precise control over their structure, hence over their synthesis pathways.
For a better understanding of the synthesis of HOIPs by ligand assisted re precipitation (LARP) and to control their structures and properties, we developed a new approach for observing the structural evolution of 3D/2D lead halide hybrid perovskites based on a time-resolved acquisition protocol of the structural data. By combining in situ liquid transmission electron microscopy (TEM) and X-ray absorption techniques, we can monitor in real time the birth and the structural and chemical evolution of the different phases in well-controlled and realistic conditions and have a better understanding of the associated mechanisms. Specific microfluidic devices were developed for this work, which were used to perform in situ X-ray absorption studies and can be applied to other X-ray techniques as well. This new device reproduces the precipitation of 3D/2D lead halide hybrid perovskites under X-ray in particular for X-ray absorption near edge structure (XANES), for Extended X-ray Absorption Fine Structure (EXAFS) and for Small-angle X-ray scattering (SAXS) analyses. This micro fluidic chip has been designed to be versatile and adaptable to the specific needs of synthesis. The internal microfluidic pathway can be easily changed in design, from a T to observe the interface between two fluids, or a mixer to reproduce the conditions required for precipitation. By combining this information with those obtained from in situ liquid TEM with the Protochips technologies Poseidon AX and X-ray diffraction, we propose mechanisms for the formation and structural transition of different phases of this family of perovskites. This method highlighted the importance of studying the precursor solution to the LARP method, at which stage an atomic arrangement was found. This indicates that the synthesis of HOIPs begins before precipitation with the formation of a

forerunner atomic structure of the intermediate phase. We will also show how the method presented could be applied to the study of a variety of nanomaterials under in situ liquid conditions.

Poster Group 1

Introduction
Efficient manipulation of antiferromagnetic (AF) domains and domain walls has opened up new avenues of research towards ultrafast, high-density spintronic devices [1,2]. AF domain structures are known to be sensitive to magnetoelastic effects, but the microscopic interplay of crystalline defects, strain and magnetic ordering remained largely unknown. Recently, we have explored antiferromagnetic CuMnAs thin films in which imaging by x-ray photoemission electron microscopy (XPEEM) revealed that its AF domain structure is dominated by nanoscale crystalline defects [3]. However, even smaller magnetic objects were indirectly observed in the material, but they remained below the detection limit of the used established XPEEM methods.
Materials and Methods
Scanning transmission electron microscopy (STEM), differential phase-contrast (DPC) and 4D-STEM techniques are utilized CuMnAs epilayers grown by molecular beam epytaxy.
Results
Here, we achieve atomic resolution imaging of abrupt AF magnetic domain walls in CuMnAs epilayers [4]. The identification of the magnetic domain DPC signal is based on the specific symmetry of the CuMnAs crystal, where the opposite magnetic Mn sublattices occupy crystallographically distinct noncentrosymmetric sites, Fig. 1A. With focus on small field-of-view high-resolution imaging, we could associate the DPC-STEM signals with two types of abrupt Néel vector reversals, schematically illustrated in Fig. 1C and D: The first type occurs at a crystallographic antiphase boundary defect (Fig. 1C), while the second type forms in a part of the epilayer with no crystallographic perturbation detectable by STEM (Fig. 1D).
Conclusions
The results emphasized the crucial role of these defects in determining the AF domains and domain walls, and provided a route to optimizing device performance in term of scaling limits for the data density in the bulk of the antiferromagnet.

Background incl. aims
Identifying microbial virus-host interactions is essential to understand viral dynamics in ecosystems and their impact on nutrient cycling. In environmental samples, their identification relies mostly on bioinformatic approaches, i.e., detecting matches between spacers encoded in clustered regularly interspaced short palindromic repeats (CRISPR) systems and their corresponding protospacers present in viral genomes. To complement and confirm these predictions, we established sophisticated microscopy techniques. First, by employing virus-targeted direct-gene fluorescence in situ hybridization (virusFISH), we demonstrated the lytic life cycle of an in silico predicted virus to infect Candidatus Altiarchaeum hamiconexum, an uncultivated free-living, biofilm-forming archaeon, via fluorescence microscopy. Secondly, we characterized the morphological changes of altiarchaeal virocells, i.e. virus-infected prokaryotic cells, using correlative fluorescence and scanning electron microscopy. This effort culminated in a protocol to link a viral genome to the ultrastructure of its virus-like particle and to co-localize these with their host. However, the CRISPR-Cas immune response in single environmental virocells remains unexplored due to current technical constraints.
Methods
As a next step in expanding our microscopy toolkit for the study of virus-host interactions in environmental samples, we utilize various FISH-based methods to visualize the presence and activity of CRISPR-Cas systems within a biofilm of Ca. Altiarchaeum hamiconexum. In the first step, we developed HRP-probes to target the host crRNA of 11 abundant spacer that target a host-specific lytic virus. As the CRISPR spacer diversity in altiarchaeal biofilm is complex, the CARD-FISH based amplification method enhances the signal intensity of low-abundant crRNA in environmental samples.
Furthermore, we developed a distinct set of probes to traget the mRNA of the cas3 protein. Amplification of the signal was achieved by employing 50 different oligonucleotide probes, each fluorescently labeled with so called FLAP tails, targeting the same mRNA segment.
The established protocol can also be combined with virusFISH, allowing a nuanced perspective on the dynamic interplay between the CRISPR system and actively infecting viruses in a natural ecosystem.
Results
Our findings uncover the spatial expression of specific CRISPR spacer sets targeting one virus population within an environmental archaeal biofilm, with a confluence of the most abundant spacers targeting the same virus covering nearly the entire biofilm. Additionally, we are able to detect mRNA of the Cas3 protein within our environmental sample. Our two independent fluorescence microscopy methods enabled us detecting active CRISPR-Cas systems in environmental samples along with the targeted viral genomes.
Conclusions

Spacers targeting the same virus within a biofilm can be heterogeneously expressed across the individual cells, resulting in an active defense of the population. Nevertheless, active infections are observed in these biofilms, suggesting an ongoing competition between the host defense system and the virus. In sum, our results and newly developed techniques open novel avenues to understand the intricate relationships between viruses and their microbial hosts.

Poster Group 1

Magnetic multilayer systems hosting skyrmions at room temperature have attracted considerable interest for their potential application in the forthcoming generation of magnetic data storage devices. Pt/Co/X multilayer systems, where X represents a metallic element, stand out as a prospective candidate due to their versatile adjustability of magnetic properties. Recent theoretical predictions indicate that the size of skyrmions within this multilayer architecture can be finely tuned by varying the repetition of stack layers, the thickness of individual metallic layers and the element X [1]. A pivotal milestone towards employing these multilayer systems in data storage devices lies in the capacity to both stabilize skyrmions and manipulate their movement across the material. In this work, in situ in Lorentz transmission electron microscopy (LTEM) is used to investigate nucleation, stability, and mobility of magnetic phases in [Pt/Co/Cu]x5 multilayer specimens.

[Pt/Co/Cu]x5 multilayer specimens were grown on Pt buffer layer grown on an insulator substrate (Al2O3 [111]) using molecular beam epitaxy (MBE) [2]. Cu was chosen as a X mainly for two reasons: 1) its close lattice parameter to Co and Pt favors an epitaxial grown of the layers, and 2) there isn't a magnetic dead layer in this system [3,4]. Cross-section and plan-view specimens were prepared using dual focused ion beam (FIB) instrument. High angle annular dark field (HAADF) STEM imaging and energy-dispersive X-ray (EDX) mapping analysis in cross-section specimens was performed to characterize the layered structure of specimens. L-TEM in Fresnel mode with variable applied magnetic field was used to investigate magnetic domain structure and skyrmions in plan-view specimens. As a further step, biasing experiments applying current (DC and pulses) using an in-situ TEM holder (DENS Wildfire-Lightning) connected to a pulse generator were performed to explore the stability of magnetic phases and its dynamics.

Room temperature magnetic phases as a function of applied magnetic field (from 0mT to 300mT) are identified by LTEM imaging, showing "labyrinth" texture at 0mT that evolves into magnetic stripes domains followed by a transition to isolated bubbles-like skyrmions around 135mT [2,5]. The contrast in the LTEM images, suggest coexistence of multitype bubbles-like skyrmions, Bloch-type and Néel-type. This observation is quite surprising since a Néel-type configuration is expected for such interfacial Dzyalloshinskii−Moriya interactions (DMI) system. As a result of our biasing experiments, it was observed that skyrmion's type, stability and density can be modulated by the thermal effect caused by current pulses or DC current. Ultimately, the correlation between current density and applied magnetic field for this system is summarized in a magnetic phase diagram.

Our findings reveal a broad range of magnetic conditions enabling the manipulation and control of skyrmions by varying biasing current parameters and could be considered within similar systems.

LS-03 (2), Lecture Theater 4, august 27, 2024, 10:30 - 12:30

Background incl. aims
The nanoscale topography of cells plays a key role in a variety of biological processes, particularly for T cells, where finger-like structures scan the environment to sense pathogens. Conventional imaging often considers individual protein distributions, which can result in perceived clustering due to the membrane curvature. Without considering topography, it becomes impossible to decipher protein distributions and therefore its role in biological processes. Imaging cell topography (Fig. 1a) with localisation microscopy in 3D is thus important, but challenging, due to the relatively large scales involved and the requirement to achieve sufficient localisation densities. Point accumulation for imaging in nanoscale topography (PAINT) can be used overcome these challenges, but is typically hampered by high background, particularly for large depth-of-field 3D imaging.

Methods
Here we use actively controlled probes to greatly increase the effective concentration in PAINT, without influencing the background. By building up a concentrated and reversible reservoir of photoactivatable or spontaneously blinking probes the localisation rate of PAINT can be greatly accelerated. We combine this method with double-helix point spread function engineering that enables large depth-of-field localisation microscopy, which we apply to image the cell membrane of fixed T cells. Finally, the membrane imaging is combined with conventional membrane protein localisation microscopy to characterise nanoscale T-cell protein distributions across the complex topography of the cell membrane.

Results
We demonstrate that our approach (resPAINT) can increase the localisation rate of PAINT up to 50-fold without increasing background (Fig. 1b), which is essential for achieving suitable localisation densities to study membrane topography. We then show that our approach is suitable for imaging topography as we apply it to volumetric super-resolution imaging of entire T-cell membranes (Fig. 1c). Finally, we achieve correlative membrane and protein imaging (Fig 1d) to resolve the distribution of key T-cell membrane proteins: the T-cell receptor, the phosphatase CD45 and the microvilli marker CD62. By considering the local distribution of neighbouring proteins and membrane topography, we demonstrate how eigenvector analysis can be used to decipher preferential organisation and clustering of membrane proteins.

Conclusion
We have developed a technique for performing correlative membrane topography and membrane protein imaging, which we show is key for understanding how proteins distribute at the nanoscale. This represents a new approach to understanding how proteins organise and redistribute to achieve

important biological functions, such as the recognition of pathogens by the adaptive immune response.

Active focus stabilisation using astigmatism with universal objective lens compatibility and sub-10 nm precision

Dr Aleks Ponjavic[1,2], Mr Amir Rahmani[1]
[1]School of Physics and Astronomy, University of Leeds, Leeds, UK, [2]School of Food Science and Nutrition, University of Leeds, Leeds, UK

Poster Group 1

Background incl. aims
Super-resolution microscopy techniques can resolve biological samples with nanoscale resolution that surpasses the diffraction limit. This, however, requires focus stabilisation to correct for axial drift, which is particularly important for high-throughput automated imaging. Many solutions have been developed to tackle this problem. Marker-based methods are highly accurate, but the introduction of fiducials during sample preparation can give rise to additional challenges. With a beam-based approach, it is common to monitor the reflection of an infrared laser from the coverslip-sample interface. Nevertheless, there are limitations of current beam-based approaches that can be summarised as: (i) relatively low sampling rates; (ii): only being compatible with high numerical aperture (NA); (iii) electronic components requiring soldering and custom circuit boards and (iv): the need to put a focus stabilisation module close to the objective lens as the performance is limited by laser pointing stability.

Methods
Here, we present a standalone, cost-effective, and fiducial-free focus stabilisation system that operates over a long axial range with nanoscale precision and can be implemented using off-the-shelf components. In our focus stabilisation system, an infrared laser beam is focused by the objective lens, back-reflected from the coverslip-sample interface, and then imaged onto a camera (Fig. 1a). Introducing a cylindrical lens in front of the camera creates an astigmatic point-spread-function (Fig. 1b). Real-time monitoring of variations in the shape (Fig. 1c) of this astigmatic intensity profile as a response to focal drift allows for the transmission of a control signal to a piezo z-stage, consequently facilitating the stabilisation of the sample.

Results
We characterise the performance of our astigmatism-based drift correction system and find that it is much less sensitive to optical component stability, unlike TIR-based systems that need to be close to the coverslip. We achieve sub-10 nm axial drift estimation and correction. We then show the astigmatism leads to one of the advantages of our system – its ability to operate within a large axial range, extended over 20 µm by employing cylindrical lenses with different focal length. This trade-off between precision and axial range makes it possible to achieve 20 nm precision with low numerical aperture 10x objective lenses. We have implemented our solution on a Raspberry Pi platform that can perform stabilisation at 100 Hz (Fig. 1d), which is suitable for drift correction on most super-resolution methods.

Conclusion
With compatibility across different objective lenses, we have created a straightforward and low-cost optical device that can seamlessly integrate into most microscopy setups, offering advantages such as ease of implementation, universality, and robustness.

Largely improved momentum resolution in STEM-DPC imaging of Si(110) with a segmented detector

Julius Bürger[1], Maja Groll[1], Aladin Ullrich[2], Manfred Albrecht[2], Jörg K. N. Lindner[1]
[1]Paderborn University, Paderborn, Germany, [2]University of Augsburg, Augsburg, Germany

Poster Group 2

Differential phase contrast (DPC) imaging in scanning transmission electron microscopy (STEM) is one of the promising methods to precisely characterise the electric field and the charge density distribution in solids at atomic resolution. DPC measurements are based on the detection of the lateral shift in the centre of mass (CoM) of intensity distribution in the detector plane. This shift of the CoM is detected by a position-sensitive detector such as a segmented or pixelated detector and can be related to the transferred momentum, which is imposed on the electron beam by the electrostatic potential of the specimen via the Coulomb force [1]. Besides the sensitivity to electric fields, DPC measurements are influenced by many factors such as residual lens aberrations, specimen thickness and tilt [2], as well as the detector response function. For segmented detectors the latter is determined by the polar and azimuthal detection angle intervals of the detector segments. Due to the small number of segments and their comparably large detection angle intervals, segmented detectors have a much lower momentum space resolution than pixelated detectors. This significantly influences the measurable DPC signal [3]. The detection intervals of a segmented detector can intentionally be modified: The polar detection intervals can be varied via the camera length; the azimuthal detection angle intervals can be set via the detector rotation. It is mandatory to know how and to what extend the detector response function of a segmented detector influences the features in a DPC image. For quantitative DPC imaging, it is therefore in the best interest to give methods for identification of artefacts and optimisation of the detector response function. This is presented in this contribution, including a comparison of DPC measurements of Si(110) acquired with segmented and pixelated detectors.
Experimental DPC images of a 30 nm thick Si(110) specimen are acquired with two probe-side corrected microscopes, a JEOL JEM-ARM200F and a JEOL JEM-ARM200F NEOARM, both operated at 200 kV. For DPC imaging, the former is equipped with a rotatable eight-fold segmented detector, the latter with a fast GATAN OneView camera for 4D-STEM imaging. To evaluate the DPC signal of the pixelated detector, the CoM determined from the complete intensity distribution and from intensities of virtual detector segments, which are projected onto the pixelated detector in post-processing, are utilised. While a thickness of 30 nm is ill-suited for quantitative DPC, it is appropriate to reveal and study the influence of the detector response function. Analogous image simulations are obtained using the software Dr. Probe [4], which is based on a multislice algorithm.
Comparative DPC investigations of Si(110) acquired with the segmented and the pixelated detector (Fig. 1 a-d) reveal that measured electric field and charge density distributions match in the order of magnitude. However, a strong influence of the segmented detector can be seen from significantly different image features, e.g. resulting in unexpected positive charge densities at interatomic pixels (Fig. 1b) which are not detected with a pixelated detector (Fig. 1d). To study the influence of the segmented detector's response function, series of measured and simulated DPC images are compared for different detector rotations. This is facilitated with the so-called scattergram, which is a 2D histogram of the transferred momentum distribution of the DPC image. The scattergrams exhibit characteristic intensity distributions depending on the detector rotation. A good agreement between experimental and simulated scattergrams is observed. In addition, a method is presented to find the

optimum polar and azimuthal collection angles of a segmented detector to obtain a DPC image with high similarity to the one of a pixelated detector. This is achieved by comparing the DPC images extracted from the full intensity distribution of the measured 4D-STEM data set with the DPC image acquired by projecting virtual detector segments on the same 4D-STEM data set. In case of a 30 nm thick Si(110) specimen the optimum detector response function is achieved when the direct beam illuminates the complete detector at a detector rotation of 45° to the Si dumbbell axis (inset in Fig. 1b). Ultimately, a novel method to increase the azimuthal momentum space resolution of segmented detectors is presented which uses a series of DPC images of equidistant detector rotations. Using this method, artefacts such as the positive charge density at interatomic pixels are minimised even for such large specimen thicknesses (Fig 1.f).
The results show a strong influence of the detector response function of segmented detectors and emphasise the importance of minimising this influence on DPC images for correct image interpretation. In particular, the here presented method for increasing the azimuthal momentum space resolution of segmented detectors enables to obtain equally good DPC measurements with a segmented detector as with a pixelated detector.

Poster Group 2

Background and aims:
Retroviral gene therapies are applied to treat cancers. In chimeric antigen receptor (CAR) T-cell therapy the gene for the fusion protein CAR is inserted into the patients' T-cell genome by retroviral transduction in vitro. After reintroduction into the patient, the reprogrammed T-cells expressing CAR are able to recognize and destroy cancer cells (Cappell and Kochenderfer, 2023). For cost efficient application of CAR T-cell therapy, researchers aim at enhancing transduction efficiencies. Transduction efficiencies are often low due to the low retroviral titers. Another reason is the electrostatic repulsion between the negatively charged virions and the negatively charged plasma membrane. To overcome this repulsion, positively charged peptide nanofibrils (PNF) were developed. One type of PNF, enhancing factor C (EF-C), is actively engaged by cellular protrusions and leads to a 9.3-fold enhanced transduction rate in HeLa cells (Schütz et al., 2021). However, EF-C fibrils formed large aggregates, which could clog the bloodstream when introduced into the patient and are, thus, not suitable for clinical application. A novel peptide, Derivative-4 (D4), was identified by in-silico screening (Rauch-Wirth et al., 2023). To better understand the morphology of D4 PNF and to characterize their interaction with virions and cells, electron microscopy was performed.
Methods:
The morphology of D4 PNF was characterized by negative staining and transmission electron microscopy (TEM). The binding of D4 to virions and the cell surface was then studied by scanning electron microscopy (SEM) of cells after critical point drying. To obtain a more complete view of binding of D4 to cells, samples were analyzed by TEM and STEM tomography. For both, high-pressure frozen and freeze-substituted cells were used (Bergner et al., 2022).
Results:
TEM showed that D4 PNF are shorter than EF-C. In cell culture, most of the D4 aggregates were formed by structures measuring up to a few hundred nanometers in length ("D4 network"). SEM analysis revealed that D4 networks bind to cells via cellular protrusions. When the networks were considerably smaller than the cell, the plasma membrane formed indentations close to the network, indicated starting cellular uptake. TEM analysis of cell cultures treated with PNF and virions revealed a second D4 morphology; besides D4 networks also aggregates of µm-long, thick D4 nanofibrils were found. We then analyzed virion binding patterns to these different D4 morphologies by TEM and STEM tomography. Irrespective of the D4 morphology, virions bound to D4 aggregates. However, the D4 morphology appeared to influence virion binding. Virions bound to the surface of the D4 networks and were also found within the network. In contrast, at aggregates formed by the long and thick D4 fibrils, virions were only found on the surface of the aggregate.
Conclusion:

Using 4 complementary EM techniques, we obtained a better understanding of the transduction enhancing function of D4. This understanding is important for the further development of D4 PNF and their clinical applications.

Structure retrieval by parameterised inverse multislice accounting for partial coherence and thermal effects

Prof. Dr. Knut Müller-Caspary[1], Dr. Benedikt Diederichs[1,2], Ziria Herdegen[1], Achim Strauch[1,3]
[1]LMU München, Munich, Germany, [2]HMGU München, Munich, Germany, [3]Forschungszentrum Jülich, Jülich, Germany

IM-06 (3), Lecture Theater 1, august 30, 2024, 14:00 - 16:00

Background
Inverse multislice uses experimental momentum-resolved scanning transmission electron microscopy (4D-STEM) data to reconstruct the individual slice transmission functions (phase gratings) of a specimen. It solves the problem of inverse dynamical scattering, and takes partial coherence effects into account to obtain spatial resolutions in the range of thermal vibrations [1]. Both the incident probes and phase gratings are usually optimized on a pixel-wise grid, involving the determination of 10^6 to 10^7 unknowns. In this work, we present an inverse multislice concept which uses a consequently physical parameterisation of both probes and specimen. A few aberration coefficients, focal spread and source size describe the illumination comprehensively, and the phase gratings are parameterised via atomic types, positions, occupancies and thermal vibrational amplitudes. Consequently, the number of unknowns is reduced by at least four orders of magnitude. This leads to both a more efficient and stable inversion strategy, and the capability of performing inverse frozen phonon (FP) multislice. The latter incorporates thermal diffuse scattering (TDS) and exhibits enhanced sensitivity to temperature and chemistry. We present both the methodological concept and its application to measuring ferroelectric displacements experimentally in $Pb(ZrTi)O_3$ (PZT) with picometre precision [2].

Methods
Inverse multislice starts with an initial guess for the probe and the phase gratings, performs forward multislice so as to calculate a loss with respect to the experimental 4D-STEM data. The update for the subsequent epoch is derived from the gradient of the loss as to the parameters of interest. We developed an efficient implementation of this scheme by (i) expressing the multislice as an artificial neural network following van den Broek [3] within PyTorch, being able to (ii) seamlessly allocate all gradients in a single forward run. We start with conventional, pixel-wise inverse multislice reconstructions, followed by the detection of atomic structure, types and probe parameters to initialise a parametric model. Instead of complex-valued pixels, gradients decisively update real physical parameters, especially atom positions. We then firstly employ the Debye-Waller approach with absorptive potentials for the reconstruction, and secondly switch to a full inverse FP multislice which also inverts TDS using several thermal snapshots while still considering more than 10 probes to account for partial coherence. Our method is verified using FP ground truth 4D-STEM simulations first, before experimental 4D-STEM data of PZT (EMPAD recording on probe-corrected FEI Titan, 200kV) is analysed inversely using 52 slices, corresponding to a thickness of 22nm.

Results
Concerning forward scattering the FP concept involves averaging over multiple configurations of thermal atomic displacements $\vec{u}$ from the equilibrium positions as illustrated in Fig. 1a, being responsible for TDS. Via the mean squared displacement $\langle u^2 \rangle$, TDS is explicitly accounted for in our inverse multislice as forward scattering theory demands. At the same time, our model is also

differentiable with respect to the atom positions, as shown in Fig. 1b. Here, we simulated 4D-STEM data of 20nm thick PZT using FP multislice including ferroelectric displacements. For the reconstruction, no polarisation was used as prior by initialising with a centrosymmetric model and taking projected potentials from literature [4]. For 101 epochs, Fig. 1b shows the optimisation trajectories of the Zr(0.2)Ti(0.8) site treated as a virtual atom obtained by linear interpolation, and one oxygen site. Even though the forward simulation used the discrete random mixture of the Zr(0.2)Ti(0.8) site, the reconstruction with a virtual atom yields a final position between the ground truths (dashed cross) for Zr and Ti, shifted proportionally according to the chemistry of the atomic column. Moreover, the lower graph indicates an exact reproduction of the oxygen site after 101 epochs.
Applying the methodology to experimental 4D-STEM data of PZT results in an atomic structure depicted by its projected potential in Fig. 1c for the reconstructed region, whereas the initial model started with a nonpolar crystal. The polarisation of the final state is visible by eye and free of artefacts such as mistilt which we took into account by a modified Fresnel propagation that was also optimized. The displacements from the symmetry positions are mapped in Fig. 1d, with different markers for the different atom columns and the ferroelectric displacements colour-coded. The high-precision homogeneous polarisation in the scan region becomes obvious, and is confirmed by the statistical evaluation in Fig. 1c (table). The displacements are accurate to a few picometres, can distinguish oxygen from the (ZrTi) site in the same column and fit excellently with literature for the same alloy. We discuss our findings via a quantitative comparison with atom positions retrieved a posteriori from phase gratings retrieved pixel-wise assuming a unimodal specimen. In this case, several unit cells exhibit the wrong polarisation direction.

Conclusion
Inverse multislice taking multimodal states of both illumination and specimen into account is capable of exploiting TDS in the reconstructions. Since TDS is a major contribution in thick specimen for which (inverse) multislice is designed, this opens several possibilities to accurately measure atom positions, atom types and temperature or Debye parameters, whereas sensitivity to the latter parameters will be discussed in our contribution based on simulations.

Poster Group 2

Aberration-corrected high-resolution transmission electron microscopy was used to investigate C60 fullerenes encapsulated between graphene sheets at different temperatures (ca. 93K, 293K, and 773 K), along with molecular dynamics simulations. Cryogenic and heated conditions were reached using a custom in situ MEMS heating system. The study focused on the beam-induced dynamics of the C60 fullerenes and the encapsulating graphene, measuring the critical doses for the initial damage to the fullerenes and following the beam-induced polymerization. We observe that the doses for the initial damage are not significantly affected by temperature. However, the clusters formed by subsequent polymerization exhibit more tubular shapes at lower temperatures, while sheet-like structures are generated at higher temperatures.
These experimental findings are supported by the results of first-principles and analytical potential molecular dynamics simulations. The merging of curved carbon sheets is promoted at higher temperatures and occurs rapidly over segments of only a few nanometers.

Viral replication organelles revisited by cryo-electron microscopy

Georg Wolff[1], Ronald Limpens[1], Nina de Beijer[2], Abraham Koster[1], Eric Snijder, Montserrat Bárcena[1]
[1]Section Electron Microscopy, Department of Cell and Chemical Biology, Leiden University Medical Center, Leiden, The Netherlands, [2]Molecular Virology Laboratory, Leiden University Center of Infectious Diseases, Leiden University Medical Center, Leiden, The Netherlands

LS-06, Lecture Theater 4, august 30, 2024, 10:30 - 12:30

Coronaviruses and their distantly related arteriviruses belong to the order Nidovirales. Similar to other positive-strand RNA viruses infecting eukaryotes, nidoviruses hijack host membranes converting them into specialized structures often termed viral replication organelles. These replication organelles exhibit diverse morphologies depending on the virus group but serve a common purpose: to establish specialized micro-environments conducive to viral RNA synthesis, potentially shielding viral replication intermediates from cellular immune surveillance. A hallmark of nidovirus infection is the emergence of double-membrane vesicles (DMVs) originating from endoplasmic reticulum membranes, which serve as sites of viral RNA synthesis. Typically, nidovirus genomes encode 3 nonstructural proteins (nsps) that contain multi-spanning transmembrane (TM) domains (TM1, TM2 and TM3) and that are the main drivers of DMV formation (1).

Traditionally, viral replication organelles have been studied by conventional electron microscopy (EM) methods on resin-embedded infected cells. However, recent advancements in cryo-EM, particularly the introduction of focused ion beam (FIB) milling technology that makes internal regions of cells accessible for cryotomography, have revolutionized our ability to investigate these virus-induced structures. This cutting-edge approach allowed us to investigate viral replication organelles in cells infected with coronaviruses with exquisite detail (2). Through this methodology, we uncovered a molecular pore spanning the membranes of the DMVs, potentially serving as a gateway for viral RNA synthesized within the DMVs to access the cytosol for translation or encapsidation into progeny virions. Using subtomogram averaging, this crown-shaped pore complex of around 3 MDa was solved to 3 nm resolution and revealed to have an overall 6-fold symmetry. Additionally, we identified that the largest viral nonstructural protein, which contains the TM1 domain, as a component of this complex. Furthermore, in situ cryo-tomograms provided compelling evidence of dynamic interactions between the pore complex and other macromolecules on both sides of the pore. Based on these observations, we postulated that the viral replication machinery may interact with the pore side facing the DMV interior, while the nucleocapsid protein, responsible for encapsulating new viral RNA, would associate with it on the cytosolic side.

Our investigations have extended to the distantly related arteriviruses, revealing the presence of similar DMV-spanning pore complexes. Notably, viral nucleocapsids and putative ribonucleoprotein assemblies were often observed in close association with the arteriviral DMV pores, providing further support to the notion of a functional linkage between RNA export from the DMVs and encapsidation, mediated by interactions of the pore complex with the nucleocapsid protein. Interestingly, DMV pore complexes were also formed in non-infected cells that expressed the 3 arterivirus TM-containing nsps. This indicated that the formation of a DMV-spanning pore structure is independent of the presence of viral RNA, the replication machinery, or the structural proteins. Moreover, expression of only the nsps containing TM1 and TM2 was sufficient to form DMV-like structures in which pore complexes were present. This observation is consistent with recent reports of the formation of DMV-

spanning pore complexes in cells expressing coronavirus TM1- and TM2-containing nsps (3). Taken together, these results suggest that DMV-spanning pore complexes may be a shared characteristic among nidoviruses. These pore complexes would have a similar mechanism of formation driven by TM1- and TM2-nsps, which appear to be core components of the complex, and would fulfill a critical role in coordinating viral RNA synthesis, export and encapsidation.
Interestingly, recent studies focusing on other +RNA viruses that induce a morphologically different type of viral replication organelle consisting of an invaginated spherule, have unveiled crown-shaped multimeric complexes located in the neck of the spherules (4,5). These complexes bear intriguing similarities to the DMV-spanning complexes observed in nidoviruses. Collectively, these studies define an emerging class of viral complex that seem to underscore common strategies employed in the replication of evolutionarily distant positive-strand RNA viruses. Further elucidation of their structural and functional details will not only deepen our understanding of viral replication but may pave the way for the development of novel antiviral strategies.

Influence of dynamical diffraction on DPC measurements of 2D materials

Maja Groll[1], Julius Bürger[1], Prof. Dr. Jörg K. N. Lindner[1]
[1]Paderborn University, Paderborn, Germany

Poster Group 2

Dynamical diffraction effects in (scanning) transmission electron microscopy often hamper direct image interpretation. While dynamical diffraction effects are commonly neglected in conventional STEM investigations, they are crucial in quantitative phase retrieval techniques as multiple coherent scattering events alter the intensity distribution during the interaction of the electron wave with the specimen. One of these phase retrieval techniques is differential phase contrast (DPC) imaging, which is based on the detection of the center of mass in the post specimen intensity distribution and is promising for the precise quantification of atomic electric field and charge density distributions in solids. It is commonly accepted that qualitative DPC imaging is only feasible for specimen thicknesses below 20 nm [1] due to the influence of dynamical effects resulting in beam broadening and intensity redistribution within the specimen. For quantitative DPC imaging, the maximum specimen thickness is estimated to be about 2 nm, depending on the atomic species [2].
Due to their inherently low thickness, 2D materials are therefore of great interest for DPC measurements and are intensively investigated also by other phase retrieval methods [3,4]. Among the 2D materials there is the class of transition metal dichalcogenides (TMD) which consist of molecular layers with the stoichiometric form MX2 (M: transition metal, X: chalcogenide). The molecular layers are bound to each other only by weak van-der-Waals interactions. This allows for a comparatively simple preparation of specimens that are only one or a few molecular layers thick and are therefore suitable for quantitative DPC imaging. However, the possibility that dynamical effects may influence the measurable electric field distribution even in 2D materials, has only been rudimentarily investigated.
Since slight changes in the intensity distribution along the propagation of the electron wave through the specimen alter the measurable electric field and charge density distributions measured by DPC, it is important to understand the influence of dynamical effects on DPC measurements in a few-layer 2D TMDs.
In this contribution, we present investigations on the influence of dynamical diffraction effects on the DPC images of mono- and multilayers of tungsten diselenide, which is a 2D TMD. This is achieved using multislice simulations performed with the software Dr. Probe [5] and a comparison with experimental DPC images. For the acquisition of the latter, an eight-fold segmented bright-field detector installed at a probe-side Cs-corrected microscope is used and the same configuration is assumed in the simulations. In addition to simulations for 2D WSe_2, image simulations are also conducted for isolated atomic columns to investigate the obtainable DPC images in dependence of the atomic species, the atomic spacing and the acceleration voltage. By comparison with the DPC image of a single atom, the influence of dynamic effects is revealed. Furthermore, the propagation of the electron beam in the vicinity of different atomic columns is investigated by analyzing the real space probe intensity as a function of the specimen thickness.
The DPC measurements and simulations of WSe_2 [0001] are in good qualitative agreement. However, they show an unexpected ratio of electric field magnitudes and charge densities at W and Se atomic columns, even for a monolayer: despite their lower projected atomic number, Se atomic columns exhibit an increased electric field and positive charge density magnitudes compared to W. This can be explained by dynamic diffraction effects superimposed with other influences such as lens

aberrations. These findings are supported by simulations for the isolated atomic columns which reveal that the measurable mean DPC signal of W and Se atomic columns is always smaller than the mean DPC signal of a single atom multiplied by the number of atoms in the column. In addition, the DPC image is significantly affected by the atomic spacings in beam direction and number of atoms in an atomic column. The behavior of the real space probe intensity for the interaction with different atomic columns is presented and related to the measurable DPC signal, again supporting the finding that the atomic species of the atomic columns strongly affect the influence of dynamical diffraction on the DPC image. The results highlight that for quantitative DPC measurements even on 2D materials a careful consideration of dynamic influences must be made.

Sensing the Invisible: Ultrathin (UT) Membrane Chip for In-Situ Microscopy

Professor, Director Vinayak Dravid[1]
[1]Materials Science & Engineering, NUANCE Center, Northwestern University , Evanston, United States
IM-07, Lecture Theater 2, august 26, 2024, 10:30 - 12:30

Background incl. aims
Operando or in-situ S/TEM methods utilizing amorphous silicon nitride (SiNx) membrane encapsulated chips to confine fluids for electron microscopy have become popular in recent decade, A great number of prior innovators have shown this to be an effective approach for probing fluid-surface/nanostructure interactions and related phenomena. Such “closed-cell” platform has many practical and technological advantages over the differential pumping environmental TEM (ETEM). Unfortunately, however, conventional fluid-cells suffer from additional and significant electron scattering from the top and the bottom membranes, which are typically 30-50nm thick to maintain integrity/stability during the operation. Thus, the total thickness of >60-100 nm of the encapsulating membranes imposes many adverse effects on the post electron optics, such as increased chromatic aberrations. This naturally results in significant degeneration of signal quality and loss of spatiotemporal resolution, diffuse interference in the electron diffraction, and plasmon-dominated electron energy loss spectra (EELS).
Methods
We have recently reported development of a robust, functional and scalable backing support strategy to enable the thinnest possible (<10 nm) SiNx gas encapsulation material [1, 2]. Inspired by the natural honeycomb geometry, our novel design provides for hexagonal backbone that can neatly anchor ultrathin (~<10 nm) SiNx membrane with excellent stability and consistent performance. Unlike graphene-based encapsulations, stability under the electron beam is comparable to a 50 nm SiNx membrane, which is sufficient for most high-resolution S/TEM applications on non-electron sensitive materials.
Results
We show that our UT chip increases contrast of typical nanoparticles at 1 atm Ar gas by ~70 % and the accessible information limit is enhanced by >130 % compared to the conventional encapsulation. More importantly, the t/λ_i is reduced from nominally ~1.0 to 0.3 using a 1 Atm gas cell. This greatly enhances spectral visibility and significantly improved S/N for EELS excitations. Thus, spatiotemporal detection of gas species, down to ~nanometer scale is now being routinely achieved.
Conclusions
The presentation will cover the design and implementation of UT membrane fluid-cell for in-situ gas-solid interactions. It will also argue that combining monochromatic source with UT membrane may open new opportunities for molecular-scale understanding of dynamic fluid-surface phenomena. [3]

Impact of Clostridium botulinum C2 Toxin on the ultrastructure of cells

Jasmin Christine Bellemann[1], Joscha Borho[2], Dr. Clarissa Read[1], Prof. Dr. Paul Walther[1], Prof. Dr. Holger Barth[2]
[1]Central Facility for Electron Microscopy, Ulm University, Ulm, Germany, [2]Institute of Experimental and Clinical Pharmacology, Toxicology and Pharmacology of Natural Products, Ulm University Medical Center, Ulm, Germany

Poster Group 1

Background: The C2 toxin of Clostridium botulinum is a prototypical representative of the binary actin ADP-ribosylating toxin family. It belongs to the AB toxin class, which comprises two components: the enzymatic unit A and the binding and transport unit B. In C2 toxin, C2I represents the enzymatic unit A, and C2II represents the binding component B. To gain its biological activity, C2II must be activated by proteolytic cleavage, converting it to the active component C2IIa. Upon activation, C2IIa binds to the cell surface as a homoheptameric structure and is subsequently endocytosed together with C2I into the cell. In the cytosol, the enzymatically active component, C2I, ADP-ribosylates G-actin. By this, G-actin acts as a capping protein that blocks the polymerisation of actin filaments. This alteration of the actin cytoskeleton eventually leads to cell rounding and ultimately, to cell death[1].
The effect of the C2 toxin on cells was investigated with various assays including fluorescence microscopy of labelled actin[2]. Nevertheless, to date, the effect of C2 toxin on the cellular ultrastructure was not studied. Therefore, we performed transmission electron microscopy (TEM), scanning electron microscopy (SEM) and scanning transmission electron microscopy (STEM) tomography of C2 intoxicated cells. Furthermore, to better understand the mechanism of C2 intoxication, we also investigated the effect of the individual subunits on the cell architecture.
Methods: Analysis of the ultrastructure of C2 intoxicated cells was performed using TEM and STEM tomography. For this, cells were high-pressure frozen, freeze-substituted, and embedded in Epon[3]. The impact of the C2 toxin on the cell surface was investigated using SEM of critical point-dried cells. To test whether the observed effects are mediated by actin, Cytochalasin, an actin polymerisation inhibitor, was used as a control[4].
Results: TEM analysis demonstrated that cells exposed to either C2I or C2IIa did not exhibit any ultrastructural changes compared to non-intoxicated cells. However, cells intoxicated with complete C2 toxin displayed many intracellular vesicles and a reduction in cell size. Additionally, blebs were observed along the cell membrane. Control cells, treated with Cytochalasin B, exhibited similar effects as the C2-intoxicated cells, albeit to a lesser degree.
SEM analysis revealed that C2 treated cells rounded up and confirmed plasma membrane blebbing. Furthermore, a lack of filopodia on the cell surface was observed. The combination of SEM and TEM analysis revealed that the filopodia were endocytosed by the cell. Cytochalasin B control cells seemed to be close to rounding up, with fewer filopodia on the surface compared to non-treated cells. However, the uptake of filopodia, as seen upon C2 intoxication, was not observed.
STEM tomography of C2-intoxicated cells revealed large vesicles containing cellular debris, as well as stress granules in mitochondria and swollen endoplasmic reticula. In contrast, STEM tomography of untreated cells did not exhibit any of these observations.
Conclusion: The three electron microscopic methods provided a deeper understanding of the impact of C2 toxin on cellular architecture. It was found that only the complete C2 toxin acts as a stressor

and affects filopodia, causing them to be engulfed into the cell. Further examination is necessary to gain a better insight into the mechanism behind filopodia engulfment.

Nondestructive structural characterization of 2D materials by hybrid pixel direct detector

Dr. Jakub Holzer[1], Dr. Chris Stephens[2], Dr. Tomas Vystavel[1]
[1]ThermoFisher Scientific, Brno, Czech Republic, [2]ThermoFisher Scientific, East Grinstead, United Kingdon

Poster Group 2

The remarkable properties of 2D materials, including their high carrier mobility, conductivity, and mechanical strength, have generated significant interest among researchers. However, characterizing these materials in their self-standing form or when deposited on substrates is a challenging task. As a result, there is a growing demand for SEM and FIB/SEM-based techniques. Currently, available techniques lack site-specificity and fail to accurately represent 2D materials on substrates, often requiring destructive cross-sectioning or TEM lamellae preparation [1]. Therefore, there is a need for a suitable SEM/SDB technique.
One newly developed technique that shows promise is Backscattered Electron imaging and Reflected Kikuchi Diffraction (RKD) facilitated by a hybrid pixel direct detector [2]. The detector mounted on Apreo SEM on a retractable arm consists of four Timepix1 chips configured around the optical axis on a retractable arm. This configuration allows capturing the electron backscatter patterns while also counting the amount of backscattered electrons from each analyzed point. The WSe2 flakes were deposited on the TEM supporting grid. Based on the calibration, evaluation of patterns, and intensity of measured backscattered electrons, we can elucidate layer thickness changes under the assumption that interaction volume extends to the substrate.
Figure a) shows a median electron count map of a multilayer specimen of WSe2 measured in Reflected Kikuchi Diffraction (left map) and in standard (70° tilt) EBSD geometry. Both maps were acquired at 10 keV acceleration voltage, 5 keV electron energy threshold, and approximately 3.2 nA probe current. We have taken and plotted the average values along the red area shown on both maps to demonstrate the differences in both methods. It can already be seen that the RKD method is more sensitive to the layer thickness compared to the standard EBSD. Further comparison can be seen on the graph on the right showing the averaged values along the red arrows. One can easily distinguish the three separate layer thicknesses along the profile in the case of the RKD method. No such profile is evident on the dataset acquired on a standard EBSD detector. Figure b) shows an example pattern from the RKD detector from the area under the red rectangle, whereas Figure c) shows a dynamic simulation of the pattern in Fig. b).
For the first time, it was demonstrated that the possibility of characterizing 2D materials, in this instance on WSe2 flakes, using RKD. By using the median electron counting method, it is possible to distinguish small deviations in specimen thickness. In contrast, a conventual geometry EBSD detector of an equivalent kind was unable to provide layer thickness distinction. We anticipate that this method could be developed to provide characterization down to single atomic layers.

Elucidating functionalities of N-doped carbonaceous materials by means of in-situ TEM

Dr Nadezda Tarakina[1], Dr. Diana Piankova[1], Dr. Hannes Zschiesche[1], Dr. Jing Hou[1], Prof. Dr. Markus Antonietti[1]
[1]Department of Colloid Chemistry, Max Planck Institute of Colloids and Interfaces, Potsdam, Germany

Poster Group 2

Background incl. aims
Nitrogen-doped carbonaceous materials gained broad interdisciplinary attention as low-cost, metal-free materials for photocatalysis, carbon capture, energy storage and water remediation. Their performance in real devices relies on the precise control of their nanostructure. Usually, nanostructural characterizations are done after completion of either the synthesis or the device operational cycle. Here we present two scientific questions related to functionalities of N-doped carbons, for which in-situ/in-operando TEM studies were crucial: (1) How N-doped carbons condensate from molecular precursors, and how can we thus guide their design as materials for CO_2-sorption[1] and (2) What is the nanoscale mechanism of Na storage in N-doped carbons when they are used as anodes in Na-batteries[2]. The Methods and Results sections below are structured according to these two questions. Generalized conclusions on the application of the in-situ/in-operando methods to polymeric materials exemplified by N-doped carbons are given.
Methods
In this study we combined ex-situ high-resolution STEM, energy-filtered electron radial distribution function analysis, energy dispersive X-ray analysis and electron energy loss spectroscopy (at (1) different stages of condensation and (2) at different states of charge during electrochemical cycling) with in-situ STEM investigations: (1) in-situ heating was performed using a heating/biasing Protochips Fusion Select holder; (2) an in-operando Na half-battery was constructed using a Protochips Poseidon holder. 1 M solution of $NaPF_6$ in ethylene carbonate and diethyl carbonate was used as electrolyte.
Results
(1) By combining in situ condensation inside a STEM and ex situ analysis of the products of condensation at different temperatures and atmospheres, we were able to follow the structural, morphological, and chemical evolution of the uric acid and guanine precursors on the nanoscale upon heating and correlate it with the sorption properties of the obtained materials. We showed how one can control and tune the formation of pores in nitrogen-containing carbonaceous materials by varying pressures and reaction rates. We found that these two parameters change how the porosity of the surface develops, forming particles with mesopores (in vacuum) or microporous (in nitrogen) surfaces. Since this process co-occurs with cross-linking, the porous structure of the surface governs the subsequent release of volatiles and the development of the hierarchical pore structure. These findings allow us to synthesize N-doped carbons with a 2-times higher CO_2 uptake, keeping the same selectivity.
(2) N-doped porous hollow carbon spheres (N-PHCSs), which due to their size and shape, serve as an ideal model system to investigate Na-storage at the nanoscale, have been synthesized. By combining the ex-situ characterization at different states of charge with in-operando TEM experiments we found that at the beginning of sodiation a solvated ionic layer forms on the surface of N-PHCSs, followed by irreversible shell expansion due to the solid electrolyte interface formation and subsequent storage of Na(0) within the porous carbon shell. We showed that binding between Na(0) and C creates a Schottky junction making Na deposition inside the spheres more energetically

favorable at low current densities. During sodiation, the solid electrolyte interface fills the gap between N-PHCSs, binding spheres together and facilitating the Na ions' transport in the direction of the current collector and subsequent plating underneath the electrode. The N-PHCSs layer acts as a protective layer between the electrolyte and the current collector, suppressing possible growth of dendrites at the anode.

Conclusion

In situ/in-operando characterization, setups have been successfully applied to the characterization of N-doped carbonaceous materials. However, special attention is required for separating the electron-beam-induced effects and the processes we are interested in. The synergetic combination between ex-situ and in-situ experiments is crucial for obtaining realistic models of the studied processes.

We gratefully acknowledge financial support by the Max Planck Society. We are grateful to Dr. J. Kossmann, Dr. M. Odziomek and Prof. N. Lopez-Salas for help with synthesis, CO_2 sorption characterization and valuable discussions.

Accessible STEM-DPC Imaging Using ADF Detector Allowing in-situ Magnetic Reversal Studies

Julie Marie Bekkevold[1,2], Dr. Magnus Nord[1]
[1]Norwegian University of Science and Technology, Trondheim, Norway, [2]Trinity College Dublin, Dublin, Ireland

PS-08 (1), Lecture Theater 2, august 27, 2024, 10:30 - 12:30

Scanning transmission electron microscopy (STEM) is a powerful tool for both structural and functional characterisation of materials. Phase contrast techniques such as differential phase contrast (DPC) are commonly used to observe functional properties, for example magnetic fields inside samples. However, phase contrast imaging typically requires specialised equipment such as segmented or pixelated detectors[1]. In this work we have imaged nanomagnet arrays to demonstrate the feasibility of a simplified and accessible method for DPC using a monolithic annular dark field (ADF) detector. Using the post-specimen deflector lenses, the electron beam is shifted onto an edge of the ADF detector to translate magnetic deflection into intensity variations in the image[2]. By acquiring such images at four opposing edges of the ADF detector we were able to qualitatively image the magnetic landscape of our nanomagnet structures. The images were corrected for de-scan background intensity variation and then processed like data from an annular four-segmented detector. The resulting DPC image is very well in agreement with that acquired from a center-of-mass calculation from a pixelated detector. Additionally, we show that the increased speed and lowered data set size of this accessible STEM-DPC method, when compared with 4D-STEM, allows for characterisation of the magnetic hysteresis of nanomagnet arrays with different geometries. DPC images of a nanomagnet array in three different magnetic configurations can be seen in Fig. 1. In conclusion, this method makes qualitative DPC available in most STEM-capable TEMs, enables fast and easy in-situ magnetic experiments, and paves an accessible route to correlation of observed function with structural properties.

Label-free imaging of virus-cell interactions using 200 Hz ROCS microscopy

Dominik Huber[1], Prof. Dr. Alexander Rohrbach[1]
[1]Lab for Bio- and Nano-Photonics, University of Freiburg, Freiburg, Germany

LS-06, Lecture Theater 4, august 30, 2024, 10:30 - 12:30

Background incl. aims
The emergence of SARS-CoV-2 has shown the profound impact that viruses can have on human health and society. Due to their small size and remarkable speed it is very challenging to observe cell-virus interactions in life-cell imaging. Techniques like fluorescence microscopy, often struggle to visualize these interactions, especially due to their susceptibility to bleaching and the difficulty to label different structures without altering their function. This underscores the ongoing need for innovative approaches to unravel the complexities of virus-cell interactions and advance our understanding of infectious diseases.
Methods
In our research we use Rotating Coherent Scattering (ROCS) microscopy in order to visualize the diffusion of 100 nm sized virus-mimicking particles and their interactions with macrophages or epithelial cells. Rotating Coherent Scattering (ROCS) microscopy, a label-free imaging technique, harnesses the coherent backscattering of a rotating laser beam for super-resolution (150nm). The method involves oblique illumination of the sample from all azimuthal directions, producing nearly artifact-free images by integrating all scattered light during a single laser rotation. Currently operating at a frame rate of 200 Hz, ROCS minimizes motion blur, without any need for extensive post-processing. With its capability to adjust the illumination angle up to 70° and to utilize 4 distinct illumination wavelengths in the range of 405 nm to 561 nm, ROCS proves highly versatile in brightfield or darkfield mode, transitioning between total internal reflection (TIR) and non-TIR.
Results
By tracking particle trajectories and analyzing their fluctuations we are able to analyze the speed of our diffusing virus-mimicking particles and are able to follow binding events of single particles to cells. After binding of particles to filopodia or lamellipodia the observed fluctuations decrease over time and Additionally, by using multiple illumination angles and wavelengths in ROCS microscopy we observe different appearances of differently absorbing structures, enabling the analysis of subtle z-motions of particles and the visualization of distinct cellular structures.
Conclusion
Our research highlights Rotating Coherent Scattering (ROCS) microscopy, as a powerful tool to observe virus-cell interactions. Through ROCS, we successfully image the diffusion of virus-mimicking particles and visualize discrete binding events to cells, enabling detailed analysis of particle trajectories and binding properties. Furthermore by capturing scattered light from multiple wavelengths at once, we extend the capability of ROCS towards obtaining specificity for different structures.

The ultrastructural analysis of plant-microbe interfaces

Isabella Gantner[1], Dr. Julia Buchner[1], Prof. Dr. Andreas Klingl[1]
[1]Plant Development and Electron microscopy, Ludwig-Maximilians-Universität, Munich, Germany
LS-07 (2), Lecture Theater 5, august 28, 2024, 14:00 - 16:00

Background incl. aims
In natural environments, plants share their habitat with various microbes and are colonized by a rich diversity of bacteria and fungi. Over time, different types of plant-microbe interfaces (PMIs) developed to enable interactions between a specific microbe and its host. The most famous PMI are e.g. the symbiosomes in root nodules of legumes, containing nitrogen-fixing bacteria, the arbuscules of mycorrhiza fungi, which are used for the nutrient exchange with the plant and the so called haustoria of some parasitic fungi or oomycetes. Knowing the ultrastructural details of PMIs is central for the biological and functional understanding of plant microbe interactions. This project aims to generate sample preparation methods for TEM and FIB/SEM techniques, visualize PMIs in 2D electron microscopy images and identify their 3D structure.
Methods
Mesorhizobium loti infected plant tissue of Lotus japonicus root nodules was prepared for TEM and FIB-SEM by chemical fixation and embedding in epoxy resin blocks. After ultra-thin sectioning, 2D images were generated with TEM. Furthermore, image stacks were generated by FIB/SEM to enable 3D modeling of the PMI region of interest by structure segmentation.
Results
TEM images of infected root nodule cells confirmed the presence of symbiosomes, which have a plant derived membrane that encloses a peribacteroid space with rod shaped bacteria of Mesorhizobium loti. The 3D model of a symbiosome visualized the arrangement of bacterial cells in the peribacteroid space tightly sourrounded by the symbiosome membrane. With regard to the TEM images, the model revealed further, that the number of bacteria in one symbiosome can be much higher than it was previously assumed by 2D image data of this symbiosis.
Conclusion
Ultrastructural details of plant-microbe interfaces visible in 2D TEM images were verified and analysed by 3D structure construction using FIB/SEM, which gives insight in the complex arrangement of microbes within infected plant cells.

Event-responsive Beam-modulated STEM with Multi-frame and Sparse Scanning

Dr Jonathan Peters[1,2,3], Matthew Mosse[1,2], Bryan Reed[4], Daniel Masiel[4], Michele Conroy[5], Lewys Jones[1,2,3]
[1]Advanced Microscopy Laboratory (CRANN), Trinity College Dublin, Dublin, Ireland, [2]School of Physics, Trinity College Dublin, Dublin, Ireland, [3]turboTEM Ltd., , Ireland, [4]Integrated Dynamic Electron Solutions, Inc., Pleasanton, USA, [5]Department of Materials, London Centre of Nanotechnology, Imperial Henry Royce Institute, Imperial College London, London, UK

Poster Group 2

Recent advances in high-speed signal processing electronics allow any analog STEM detector to operate in an event-counting mode, measuring individual electron detection events in real time. This technology delivers images with zero dark-noise, improved linearity, and SNR limited only by ideal Poisson counting statistics [1]. By combining such event-counting hardware with fast electrostatic dose-modulators (EDM) [2], a real-time 'event responsive' imaging mode can be realised [3]. We call this Trigger Event Modulated Probability Observation STEM, or TempoSTEM for short.
TempoSTEM operates in a fundamentally different way from classical STEM imaging. In classical STEM, we observe fixed periods (dwell times) and record the varying numbers of transmitted/scattered events that arrive at a detector. In TempoSTEM, we specify a fixed number of events and measure the varying time needed for the image signal to reach that number of events in each pixel location. In both pulse counted STEM and TempoSTEM the operator sees images expressed in quantitative units of events-per-microsecond. However, there is one key difference; in TempoSTEM the beam is blanked for the remainder of the pixel once the threshold is met, significantly reducing dose and sample damage. The beam is un-blanked at the start of the next pixel and a fresh measurement begins.
Information theory predicts that for every successive electron detected within each pixel time, there is a diminishing return on information content; this has also been confirmed experimentally [3]. This creates a balance where a lower Tempo trigger exit condition ensures the most efficient detection per-electron, but it does not ensure the most readily analysable SNR overall. Here we present a mode to iteratively update noisy high-variance pixels to achieve improved resolution and SNR.
Another common approach to increase the SNR of an image is through the stacking of multiple frames. Where a hardware EDM is present [2], a further option is to only revisit a subset of pixels in subsequent frames in the series. After the first noisy scan-frame of a TempoSTEM acquisition, such as with a trigger of n=1 electron, we can calculate the local variance of image pixels. On the second scan frame, we can revisit only pixels that are outliers by, say, more than one standard deviation of their neighbours. This might be around 25-30% of the pixels for example. For these pixels, an additional TempoSTEM observation can be made and the beam blanked elsewhere to minimise dose. The rescanned pixels have now received the dose equivalent to an n=2 TempoSTEM exit condition, and the scattering rate estimate is updated. On a third scan for example, the number of outlier pixels reduces and even fewer are rescanned to an effective n=3 exit condition. After some number of rescans the variance is converged, and the image acquisition can be considered complete. For an equivalent target resolution a dose saving of around 2x is achieved even relative to the already low-dose TempoSTEM approach. This method pushes below one event per-pixel-per-frame, maximising the information from each electron, increasing the best achievable combination of resolution and beam damage.

Identification of the phases resulting from the thermal crystallization of Ge-rich GeSbTe alloys using EELS

Dr. Minh Anh Luong[1], Dr. Eloïse Rahier[1], Dr. Sijia Ran[1], Dr. Alain Claverie[1]
[1]CEMES-CNRS and University of Toulouse, 29 Rue Jeanne Marvig, 31055 Toulouse, France

Poster Group 2

Background incl. aims

Among many phase change materials, Ge-rich GeSbTe (GGST) alloys are of considerable interest due to their high thermal stability, a specification required for the next generation of embedded digital memories. This stability results from the fact that these alloys do not crystallize congruently but experience phase separation and finally form a polycrystalline material in which small grains of Ge and of several GeSbTe (GST) cubic phases coexist [1-3]. As all these phases, which have different chemical compositions, have almost the same lattice parameters, they cannot be differentiated by X-ray diffraction. On the other hand, as the grains are much smaller than the thickness of the lamella, the compositions measured by energy-dispersive X-ray spectroscopy (EDX) or electron energy loss spectroscopy (EELS) in the transmission electron microscope result from the overlapping of many small grains and do not give access to their individual stoichiometry (Figure 1). Herein, we report an efficient method to deduce the stoichiometry of the different phases of the grains which overlap by exploiting “pixel by pixel” EELS data and by extracting their characteristic Sb/Te ratio. Using this method, we show that the crystallization of the GST phase proceeds through the initial formation of cubic GeTe and its progressive enrichment in Sb during thermal annealing, ultimately leading to the formation of the well-known stable GST-225 phase.

Methods

A 100 nm-thick GGST layer was deposited by physical vapor deposition (PVD) onto a naturally oxidized 300 mm Si(100) wafer and covered by a 20 nm-thick TiN cap layer. The samples were annealed in a conventional furnace under nitrogen flux. Cross-sectional specimens were prepared by focus ion beam (FIB) technique operating with a 30 keV Ga ion beam and finally polished and cleaned at 2 keV–3 pA. High-angle annular dark-field (HAADF)-STEM and dual-EELS data were acquired on a probe corrected ARM JEM JEOL 200F microscope, operated at 200 kV. The convergence and collection angles for EELS were 29.6 and 75.9 mrad, respectively. The quantification process was carried out through the following steps: 1) the zero-loss spectrum is used to subtract the background and plural scattering signals caused by the specimen thickness, 2) high-loss elemental peaks are fitted using the Hartree-Slater model, after exclusion of the ELNES edges (about 50eV width) and 3), the Ge, Sb and Te ratios are normalized and the result obtained at each pixel is plotted in a ternary diagram for visualization.

Results

Figure 2 shows HAADF STEM images and corresponding plotted Sb/Te ratio for GGST samples, annealed at different temperatures and time durations. After 320°C/8h annealing, when the first GeSbTe cubic phase forms, the compositional data points spread along an almost horizontal line (Sb/Te = 0.05). The alignment of the pixels on such a horizontal line indicates that the compositions

which are measured result from the superposition of pure Ge and almost pure GeTe grains in varying proportions, depending on the overall composition of the layer and statistical fluctuations. The vertical shift of this horizontal line upwards reflects the homogeneous distribution of Sb in the material and should be interpreted as being due to the presence of a third highly dispersed "phase" containing all the Sb. When annealing for longer times or at higher temperatures (320°C/16h, 400°C/30min and 400°C/3h), the Sb/Te ratio characteristic of the GST phase which is formed slowly and progressively increases, from 0.05 (horizontal line) to 0.4, the signature of the well-known stable GST-225 phase. In the meantime, the horizontal shift due to dispersed Sb decreases. This shows that Sb, which was initially diluted in the matrix, progressively incorporates into the GeTe crystals during annealing (by substitution, necessarily on Ge sites). Moreover, some pixels point toward Sb-rich GST phases. Complementary TEM analysis shows these phases have the hexagonal structure, the most common being Sb2Te3. Pure Sb2 lamellas can also be identified by HAADF STEM imaging and EELS mapping, as shown in Figure 1.

Conclusions

We have thoroughly investigated the phases resulting from the thermal crystallization a GGST alloy using advanced transmission electron microscopy based techniques. While X-ray diffraction cannot differentiate the various phases found in the polycrystalline material due to their “close” lattice parameters, the careful analysis of the Sb/Te ratio obtained from pixelated EELS data gives access to the stoichiometry of the GST phases in the samples. Based on such analysis, we demonstrate that the thermal crystallization of GGST alloys proceeds through the initial formation of GeTe and Sb-poor GST grains which get progressively enriched in Sb during annealing until forming GST-326 (Sb/Te=0.33) and GST-225 (Sb/Te=0.4) grains. Moreover, excess of Sb and Te can be accommodated within Sb2 lamellas and Sb2Te3 hexagonal grains.

Multi-scale electron tomography in liquid state and its application to the study of beam-sensitive nanomaterials

Dr. Louis Marie Lebas[1], Dr Lucian Roiban[1], Dr. Victor Trillaud[1], Dr. Mimoun Aouine[2], Professor Karine Masenelli-Varlot[1]
[1]INSA Lyon, Université Claude Bernard Lyon 1, CNRS, MATEIS, UMR5510, Villeurbanne, France, [2]IRCELYON, UMR 5256 CNRS & Université Lyon 1, 2 avenue Albert Einstein, F-69626 , Villeurbanne, France

IM-01, Lecture Theater 1, august 26, 2024, 14:00 - 16:00

Background incl. aims

Electron tomography is a technique that allows 3D data analysis at the nanometer scale. In its early days, it was performed in high vacuum and only beam-resistant samples were analyzed due to its time-consuming nature. In the last decade, tremendous technical developments have been made to make tilt series acquisition faster and faster, and to make fast electron tomography compatible with environmental electron microscopy. [1,2]
Environmental electron tomography in gas, and even more so in liquid state, is very sensitive to the electron beam, so acquiring fast tilt series in STEM mode with a very low electron dose received by the sample is a real challenge even for the most experienced users. In this presentation the application of the M-SIS software, developed in our group, in the analysis of aluminum hydrogel suspended in liquid will be shown.

Methods

Al(OH)3 is an extremely beam sensitive sample, so care must be taken to avoid beam damage, especially when the sample is in a liquid state. An aqueous suspension of aluminum hydrogel was inserted into the ESEM in the liquid state, then dried and rehydrated in situ. At each hydrated state, a fast tilt series in STEM mode from -70° to +70° was recorded on the region of interest at low electron dose in order to preserve the sample. In addition, ETEM experiments were carried out without encapsulating the sample. A careful control of the sample temperature and the water vapor pressure enabled the 3D study of the hydrated material at nanometer scale and the pore size distribution was measured. The tilt series were recorded using the custom code M-SIS build in Python that is an automatic tool for electron tomography and can be installed on an ESEM and on an ETEM.[1-3]

Results

Three hydration states of Al(OH)3 were investigated in 3D by ESEM. It was found that the global volume of the sample does not change its structure during the dehydration-rehydration cycle. Its change in volume was measured to be about - 3.4 ± 1.3% during dehydration, followed by a + 1.2 ± 1.0% expansion during rehydration. The spatial resolution of the tomograms was about 10 nm and the total electron dose of each tomogram was between 1050 and 1250 e-nm-1.
In ETEM, tilt series could be acquired with 260 frames in 12 min, with a pixel size of 0.6 nm and a total electron dose of 16,000 e-nm-1. No significant change of the sample structure could be detected during acquisition. The pore size distribution in the hydrated state was found to vary from 5 to 30 nm (Figure 1).

Conclusion

Thanks to the development of the M-SIS software, we are now able to study beam-sensitive materials in liquid in 3D. Al(OH)3, an extremely beam-sensitive material, was analyzed in ESEM in 3D in different hydration states. The morphological changes were quantified with a spatial resolution of 10 nm. The pore size distribution in the hydrated sample was quantified with higher resolution in liquid using electron tomography in ETEM.

PS-12, Lecture Theater 2, august 29, 2024, 10:30 - 12:30

Background incl. aims

Silicon (Si) particles are excellent candidates for the development of optical metamaterials with high scattering efficiency for applications in anti-counterfeiting, nonlinear nanophotonics and enhanced Raman scattering. An optimized synthesis method that allows the fabrication of Si nanoparticles with resonant properties that depend on their size, crystallinity and density would open the way to the large-scale production of such so-called metamaterials. Today, one of the most promising synthesis methods is the thermal disproportionation of hydrogen silsesquioxane (HSQ), which produces resonant silicon particles with the desired criteria. However, the disproportionation of HSQ occurs at very high temperatures and the particles produced are polydisperse in size, requiring a separation process to obtain a monodisperse particle.
In this work, the nucleation and growth of Si particles from the thermal disproportionation of HSQ and the formation of silicon nanoparticles with diameters up to 70 nm were investigated. Advanced in situ environmental transmission electron microscopy (ETEM) was used to directly observe the formation of Si particles from HSQ to resonant particles at high temperature under 20 mbar of gas pressure.

Methods

In situ experiments were performed using a FEI ETEM Titan 80-300 environmental microscope operating at 300 kV equipped with a OneView camera from Gatan. HSQ grains were crushed in a mortar and then dispersed in 2-propanol, a drop of the highly dilute dispersion was placed on a Si3N4 chip compatible with DENSsolutions Wildfire sample holder then dried. The experiments were performed under a gas pressure of around 20 mbar. The gas employed was argon or a mixture of N2 - H2 (95%-5%). The temperature was raised from RT to 800 °C at a rate of 10 °C/sec with about 2 min of plateau every 100 °C. From 850 °C to 1300 °C, the temperature was increased by step of 50 °C, at a rate of 10 °C/sec with plateaus of about 20 min – 1h at 900 °C, 1000 °C, 1100 °C, 1200 °C and 1300 °C in order to record images and videos of the nucleation and growth processes. Cooling of the sample to RT was carried out by step of 100 °C at a rate of -10 °C/sec.

Results

As expected, the thermal decomposition of HSQ was found to begin at temperatures above 1000°C. Once the Si crystalline nuclei are formed, two main growth processes are observed, including particle-particle coalescence and, more surprisingly, particle displacement through the matrix, leaving traces through the HSQ matrix due to interfacial chemical reactions. At 1000°C, small particle

nuclei of about 1 nm are visible, then with increasing temperature to 1200°C, particles of 7-11 nm are observed. Then these particles begin to coalesce, indicating high mobility within the system, and the particles formed have a larger projected diameter (Figure 1a).
The second growth mechanism observed shows that the particles move through the sample by changing shape and growing up to 70-80 nm (Figure 1b). They show a liquid-like behavior, are very mobile and change shape rapidly. This liquid-like behavior below the typical melting point of silicon is attributed to a beam effect lowering the melting point during in-situ observation.
The in-situ experiments were complemented by in-situ XRD measurements up to 1200 °C, demonstrating a solid-state growth mode below the melting point of Si. [1,2]

Conclusion

This study was conducted under extreme conditions using an ETEM under 20 mbars of gas and at 1300°C and helped to illuminate the growth mechanism of Si nanoparticles from a silicon rich oxide precursor. It was found that crystalline Si domains grow easily in the solid state starting from 1000°C. For the first time, a highly malleable and mobile phase was observed in real time, suggesting an intermediate liquid-like behavior that facilitates particle growth. Growth processes by coalescing and moving within the matrix after the crystallization were identified. This study was complemented by an ex-situ investigation of the role of the reducing atmosphere in the disproportionation reaction.

Figure 1: Si particles formed after thermal decomposition of HSQ grew by two different mechanisms: a) Particles coalescence, the Si particles have high mobility at 1200°C and during the encounter they form larger nanoparticles. b) At 1300°C the particles have liquid like behavior with high mobility moving through the matrix while growing.

Poster Group 2

Background incl. aims
CuBi alloys are predicted to exhibit a giant spin Hall effect (SHE), making them promising materials for developing spintronic devices. This prediction was supported by the direct observation of SHE in Cu95Bi5 films by X-ray spectroscopy. However, the material composition and structure, e.g. crystallinity, crystallite size, effective Bi insertion into the Cu lattice or formation of metallic clusters of Bi, can affect the spin Hall angle, which is related to the efficiency of the spin-to-charge current conversion. This efficiency becomes more and more critical in the case of reduced dimensionality systems, where some dimensions may become smaller than the spin diffusion length. Changes taking place during device operation, such as those related to Joule heating, may also affect the system performance.

Methods
Here, we present a detailed structural characterization of Bi-doped Cu nanowires (NWs) with a high Bi doping level (up to 7% Bi) and different degrees of crystallinity, grown by template-assisted electrochemical deposition. The combination of in-situ atomic resolution scanning transmission electron microscopy (STEM), diffraction, electron energy-loss spectroscopy (EELS) and high-resolution synchrotron powder X-ray diffraction (PXRD), allows studying in detail the atomic structure of the NWs, which is critical for optimization of the spin transport related properties.

Results
Nanodiffraction (4DSTEM) measurements were used to analyze the crystallite size and orientation of the nanowires (see Figure 1(a,b)), allowing to harness the growth procedures in order to achieve a controlled distribution of grain boundaries, with average crystal sizes ranging from tens of nm to the micron scale. In-situ heating experiments, using both STEM and PXRD techniques, were carried out to reproduce operando conditions subject to Joule heating effects. After heating for an interval of several minutes at 400°C, in-situ PXRD measurements show that a temperature induced structural transition takes place. For an initial Bi doping of 6%, diffraction peaks typical of pure Bi appear after heating, pointing to the presence of significant Bi diffusion (Figure 1(c)). EELS chemical quantification reveals that the NWs average doping decreases to 1 at. % of Bi after heating. A decrease in the unit cell lattice parameter can be detected both by PXRD analysis and STEM images, suggesting that Bi is coming out of solution in a thermally activated process. In fact, a pure Bi phase is detected after the annealing, associated with Bi nucleation on external surfaces and also at grain boundaries. Indeed, high angle annular dark field (HAADF) images show the early stages of Bi nucleation, coming out of

solution from the Cu cubic matrix along the edges of the NWs, indicating preferred orientations for Bi segregation during heating (Figure 1(d)). Density-functional theory will be used to explain these processes, which must be taken into account when trying to understand the behavior of these nanosystems under working conditions in future devices exploiting SHE.

Conclusions
Our study explores Bi-doped Cu nanowires grown via electrochemical deposition. Synchrotron and Advanced microscopy techniques reveal structural details critical for spin transport optimization. In-situ heating experiments expose a temperature-induced Bi diffusion, leading to nucleation of a pure Bi phase. This suggests a thermally activated process affecting NW doping and lattice parameters. Understanding these phenomena is crucial for developing efficient spintronic devices driven by the spin Hall effect.

Transfer of Nanomaterials for in-situ TEM with electrical Currents

Simon Hettler[1,2], Mohammad Furqan[1,2], Raul Arenal[1,2,3]
[1]Instituto de Nanociencia y Materiales de Aragón (INMA), CSIC-Universidad de Zaragoza, Zaragoza, Spain, [2]Laboratorio de Microscopías Avanzadas (LMA), Universidad de Zaragoza, Zaragoza, Spain, [3]Araid Foundation, Zaragoza, Spain

Poster Group 1

Background incl. aims
In-situ transmission electron microscopy (TEM) has evolved to be a crucial tool for studies of dynamic processes in a large variety of specimens. While numerous examples exist that use gaseous/liquid environments, heating, biasing or the application of a mechanical force, studies in which the electrical current (and not bias) has been used as external stimulus are scarce. [1,2] A possible reason is the necessary controlled contacting of the specimen, which is challenging, especially for nanomaterials that need to be kept free from any source of damage and contamination. Here we present a preparation technique that allows a clean and almost damage-free preparation to focus on the materials during the application of electrical currents inside the electron microscope. [3]
Methods
The key element of the process is a holey silicon nitride membrane, which supports the nanomaterial during the transfer with the focused ion beam (FIB) technique using Ga+ ions. In brief, the specimen is first prepared conventionally on a TEM grid made of such a holey silicon nitride membrane (PELCO). In a TEM analysis, a suitable individual nanomaterial can be selected, as exemplarily shown in Figure A for a nanotube (NT) and a flake made of the misfit-layered compound LaS-TaS_2. [4] The grid is then loaded into a dual-beam (SEM-FIB) instrument and the nanomaterial with the supporting membrane is transferred to a microchip using a microneedle and FIB induced deposition (FIBID) of Pt/C (Figures B and C). The properties of the silicon nitride facilitate easy contacting of the membrane to the contact pads of the chip by FIBID. Finally, the membrane is removed in the central part to leave the nanomaterial as only conductive bridge.
Results
Using the above-described transfer technique, we have prepared a range of different devices based on nanomaterials and evaluated in detail the transfer quality. Figure D shows a HRTEM image of the transferred LaS-TaS_2 (NT and flake) sample revealing no contamination or charging. The limits of the methods were tested with a monolayer of WS_2, which was successfully transferred and revealed that Pt/C contamination during FIBID is kept well below a monolayer. For 1D nanomaterials, Ga implantation can be kept to zero, while for 2D materials or thin films, a small amount of Ga is implanted at the edge of the specimen in the final step of removing the membrane in the central part. We will present exemplary experiments conducted on different prepared devices.
Conclusion
The development of a support-based transfer and contacting procedure of individual nanomaterials to microchips, e.g. used for in-situ TEM investigations, allows an almost artifact-free preparation of nanomaterial specimens for electrical in-situ TEM. Suitable nanomaterials can be selected by previous TEM analysis and correlative microscopy techniques. The resulting devices can be used to electrically characterize the nanomaterials and to dynamically study the effect of an electrical current on the sample. This includes Joule heating, which can be used to heat samples to extremely high temperatures, not reachable by standard heating in-situ TEM studies. Further possible investigations

concern electromigration, electrical failure analysis or EBIC. In addition to in-situ TEM, the preparation method can equally be used to prepare devices on related microchips.

Zernike Phase Plates for aberration-corrected TEM in Material Science

Simon Hettler[1,2], Raul Arenal[1,2,3]
[1]Instituto de Nanociencia y Materiales de Aragón (INMA), CSIC-Universidad de Zaragoza, Zaragoza, Spain, [2]Laboratorio de Microscopías Avanzadas (LMA), Universidad de Zaragoza. Zaragoza, Zaragoza, Spain, [3]Araid Foundation, Zaragoza, Spain

Poster Group 2

Background incl. aims
Aberration correctors are tools to manipulate the phase of the electron wave, which have strongly increased the resolution and the impact of transmission electron microscopy (TEM) studies in multiple scientific fields. However, the phase cannot be adjusted in a completely random way by such correctors. Specifically, although the aberrations can be corrected for a large range of spatial frequencies allowing to resolve almost all crystal lattices, the overall phase contrast in acquired images is low. In fact, for perfect aberration correction, phase-contrast transfer and thus phase contrast in the image would be zero. Physical phase plates (PPs), developed for life science specimens [1], potentially allow to obtain maximum phase contrast if combined with aberration correction [2]. The aim of this investigation [3] was to demonstrate the promising application of PPs in material science.
Methods
For this study, we fabricated a Zernike PP, consisting of a thin amorphous carbon film with a central hole milled by a focused ion beam. Figure (a) shows a sketch of the objective aperture stripe with mounted PP consisting in a conventional Cu TEM grid (SEM image in (a)), which was implemented in an aberration-corrected (image) transmission electron microscope (Titan3, Thermo Fisher Scientific). Figure (b) shows a SEM image of one of the grid frames showing the carbon film with central hole. The PP was applied to different nanomaterial samples, for example to Fe_3O_4 nanoparticles [4].
Results
Figure (c) shows an example TEM image of Fe_3O_4 nanoparticles at the edge of an amorphous carbon film acquired with PP. While the lattice-fringe contrast of the nanoparticles is clearly resolved, the PP causes a strong phase-contrast transfer also for intermediate spatial frequencies making the carbon film and the nanoparticle morphology visible. The power spectrum of the TEM image (d) shows that the phase contrast is increased for spatial frequencies larger than the cut-on frequency corresponding to the radius of the hole. The power spectrum also reveals the reflections linked to the crystalline nanoparticles. The application of the unheated Zernike PP is limited to thin samples with small crystalline structures as the PPs charges if hit by a diffracted beam with increased intensity [3].
Conclusion
The experimental results obtained with an unheated Zernike PP clearly prove the benefits of applying a PP for high-resolution TEM studies in material sciences allowing to image features at the atomic and nanometric scale at the same time [3]. The combination of aberration correction TEM with PPs is especially promising as it potentially allows to perform a wave-function reconstruction with only two images, containing pure amplitude and phase contrast, respectively. Further technological improvement, such as the implementation of a PP heating device to avoid charging, or the use of electrostatic PPs could overcome the limitations of the unheated Zernike PP used for the presented results.

Enhanced time resolution with a room-temperature energy dispersive X-ray PIN photodiode detector

Luca Serafini[1,2], Mr. Mylo Gijbels[1,2], Prof. Dr. Jo Verbeeck[1,2]
[1]EMAT, University of Antwerp, Antwerp, Belgium, [2]NANOlab Center of Excellence, University of Antwerp, Antwerp, Belgium

IM-04 (2), Lecture Theater 1, august 27, 2024, 14:00 - 16:00

Energy dispersive X-ray spectroscopy (EDX) has demonstrated its utility across diverse fields, ranging from materials science to biology, serving as a user-friendly analytical technique in electron microscopy for elemental analysis and mapping of specimens. Detector technology has evolved from liquid nitrogen-cooled lithium-drifted silicon detectors (Si(Li)) to configurations featuring multiple large, tear-drop-shaped thermoelectric-cooled silicon drift detectors (SDDs). The former type allows for high count rates by having a large active area while keeping the anode capacitance low. Incident X-rays are absorbed in the bulk Si region and generate electron-hole pairs. The electrons then drift towards the anode under guidance of an electric field which is established and controlled by several increasingly reverse-biased ring electrodes covering one surface of the detector.
While this method is effective for elemental mapping and offers reasonable acquisition times, the precision of X-ray arrival time is limited by the relatively slow drift speeds and large active area size. X-rays absorbed near the anode are read out significantly faster than those absorbed farther away. This forms a major bottleneck for another promising electron microscopy application, namely EDX and energy electron loss (EELS) coincidence detection. Here the aim is to correlate transmitted electrons and X-rays in time. The coincidence information can greatly enhance the sensitivity for detecting trace elements in a matrix as compared to conventional EELS and EDX. Furthermore, the method allows the determination of the collection efficiencies without the use of a reference sample and can subtract the background signal for EELS and EDX without any prior knowledge of the background shape and without pre-edge fitting region. Another advantage is that the correlation data is revealed while preserving the full EELS and EDX signal without compromise in speed or acquisition time.
To tackle this issue, we are working on a proof-of-concept detector design consisting of a small reverse-biased Si PIN photodiode with a low-noise charge amplifier circuit. Si PIN photodiodes are reported to be suited for X-ray detection and are commercially available at low prices and in small sizes. What truly sets our approach apart is that contrary to the ongoing trend of ever-increasing size of active areas and number of detectors to increase solid collection angle and thus acquisition rates, we ensure sufficient collection by bringing our sensitive area and specimen very close together. The sensitive area can thus remain small, keeping the photodiode's capacitance low enough to allow for high acquisition rates and low noise levels. Moreover, the small size minimizes the temporal broadening as initially aimed for. Regardless of where the X-ray is absorbed, the readout speed in a PIN photodiode will have little spread as the anode stretches over the entire back side of the PIN junction. Besides the fundamental improvement in time resolution, our concept offers numerous practical advantages. It provides a cost-effective method for integrating EDX capabilities into an electron microscope. Additionally, the use of a small PIN photodiode minimizes the necessity for cumbersome cooling, as the limited active area (and thus cross-section of the depletion layer) ensures that dark current (noise) remains limited even at room temperature.
So far several prototypes have been made and tested in a scanning electron microscope (SEM) as this allows for convenient piloting. Over the different iterations the leakage current, signal-to-noise ratio

(SNR) and form factor have been improved. With Cu X-rays the current SNR of the single X-ray pulse signals we are measuring is above 5, with pulses exhibiting sub-50ns rise times (see left side of figure). The entire system consumes less then 750mW of power. We are on the brink of obtaining our first energy spectrum and determining the energy resolution using the XG-lab digital DANTE pulse processor. Currently different photodiodes are being tested and compared as well as ways of preventing the X-rays from landing outside of the depletion layer of the photodiode where they lead to a slow and distorted signal.
In conclusion, we present the development of an in-house build room-temperature PIN photodiode X-ray detector to improve time resolution and allow for advancements in EDX and EELS coincidence experiments that so far have been hampered by the slow drift mechanism in SDD setups.

IM-04 (2), Lecture Theater 1, august 27, 2024, 14:00 - 16:00

Background incl.aims
Due to increasing demands on better performance of materials of various fields working under harsh and complicated conditions and the constant minimization of devices, it is essential to reveal structure-composition-property correlation of materials from atomic-scale under working conditions in real-time. In-situ TEM technology is one of the most promising solutions to the above needs and has advancing rapidly in recent decades. However, it is greatly difficult to simulate working environment involving harsh thermal, mechanical, electrical stimuli, while performing real-time atomic-resolution observation and analysis of materials. For this reason, our group has dedicated to the development of an in-situ atomic-scale straining, heating and biasing system for TEM and has successfully applied the platform to study the atomic-scale response of various materials and revealing the mechanisms underneath.
methods
The multi-functional in situ TEM testing platform was developed mainly based on micro piezoelectric ceramic actuator and dedicated designs of MEMS chips with various heating and/or biasing functionalities. With a unique truss-like design, the heating chip can heat the sample from room temperature to 1200℃ with an accuracy of ±1℃ while allowing straining of the sample at any given temperature. The miniature straining actuator can apply a GPa-level stress, over 4 microns actuation displacement and an actuation resolution of 0.1 nm. The in-situ biasing chip can achieve precise application of electrical signals and pA and μV level measurement. The MEMS chips for heating and biasing and the miniature actuator for straining are fixated onto a rigid frame. A flexible printed circuit (FPC) connects the electrodes on the MEMS chips and the actuator to an outside control unit for the application and measurement of subtle signals. The rigid frame and the FPC comprises a functional cartridge, which can be conveniently connected to a specially designed double-tilt TEM holder.Various kinds of thermal/electrical/mechanical loading of samples can be carried out inside a TEM column. Throughout the entire loading process, the sample can be tilted freely around two orthogonal axes for ±15°. This capability is essential for achieving atomic-scale resolution, which requires precise alignment of the electron beam to a low-index zone axis of the sample during in-situ testing.
Results
With this in-situ platform, we carried out an in situ atomic-resolution study on the sliding-dominant deformation at general tilt grain boundary (GB) in platinum bicrystals. Both atomic-scale sliding along the GB and sliding with atom transfer across the boundary plane were observed directly in real-time.1 For the first time, we uncovered that tungsten fractures at 700℃ in a ductile manner via a strain-induced multi-step body-centered cubic (BCC)-to-face-centered cubic (FCC) transformation and dislocation activities within the strain-induced FCC phase.2 Using this technique, researchers has also

revealed the atomic-scale process of GB dislocation climb in nanostructured Au during in situ straining.3

Conclusion

Based on highly integrated MEMS chips, miniaturized piezo actuator and unique double-tilt system, we have developed an in-situ TEM testing platform that allows real-time observation of micro-structure evolution at atomic scale under flexible coupling of mechanical, thermal and electrical fields. Researches on revealing the atomic scale mechanisms of GB plasticity and brittle-to-ductile transition of various metallic materials were carried out.

PS-03 (2), Lecture Theater 2, august 30, 2024, 10:30 - 12:30

Background incl. aims
Alloying group IV elements in out-of-equilibrium conditions when there is a significantly different atomic size between the atoms of the host lattice (Ge) and the alloying element (Sn) results in peculiar modifications of the structure and electronic properties of the parent phases. Growing alloys in the form of core-shell Ge-GeSn heterostructures adds an additional degree of freedom for strain accommodation. Moreover, such core-shell configuration induces changes in their morphological, chemical, electronic, and optical properties. Investigating these heterostructures, where Ge acts as the core and GeSn as the shell in hexagonally faceted nanowires with a diameter in a range of 80-100 nm and length exceeding tens of µm, poses significant challenges. While there are challenges, these heterostructures offer numerous opportunities for developing silicon-compatible devices with enhanced capabilities in the mid-infrared wavelength range (5-20µm). These capabilities include, among others, CMOS and MOSFET devices, night-vision devices, and lasers [1], owing to their advanced band-to-band transitions and enhanced carrier mobility. Consequently, a thorough investigation and precise characterization, at the atomic level, are crucial for these heterostructures, requiring a high degree of sensitivity and high-spatial resolution. The introduction of Sn to Ge, a high carrier mobility element, will undoubtedly have a profound impact on its bandgap characteristics, influencing transitions within the bandgap [2]. We observe and extract information locally and detect features using the Scanning Transmission Electron Microscopy (STEM) technique, employing an extremely narrow electron probe directed at the sample to obtain detailed insights into the structure and chemical composition of these intriguing core-shell structures. The initial Sn content ranges from below 8 at. % to above 14 at. % representing a substantial amount of Sn. It has been predicted that the transition from an indirect to a direct bandgap will occur at approximately 8 at. % Sn [3], a hypothesis we aim to experimentally confirm and deepen further.

Methods
To study such core-shell heterostructures, we utilize a High-Resolution (HR) STEM with the High-Angle Annular Dark Field (HAADF) detector and Energy-Dispersive X-Ray Spectrometer (EDS). For such purpose we employ the ThermoFisher Scientific Spectra Ultra double-corrected TEM operated at 300 kV with a segmented Ultra-X EDS detector enabling atomic-resolved EDS maps. Additionally, we implement electron energy-loss spectroscopy (EELS) in STEM mode using the Nion HERMES 100 instrument operated at 60 kV, with optimal energy resolution of 4.8 meV for detailed examination of electronic and optical properties.

Results

The results of this investigation unveil a substantial impact of increased Sn content in the core-shell Ge-GeSn nanowires on their structural, electronic, and optical characteristics. The performed EDS analysis validates the distinctive core-shell configuration, highlighting a region depleted of Sn in the core, alongside a discernible degree of its uniformity in the shell (Figure 1a). Additionally, findings show that the notable segregation of Sn adatoms along the hexagonal facets promotes the generation of complex defects and that their complexity is more prominent with the elevated Sn content and incorporated strain. The presence of twinning may contribute to the growth of supplementary structures such as nanobelts (NB) with unique non-hexagonal cross-sectional shapes. Moreover, the coexistence of both diamond cubic (DC) and hexagonal-wurtzite (WZ) structures (Figure 1b) or polytypism, results in notable changes in the polarity of these initially presumed non-polar elements (i.e. we alloy within the same group IV elements), enhancing the complexity and interest in the ordered nature of these structures. The investigation of electronic transitions at a high level of locality with high-energy resolution EELS confirms that the increase of the Sn content from 8 at.% up to 18 at.% leads to a transition from an indirect bandgap of Ge (measured 0.67 eV) to a direct bandgap of GeSn, and a shift from 0.56 eV for 8 at.% Sn to approximately 0.3 eV for 18 at.% Sn (Figure 1c).

Conclusion

In summary, our findings demonstrate that core-shell Ge-GeSn nanowires exhibit a unique morphology and crystalline structure ascribed to the Sn content within the GeSn shell. Furthermore, an in-depth investigation of high-spatial resolution HAADF data unveils that the presence of Sn segregation, occurring with higher Sn concentrations in the shell, significantly impacts the occurrence of intricate defects like twinning. As evidenced by the EELS data, the transition of the bandgap from indirect to direct concomitant with a reduced value (measuring below 0.67 eV for Ge), was confirmed with higher Sn concentrations surpassing approximately 8 at.%.

Cryo-ET Structures of Huntingtin-Actin Complexes Reveal that Huntingtin Organizes Actin Cytoskeleton in Neurons

Professor Ji-Joon Song[1]
[1]Korea Advanced Institute of Science and Technology, Dajeon, South Korea

Poster Group 1

Huntingtin (HTT) is a causative protein for Huntington's disease (HD) and facilitates intracellular dynamics along the cytoskeleton network. Here, we identify that HTT directly binds to actin filament, inducing a bundling. Furthermore, we determined the sub-atomic resolution structures of Q23 HTT complexes with actin filament via cryo-electron tomography (cryo-ET) followed by subtomogram averaging (STA), revealing that N-HEAT and Bridge domains in HTT wrap around actin-filament, concomitantly, C-HEAT domain being displaced away. In addition, we show that HTT depletion leads to a defect in the axonal growth cone with abnormal cytoskeletal organization. Our data demonstrates that HTT directly interacts with actin-filament and is a dynamic modular scaffold protein organizing cytoskeleton.

Ultrastructural investigation of human cytomegalovirus tegument protein UL71 and its role in secondary envelopment

Benedikt Küß[1], Annika Metzner[2], M.Sc. Laura Cortez Rayas[2], Prof. Dr. Paul Walther[1], Dr. Gregor Neusser[3], apl. Prof. Dr. Christine Kranz[3], Dr. Clarissa Read[1,2], apl. Prof. Dr. Jens von Einem[2]
[1]Central Facility for Electron Microscopy, Ulm University, Ulm, Germany, [2]Institute of Virology, Ulm University Medical Center, Ulm, Germany, [3]Institute of Analytical and Bioanalytical Chemistry, Ulm University, Ulm, Germany

LS-06, Lecture Theater 4, august 30, 2024, 10:30 - 12:30

Background
The molecular mechanisms underlying the assembly of infectious virions of human cytomegalovirus (HCMV), an important human pathogen associated with complications in immunocompromised patients and the leading cause of birth defects after congenital infection, are still not well understood (Griffith et al., 2015). An important step of HCMV morphogenesis en route to infectious virions is a cytoplasmic envelopment process, referred to as secondary envelopment. Tegument protein pUL71, which is highly conserved among herpesviruses, is known to play an important role in the envelopment process (Schauflinger et al., 2011). Several functional motifs, mainly located in the conserved N-terminus of pUL71, have been characterized in detail (Read et al., 2019; Metzner, 2022), whereas the role of the non-conserved C terminus of pUL71 is mainly unclear. However, a tetralysine motif in the C terminal region of pUL71 has revealed a mechanistic involvement of this region in HCMV morphogenesis (Read et al., 2019). Dissecting the functions of pUL71 during secondary envelopment brings us further to unravel the molecular mechanism of secondary envelopment and could lead to the identification of new antiviral targets.
Methods
The role of the C-terminus of pUL71 was investigated by generation and characterization of a mutant virus (TB71insHA-299) expressing a truncated version of pUL71 fused to an HA epitope lacking the last 61 amino acids with the tetralysine motif and the MIM2 domain. A first phenotypic characterization of TB71insHA-299 after infection of human fibroblasts was performed by immunofluorescence microscopy (IF). For direct visualization of secondary envelopment, transmission electron microscopy (TEM) was carried out on human fibroblasts infected with TB71insHA 299 that were fixated by high-pressure freezing and freeze substitution at five days post infection and embedded in epoxy resin. Stages of secondary envelopment were analysed on ultrathin sections by TEM and compared with cells that were infected with wild-type virus or a previously published virus mutant carrying a mutation in the C-terminal tetralysine motif of pUL71 (Read et al., 2019). In addition, 3D analysis was performed on these samples by focused ion beam scanning electron microscopy (FIB-SEM) and scanning transmission electron microscopy (STEM) tomography (Villinger et al., 2014).
Results
In IF experiments, TB71insHA-299 infected cells showed an accumulation of viral particles at the periphery of the cytoplasmic viral assembly complex (cVAC) at large circular structures which is similar to a mutant lacking pUL71. Quantification of secondary envelopment stages by EM analysis of TB71insHA-299 infected cells revealed an impaired secondary envelopment compared to the wild-type virus but no further defect compared to the well characterized virus with a mutation in the

tetralysine motif at the C terminus of pUL71 (Read et al., 2019). Furthermore, it was shown that the accumulation of viral particles at the periphery of the cVAC at large circular structures in TB71insHA 299 infected cells were multivesicular bodies (MVB) with viral capsids attached to the whole cytoplasmic face of the MVB membrane. Additionally, EM revealed abnormal budding of capsids at multiple budding sites (MBS). These ultrastructural differences and the impaired secondary envelopment are similar to a virus that is unable to express pUL71 (Schauflinger et al., 2011). In the virus with the mutated tetralysine motif, these ultrastructural differences could not be observed (Read et al., 2019).
Conclusion
In conclusion, the last 61 C terminal amino acids of pUL71, containing the tetralysine motif and especially the MIM2 domain of pUL71, seem to be of great importance for HCMV morphogenesis. This work demonstrates that additionally to the already characterized secondary envelopment defect caused by the mutation of the tetralysine motif, the other amino acids, most likely the MIM2 domain, carry additional functions for the formation of an intact cVAC and efficient secondary envelopment. This data argues for the controversially discussed involvement of the ESCRT machinery in HCMV morphogenesis and membrane remodelling.

Strain mapping and simulation of transistor structures in a 22nm FDSOI technology

Dirk Utess[1], Dominik Martin Kleimaier[1], Etienne Billan[1], Tashfain Youssuf[1], Zhixing Zhao[1], Thorgund Nemec[1], Dr. Moritz Andreas Meyer[1], Dr. Jochen Rinderknecht[1]
[1]GlobalFoundries, Dresden, Germany

Poster Group 2

Background & aims
With the advent of the AI/ML and 5G/Satellite internet era, modern electronic devices need to be operated with low energy consumption, high performance, radiation hardness and manufactured at low cost. One of the technologies is 22FDX offered by GlobalFoundries® which utilizes a fully depleted silicon-on-insulator (FDSOI) technique. Speed and power consumption of devices are improved accordingly. Introducing mechanical strain to transistor channels e.g. by epitaxial growth or process-induced pre-stressed overlayers or periphery layouts alters the crystal lattice and thus also the band structure of the semiconducting channel. As different requirements of strain for N- or P-type transistors e.g., along the direction of the channel, the characterization of strain in electronic devices is necessary, both for monitoring the intended engineered strain but also the unintended strain states. However, for verification as well as enhancing strain, FEM Simulation of Strain is crucial. The second part of this study focuses on the simulation of transistors. A detailed model is developed that includes mechanical and structural parameters. [1, 3]
Methods
Precession Electron Diffraction (PED) is a specialized technique in Transmission Electron Microscopy (TEM) employed to gather electron diffraction patterns while scanning across the designated region of interest. During the scanning process, the electron beam rotates around the central axis, while the beam itself is tilted at a specific angle. This results in a quasi-kinematical diffraction pattern, which facilitates the use of a more sophisticated algorithm for crystal structure determination. The strain simulation, based on the finite element method, started with a basic structural model and mechanical parameters. After validating this fundamental model with corresponding structures at the transistor size level, increasingly complex models were developed and subsequently verified. [2, 4]
Results
In this study, strain maps and graphs will be presented obtained from both experimental data using PED and simulated data from various transistor devices. These strain maps exhibit excellent agreement with each other as well as with electrical measurements. Furthermore, they enable the verification and identification of new stress elements, highlighting potential areas for improvement by adjusting structural dimensions and addressing distinct stress elements.
Conclusion
This holistic approach—combining simulation and measurement—enables a comprehensive understanding and optimization of strain effects in electronic components. It also promotes the progression of 22FDSOI technologies and beyond. Finally highlighting the Significance of Advanced TEM Techniques in the Semiconductor industry.

Revolutionizing Electron Microscopy Through Intuitive Language-Driven Interfaces: The Emergence of the EM CoPilot

Remco Geurts[1], Pavel Potocek[1], Remco Schoenmakers[1], Giovanni Mariotta[1]
[1]ThermoFisher Scientific, Eindhoven, Netherlands

IM-10 (2), Lecture Theater 3, august 29, 2024, 14:00 - 16:00

The field of electron microscopy (EM) has long been constrained by the complexity of its operating systems, which require extensive training and expertise to navigate. Traditional graphical user interfaces (GUIs) provide a layer of abstraction that, while useful, can distance the operator from the most efficient and intuitive interaction with the instrument. This study introduces the EM CoPilot, an innovative application of Large Language Models (LLMs) [1-4]. designed to transform the operation of electron microscopes by enabling control through intuitive language commands. This paradigm shift signifies a new era in microscopy, where accessibility, efficiency, and user-friendliness are paramount.
Methodology involved the development of an LLM capable of understanding and translating natural language commands into specific function calls for electron microscopes. The system supports a wide range of commands. The code was integrated into an EM control system, equipped with voice and text recognition capabilities, supporting multiple languages to cater to a global user base.
Key findings demonstrate that the EM CoPilot significantly reduces the learning curve for new users, while enhancing the operational efficiency and flexibility for seasoned experts. Users can execute complex sequences of operations with simple commands, automate routine tasks, and receive operational guidance, thereby reducing operational errors and increasing throughput. Furthermore, the system's ability to handle complex sequence function calls and integrate basic classical image processing tasks directly through language commands opens new avenues for advanced microscopy techniques.
The implications of this study are profound, signaling a move towards more user-centric approaches in the design and operation of scientific instruments. By bridging the gap between advanced technology and user interface design, the EM CoPilot not only democratizes access to high-level electron microscopy but also sets a precedent for the application of LLMs in scientific instrumentation. The integration of LLMs into EM operation paves the way for future innovations in instrument control, potentially revolutionizing how scientific research is conducted across multiple disciplines.
This abstract encapsulates the essence of the EM CoPilot study, highlighting its innovative approach, methodology, key findings, and the broader implications for the field of electron microscopy and beyond.

Structural basis of rotavirus spike proteolytic activation

Dr Dunia Asensio-Cob[1], Dr Carlos Perez-Mata[2], Dr Josue Gomez-Blanco[3], Dr Javier Vargas[3], Dr Javier M Rodriguez[2], Dr Daniel Luque Buzo[4]
[1]The Hospital for Sick Children, Toronto, Canada, [2]National Centre for Biotechnolgy, Madrid, Spain, [3]Universidad Complutense de Madrid, Madrid, Spain, [4]The University of New South Wales, Sydney, Australia

Poster Group 2

Rotavirus (RV) is the leading cause of severe gastroenteritis with dehydration in children under 5 years of age and causes ~590 million infections per year in all age groups. Rotavirus infectivity depends on the activation of viral particles by spike proteolysis by trypsin-like proteases. Although it has been described how the entry into the cell is mediated by a conformational change in the spike, the molecular mechanisms underlying this proteolytic activation process are unknown. Using cryoEM we have resolved the structure of the infective particle of group A RV before and after proteolytic activation. Despite the low occupancy and high flexibility of the spike, we have built an atomic model of both spikes by combining various computational methods. The resolved structures show that the conformation of the non-proteolyzed spike is conditioned and limited by the position of the loops that surround its structure and that join the lectin domains that form the head of the spike with its body. The proteolysis of these loops breaks this structural limitation allowing the transformation of the spike to a state competent to make the necessary conformational changes to penetrate the cell membrane.

Poster Group 2

Background

Mesoporous materials are important for industry and society given their wide-ranging application areas including sorbents, separation, energy storage, biomedicine, or heterogeneous catalysis. Particularly heterogeneous catalysts have played a major role in our fossil-based society but they are also facilitating the transition towards a sustainable chemical industry based on renewable feedstocks and energy. One of the most commonly used methods to prepare a supported heterogeneous catalyst is incipient wetness impregnation (IWI). In IWI, the mesopores of the support material (e.g. silica, titania and alumina) are filled with a metal-salt solution that matches the volume of available pore space. Subsequently, the impregnated material is dried, calcined, and reduced yielding supported metallic catalyst particles within the mesopore network of the support. However, fundamental aspects of IWI such as pore filling, solute-support interactions, solid precipitation and/or (re-)deposition are still not fully understood. Furthermore, the corrugated surface and typically disordered mesopore structure of supports, both before, during, and after liquid impregnation have remained unexplored so far.

Methods

We employed cryogenic electron tomography (cryo-ET) to quantitatively assess the 3D structure of wet impregnated and freeze-dried disordered mesoporous supports. To this end, alumina extrudates of a few mm in diameter and length were crushed into small particles and IWI was performed with either water or aqueous solutions containing different molarities of Mo and Ni. Impregnated support particles were deposited on TEM grids and vitrified in liquid nitrogen. In addition, to study the solid deposition upon drying, impregnated support particles were freeze-dried by equilibrating the TEM to room temperature overnight. To capture the liquid-filled and freeze-dried state of a particle in 3D, tomographic tilt series were acquired under cryogenic conditions. A low-dose acquisition scheme combined with a direct electron detector (Falcon 4i) were utilized to minimize electron beam induced damage to the samples. Tilt series alignment and reconstructions were performed in IMOD or Inspect3D. Image processing, segmentation and quantitative analysis were carried out using a combination of Ilastik, MATLAB and AMIRA3D. We quantitatively evaluated the pore size distribution (PSD), specific surface area (SSA), pore volume (PV), pore tortuosity, surface shape index, and surface curvature to explore the change in pore structure and support surface induced by impregnation and solid deposition after drying.

Results

The degree of mesopore filling by a liquid was assessed from tilt series acquired with a cumulative electron dose ranging from 200 to 300 e-/Å2 which prevents beam-induced damage such as liquid bubbling. Numerical slices extracted from the 3D reconstructed volume show good contrast between water and the alumina support structure. However, the contrast decreases with increasing concentration of metal components in the solution (i.e., 1.3 M, 3.0 M, 5.1 M, 8.1 M of Ni andMo). The PSD, SSA, and PV derived from these cryo-ET measurements were close to the bulk values, as determined by N2 physisorption. The additional morphological information uniquely provided by cryo-ET are pore tortuosity, surface shape index, and surface curvature, which were comparable for all samples. However, the sample with the highest molality was an outlier, which we attribute to the much-reduced contrast between alumina and the impregnation solution, hampering precise segmentation.

To study solid deposition during the drying step, an impregnated support particle (5.1 M precursor solution) was 3D imaged in the wet state and after freeze drying. The sufficient contrast between the solution and the support in the wet state allows observing the removal of water after freeze drying. The surface of the dried impregnated particle is covered with precipitated solids, substantially impacting the morphology of some of the pores, while other pores remain unaffected. Due to the low contrast between the precipitated solids and the support, it is not possible to measure the thickness of the deposited layer. Nevertheless, the darker regions at the outer rim of the freeze-dried support particle suggest preferential solid deposition in the outer regions of the impregnated and dried particle. In this state, cryo-ET-derived PSD, SSA, and PV values were lower than those of the bare support. The less tortuous pore structure together with the decrease of the average solid surface shape index, corresponding to an average surface change from ridge-like to saddle-like, suggests preferential deposition in pockets with initially a high negative curvature.

Conclusion

We employed a cryo-ET workflow to study the impregnation and drying steps of IWI performed on disordered catalyst support particles. To this end, wet impregnated support particles were successfully vitrified and imaged in 3D under cryogenic conditions. Good contrast was obtained between liquids containing up to 5.1 M metal (Ni and Mo) precursor and the alumina support, demonstrating the potential of this cryo-ET approach to investigate different liquid-solid systems. Furthermore, solid deposition was evaluated by quantification of the pore network and particle surface before and after freeze drying. Although it was not possible to directly distinguish the deposited solids from the support particles after drying, the deposited solids affected the pore size and particle surface as probed by quantitative analysis of cryo-ET reconstructions. In conclusion, this study shows the potential of cryo-ET to explore the liquid impregnation and/or drying processes across a diverse range of mesoporous materials applications.

Poster Group 2

Background incl. aims
The coupling between catalytic activity and the structure of supported nanoparticles under reaction conditions has been a significant driver for the development of in situ and operando characterization techniques in catalytic research. Traditional photon-techniques provide spatially averaged structural information of nanoparticle ensembles in miniaturized reactors, with conversion of reactants measured at the reactor exit by use of e.g. Mass Spectrometry (MS). To improve the spatial resolution of local structure and catalytic function of nanoparticle ensembles it is, however, beneficial using miniaturized reactors in conjunction with Transmission Electron Microscopy (TEM) [1,2,3,4].

Methods
Herein we focus on operando electron microscopy based on a nanoreactor. The nanoreactor is a Micro Electro-Mechanical System (MEMS) device equipped with a unidirectional and micrometer-sized gas channel, including a heating element, which facilitates MS of the exhaust gas from the nanoreactor as well as reaction calorimetry. With an array of electron transparent windows, the nanoreactor permits atomic-resolution TEM imaging of the nanoparticles under ambient pressure levels at different positions along the heated reactor zone [1,2,3]. Previously, we demonstrated how this system offered unprecedented insight into the oscillatory CO oxidation reaction catalyzed by an ensemble of Pt nanoparticles at ambient pressure levels by correlating high-resolution TEM of individual nanoparticles with global MS and calorimetry data. Moreover, a time-dependent first-principal reactor model was established that suggested marked gradients in the reactants along the gas flow channel under conditions of finite conversion levels.

Results
Herein, we will examine experimentally such gradients in the reaction environments by means of Electron Energy-Loss Spectroscopy (EELS). EELS offers sensitive detection of lighter elements in the gas phase with a special resolution defined by the area of illumination with the electron beam. EELS has therefore previously been used investigate gradients in temperature of heating devices [3] and gas composition[4]. Here we employ EELS for the first time to a gas flow reactor. By recording EELS at the Carbon K ionization edge, we examine the CO conversion profile along the nanoreactor and compare with mass-flow calculations through the nanoreactor and we relate the local structure and conversion to resolve spatially dependent structure-activity relationship during the Pt-catalyzed CO oxidation reaction.

Conclusion
In perspective, this operando electron microscopy and spectroscopy approach sets apart from the vast number of operando photon-techniques by the ability to relate nanoparticle structures with

their catalytic activity, selectivity, and stability. However, such analyses take the reactor and mass-flow conditions into account conditions in order to develop chemical meaningful insight.

LS-06, Lecture Theater 4, august 30, 2024, 10:30 - 12:30

Introduction
Plasmodium falciparum, the deadliest species of malaria parasites infecting humans, has a complex life cycle which requires transition between two intrinsically different hosts (human and mosquito). Hence, the parasite faces the challenges of having to navigate growth, proliferation, transmission, and sexual reproduction in vastly different host environments. Each of these cellular processes rely on coordinated lipid access and metabolism mechanisms, with the parasite either synthesising essential lipids de novo or acquiring them from its host environment in order to propagate. Lipid droplets (LDs) are organelles central to lipid and energy homeostasis across all eukaryotes but their roles and importance in P. falciparum are poorly understood.
We therefore set out to characterise the size, composition and dynamics of LDs across the disease causing intraerythrocytic stages of the parasite life cycle.

Methods
We applied a combination of advanced light microscopy techniques (split fluorescence emission analysis) and volume imaging using Focused Ion Beam Scanning Electron Microscopy (FIB-SEM) in combination with inhibitors of essential enzymes in neutral lipid metabolism to characterise the dynamics and importance of LDs in the parasite's asexual life cycle stages.

Results
We observed significant LD changes in late schizont stages, suggesting a switch from lipid accumulation to lipid utilisation that precedes parasite egress from the host erythrocyte. We will furthermore report on observed connections between LDs and several other organelles, pointing to potential functional interactions. Employing inhibitors that specifically interfere with the synthesis or break-down of triacylglyerols (TAG), we found that LD function is essential for schizogony and counteracts lipid toxicity.

Conclusions
Our study of LDs across the asexual life cycle grants new insights into the dynamics of lipid synthesis, storage and utilisation in P. falciparum, which might provide a novel avenue into new intervention strategies to combat this devastating disease.

Poster Group 1

Background incl. aims

To understand the structure-property relationship of nanostructures, reliably quantifying parameters, such as the number of atoms along the projection direction, is important. Advanced statistical methodologies made it possible to count the number of atoms for monoatomic crystalline nanoparticles from a single annular dark field scanning transmission electron microscopy (ADF STEM) image [1]. For this purpose, the so-called ADF STEM scattering cross-sections (SCSs), which correspond to the total intensity of electrons scattered by a single column, are a useful measure. Those SCSs scale with the number of atoms and the atomic number Z. Because of the presence of this Z-contrast, for mixed columns, different elements will contribute differently to the SCSs thus significantly complicating a quantitative interpretation. Progress was made to extend atom-counting from homogeneous to heterogeneous nanostructures by combining ADF STEM with energy dispersive X-ray (EDX) spectroscopy [2]. Although this method can be used to unscramble elements even when the difference in atomic number is only one, EDX measurements may not always be the most viable option for beam-sensitive materials due to the substantial electron dose needed to achieve a sufficiently high signal-to-noise ratio in the EDX elemental maps. As an alternative, we investigated multimode atomic resolution ADF STEM [3]. In this technique, distinct scattering behaviours in different annular detector collection regions will help to unscramble the composition and thickness. Both approaches will be discussed and in addition, the feasibility of novel dose-efficient 4D STEM techniques will be explored for atom-counting, since the simultaneous acquisition of both light and heavy elements remains challenging based on ADF STEM images [4].

Methods

As a first step to count the number of atoms, the atomic columns in the ADF STEM image are modelled by a superposition of Gaussian functions. The volume under each Gaussian corresponds to the scattering cross-section. When counting the number of atoms in heterogeneous nanostructures by combining EDX and ADF STEM, EDX STEM SCSs are also derived by integrating the intensity over the atomic column positions from the noisy elemental maps. Since both ADF STEM and EDX imaging are incoherent techniques, a linear relationship between the EDX and ADF STEM SCSs exists. By exploiting this linear relationship, the experimental SCSs are matched to the simulated SCSs by estimating normalisation constants for the EDX SCSs, using an iterative weighted least squares minimisation. Similarly, with multimode atomic resolution ADF STEM, the nanoparticle SCSs are matched with simulated SCSs by minimising the uniformly weighted sum of squared differences in the SCSs from multiple ADF STEM images. The latter method only considers ADF STEM images, i.e.

images obtained by integrating from regions in the convergent beam electron diffraction (CBED) pattern with angles larger than the convergence angle of the probe. When using the flexibility of the 4D STEM datasets, the electrons scattered at low angles can also be employed, facilitating the quantification of light elements. To this end, first-moment STEM images, which measure the centre of mass (COM) position from the CBED pattern are quantified by modelling the COMx(y) image as a superposition of 2D Lorentzian derivatives.

Results

The combination of EDX and ADF STEM images to count atoms is applied to experimental EDX and ADF STEM images of an Au@Ag core-shell nanorod. For this purpose, the EDX mapping was done for 60 minutes, with the results stored every 5 minutes followed by the acquisition of a calibrated ADF STEM image. This resulted in a times series of 12 EDX Ag and Au elemental maps and 12 ADF STEM images. The counting results for both types of elements agree well with the expected results for a symmetrical Au@Ag core-shell nanorod. The average error on the number of atoms in a column equals ±5.6, ±2.5, and ±3.2 atoms for respectively the number of Ag, Au and total number of atoms. With this methodology we also explored the possibility of characterising a simulated Au@Pt nanorod, with adjacent atomic numbers. Those analyses quantitatively demonstrate the opportunities to count the number of atoms corresponding to each specific element, even when the difference in atomic number is only one.
As a more dose-efficient method to reveal the thickness and composition information, we counted the number of atoms of a simulated Au@Ag core-shell nanoparticle based on multiple STEM images originating from non-overlapping detector regions retrieved from a 4D STEM dataset. When using a set of SCSs obtained from 3 independent ADF STEM images, the average root mean squared error for the atom-counting results is ±5.4, ±2.2, and ±3.5 atoms for respectively the number of Ag, Au, and total number of atoms. This is the same order of magnitude as for the EDX analysis, although the incident electron dose was much lower, i.e. 10^5 e/Å² in a single frame, whereas for the EDX experiment the incident electron dose per frame was approximately $4x10^4$ e/Å² and $4x10^6$ e/Å² for ADF and EDX respectively, clearly highlighting the dose-efficiency of multimode ADF STEM.
For light elements and COMx(y) imaging, the possibilities for atom-counting are explored using a simulation of an aluminium crystal. By fitting the 2D Lorentzian derivatives, the integrated intensities of the atomic columns as a function of thickness are calculated. A monotonic increase up to a thickness of 30 atoms is observed, suggesting that the COMx(y) images can be used for atom-counting.

Conclusions

In conclusion, different multimodal strategies are presented to count the number of atoms in heterogeneous nanocrystals. When combining EDX and ADF STEM imaging the number of atoms can be counted even for elements with adjacent atomic numbers, albeit at the expense of high incident electron doses. The analysis of images obtained from processed 4D STEM datasets will be more dose efficient. Given the promising results, it is a viable alternative for atom-counting of beam-sensitive materials.

Microfabricated Sample Carrier for Cryogenic Electron Microscopy

Dr Vasilis Papadimitriou[1], Dr Evgeniya Pechnikova[1], Mr Merijn Pen[1], Hugo Pérez-Garza[1]
[1]DENSsolutions, Delft, The Netherlands

IM-11 (2), Lecture Theater 5, august 30, 2024, 10:30 - 12:30

Cryo-electron microscopy (CryoEM) has been proven as invaluable tool for small biomolecule structure determination ranging from proteins to viruses and DNA. Nevertheless. since the introduction of TEM and cryoEM the sample carrier (grid) has remained largely unchanged. Meanwhile microfabrication has made leaps due to the semiconductor industry. In this abstract we present a silicon-based sample carrier made with microfabrication techniques.

Current sample carriers consist of grid made by soft metals typically copper or gold and covered by a holey carbon film or lately higher end carriers are covered by a gold film[1] . Despite their desirable high thermal conductivity, soft metals carriers are very easy to bend, and require gentle handling . Clipping the grid (i.e. to create AutoGrids) is required to be compatible with autoloaders. In addition, due to their low robustness, their surface is typically wavy (not flat), making sample preparation far from ideal, especially for applications such as cryo-tomography. The carbon film transfer typically happens on an individual carrier level, resulting in surface inconsistencies between carriers even from the same fabrication batch. Furthermore, any process in the individual carrier level lengthens the fabrication process and hence the lead times.

Our proposed carriers use nanotechnology materials and, via the introduction of microfabrication techniques, we aim to improve all the aforementioned limitations of the current carriers. Our microfabricated devices consist of a silicon frame, holey silicon nitride membrane and a monolayer Graphene layer (Figure 1). Silicon offers a rigid and robust frame, making the handling and sample preparation much more forgiving. Our carriers can be clipped in the standard AutoGrid following the same process and tools as the current grids, but our microfabrication process enables the possibility to produce carriers with the geometry of an assembled AutoGrid, which would help to skip the tedious process of clipping. By meticulously controlling the deposition of silicon nitride on the silicon substrate, we produce a highly reproducible, atomically flat surface. In addition, microfabrication allows precise control material properties such as internal stress that can improve robustness. A large amount of literature reports the advantages of graphene for cryoEM [2-5], ranging from eliminating one air water interface to enabling affinity grids and controlling ice thickness via graphene hydrophilicity treatment. In order to guarantee the scalability of our production, we have developed the processes to introduce graphene on the wafer level, ensuring consistent quality and surface properties for carriers from the same batch.

Initial characterization of the carriers has been performed, with more extensive experimental results expected in the coming months. The first results are very promising. The Graphene coverage, which depends on the hole size, showed a coverage of 66% for 6µm holes, 85% for 3.5µm holes and 96% for 2µm holes. We have confirmed the compatibility of our chips with different vitrification methods (i.e. plunge freezing and jetting). The acquired ice quality results, obtained with an unoptimized protocol using a Vitrobot, indicate amorphous ice of a uniform thickness of approximately 40nm (Figure 2). Several methods for the hydrophilization of graphene have been investigated depending on the users equipment, ranging from O2 & H2 plasma and glow discharge, to annealing and chemical modification of graphene.

We believe that silicon-based sample carriers are the logical next step to enhance and advance the capabilities of cryoEM. Leveraging microfabrication technologies provides us with

unprecedented possibilities to customize the layout/geometry of the chip, allowing us to meet the experiment´s specific requirements precisely.

Understanding phase and chemical transitions in Ge-rich GeSbTe based phase change memory: a (S)TEM tribute

Sijia RAN[1], Minh-Anh LUONG[1], Eloïse RAHIER[1], Elisa PETRONI[2], Daniel BENOIT[3], Alain CLAVERIE[1]
[1]CEMES-CNRS and University of Toulouse, Toulouse, France, [2]STMicroelectronics, Agrate Brianza, Italy, [3]STMicroelectronics, Crolles, France

PS-03 (3), Lecture Theater 2, august 30, 2024, 14:00 - 16:00

Background incl. aims
Phase change memory (PCM) has demonstrated potentials to become the mainstream of the non-volatile memory technique at 28 nm node and below and is promising for applications in future computing hierarchy [1]. The data storage of PCM relies on the reversible phase transition of its active material, which exhibits distinct electrical resistances between crystalline (high conductivity, logic “1”) and amorphous (low conductivity, logic “0”) states.
To meet high-temperature data retention requirements, compositional optimized Ge-rich GeSbTe (GGST) alloys are used by the industry for fabricating PCM for embedded applications [2]. While being the key for the improved thermal stability, GGST alloys undergo chemical phase separation during thermal annealing [3]. The crystallized GGST has been found to be a “composite” material, resulting from the formation of multiple crystalline phases, such as GeTe, Ge, GST-225, and Sb2, at different crystallization stages [4].
In PCM cells, GGST alloys experience different kinds of thermal cycles after deposition. In particular, to allow for the switching between 2 logic states, the GGST layer is locally heated by Joule heating generated by applied current pulses, which provide adequate temperatures either to melt-quench or to crystallize it. Owning to the off-stoichiometry nature of the as-deposited GGST, these heating processes may result in different microstructures and elemental distributions within the cell.
While understanding the evolution of GGST materials is critical for building up the physics behind the functionality of such devices, experimental observations are challenging due to the confinement of the active material to the nanometer scale in integrated PCM. We have thus worked at developing a methodology combining various (scanning) transmission electron microscopy ((S)TEM) techniques to identify grains of different phases that define the cells’ microstructure and the structural and chemical transitions that affect them during electrical programming.
Methods
The studied devices were integrated PCM with a “wall architecture”. The cell consists of a GGST active layer of a few tens of nanometers thick, which is deposited on top of the heater and encapsulated by a metallic top electrode. Extremely thin (<30 nm) TEM lamellas were prepared using focused-ion beam (FIB) from cells after electrical programming. The active region of PCM is a dome which can be amorphous (RESET state, see Fig. a) or crystalline.
TEM samples were characterized by various (S)TEM-based techniques: dark-field (DF) and high-resolution (HR) imaging to access crystallographic information, and high-angle annular dark-field (HAADF) imaging and electron-energy loss spectroscopy (EELS) for chemical mapping. In-situ TEM heating was conducted on cells in RESET state under DF imaging conditions using a furnace-type holder. Results were cross-compared with samples after ex-situ baking.
Results
Fig. b shows a typical (S)TEM analysis of the GGST cell for a region near the heater. The cell was programmed by a forming pulse, which is used to activate the material by melting it followed by slow cooling during which the melt recrystallizes [5]. The STEM HAADF image and associated EELS maps

show chemical segregation near the heater: the material is separated into an outer Ge-rich region surrounding a core made of a Sb-rich (left) and a Te-rich (right) regions. TEM HR images of 2 regions in the core show quite similar crystalline lattices. However, when compared using geometric phase analysis (GPA), the corresponding "strain" map indicates the lattice spacing in the Sb-rich region is ~4% larger than found in the Te-rich region. A clear interface is seen which matches with the boundary evidenced in chemical maps. In the SAED pattern, diffraction spots from 2 sets of slightly different lattices are found and show a good match with rhombohedral Sb (ZA 44$\bar{1}$) and face-center-cubic GST (ZA 111), respectively. By selecting the spot arising from one or the other, DF images of Sb and GST grains can be obtained separately. This demonstrates our ability to identify and distinguish main crystalline phases (Ge, GST, and Sb2) in GGST cells using combined chemical and crystallographic analysis.

Fig. c shows a GGST cell after being programmed by a melt-quench pulse (RESET). An amorphous dome can be evidenced in the BF and DF images. Beyond that, composite "BF & DF" images can be generated by superimposing the BF and several different DF images of either the Ge or the GST phase. A very peculiar characteristic of the polycrystalline region surrounding the dome is evidenced by DF images and the EELS map: Ge crystals preferentially accumulate at the lateral sides of the dome while GST grains are mainly located above it.

The thermal stability of PCM, notably of their RESET state, is a key factor for device reliability. Fig. d shows a GGST cell programmed to the RESET state and subjected to annealing in-situ in the TEM. DF imaging shows a GST crystal located above the amorphous dome. When heating to temperatures at which RESET resistance decreases (250 to 300 ˚C), DF images show that this grain progressively regrows by epitaxy into the amorphous region until it occupies almost the entire dome. EELS maps of the RESET state and after partial-crystallization (by ex-situ annealing) show that while the amorphous dome is initially chemically homogeneous, phase separation is observed after recrystallization (Fig. c and d): Sb segregates inside the crystallized region while the remaining amorphous material becomes more enriched in Ge.

Conclusion

In this work, we have set up a (S)TEM-based methodology to study complicated phase and chemical transitions that occur when programming GGST-based PCM cells. By combining chemical and crystallographic analyses, grain distributions of crystalline phases formed during programming can be revealed. A specific polycrystalline environment, involving two Ge "walls" and a "roof" of GST grains, has been identified. Using in-situ and ex-situ TEM, the thermal recrystallization behavior of the amorphous dome has been revealed: the growth of GST crystals from top of the dome is the mechanism dominating the crystallization. Further chemical analysis has evidenced the phase separation inside the dome, which limits the crystallization process.

Such complete (S)TEM-based analysis provides important experimental results for setting up physical models describing electrical conduction in PCM cells and to guide the process optimization.

Mechanism of WS2 nanotube formation revealed by in-situ/ex-situ imaging and cross-sectional sequences

Dr. Vojtech Kundrat[1,2], Dr. Libor Novak[2], Dr. Kristyna Bukvisova[2,3], Assoc. Prof. Miroslav Kolibal[3], Prof. Reshef Tenne[1]

Poster Group 2

Multiwall WS_2 nanotubes have been synthesized from $W_{18}O_{49}$ nanowhiskers in substantial amounts for over a decade [1]. The established growth model is based on the “surface-inwards” mechanism, whereby the high-temperature reaction with H_2S starts on the nanowhisker surface, and the oxide-to-sulfide conversion progresses inwards until hollow-core multiwall WS_2 nanotubes are obtained [2]. In the present work, an upgraded in-situ SEM µReactor [3] with an H_2S source has been conceived to study the growth mechanism in detail. Ex-situ TEM technique was developed to gain structural insight to the reaction at selected times. Further inspection was done by cross-sectional ex-situ TEM sequences where preselected long $W_{18}O_{49}$ nanowhisker was observed from the (010) direction during the sulfidation reaction as a series of lamellae. Based on these techniques, a hitherto undescribed growth mechanism, named “receding oxide core”, which complements the “surface-inwards” model, is observed and kinetically evaluated. Initially, the nanowhisker is passivated by several WS_2 layers via the surface-inwards reaction. At this point, the diffusion of H_2S through the already existing outer layers becomes exceedingly sluggish, and the surface-inwards reaction is slowed down appreciably. Subsequently, the tungsten suboxide core is anisotropically volatilized within the core close to its tips. The oxide vapors within the core lead to its partial out-diffuse out, partially, forming a cavity that expands with reaction time. Additionally, the oxide vapors react with the internalized H_2S gas, forming fresh WS_2 layers in the cavity of the nascent nanotube. The rate of the receding oxide core mode increases with temperatures above 900 °C. The growth of nanotubes in the atmospheric pressure flow reactor is carried out, as well, showing that the proposed growth model (receding oxide core) is also relevant under regular reaction parameters. The current study comprehensively explains the WS_2 nanotube growth mechanism, combining the known model with contemporary insight.

Data clustering for chemical and structural analysis of nanostructured films

Dr. Giovanni Bertoni[1], Paolo Rosi[1], Gian Carlo Gazzadi[1], Vincenzo Grillo[1], Eleonora Spurio[1], Paola Luches[1], Riccardo Magrin Maffei[1], Stefania Benedetti[1]
[1]CNR - Istituto Nanoscienze, Modena, Italy

Poster Group 2

Background incl. aims
The progresses in data clustering algorithms permit nowadays to perform data analysis relatively fast, nearly on-the-fly. The EELS datasets are suitable 3D data to explore the effectiveness of unsupervised algorithms [1]. The aim is the precise chemical characterization of nanoparticles and thin films, by reducing possible bias from a manual data analysis.

Methods
We present two cases: 1) Spectroscopy (EELS): Cu nanoparticles (NPs) for plasmonic materials [2], 2) Imaging (HRTEM): Al:ZnO thin films (AZO) for new transparent conductive oxides (TCO) based on an amorphous structure [3]. In EELS, we have explored clustering algorithms of machine learning, such has k-means (KM), gaussian mixture models (GMM), and agglomerative clustering (AGC), all supported by principal components analysis (PCA), to explore the classification effectiveness in the latent space of the principal components with the highest variances (a-c). In the first case of Cu NPs, we have followed the formation of an oxide shell (Cu2O or CuO) surrounding a metallic Cu core, which is responsible for the plasmonic behavior and shift of the NPs film, after oxygen treatment in a plasma (d). We have quantified the shell extension and composition from EELS datasets containing O-K and Cu-L_{23} edges from individual NPs. In the second case of AZO films, we quantified the amount of amorphous content in the film, by analyzing a dataset of FFTs patches (~7.5k at 128×128 pixels with 32-pixel step) obtained from single HRTEM images of cross-view AZO (FIB lift-out) grown by RF magnetron sputtering on SiO_2, and by comparison with averaged SAED patterns from plan views (e-g). We have compared a full polycrystalline sample (obtained at 5 mTorr Ar pressure), with one expected to have reduced crystallinity (at 100 mTorr Ar pressure).

Results
With the help of simulated EELS data, have found that at realistic SNR as in the experiments (~1.5 or 3.5 dB in the average spectrum) AGC gives the best results (lowest RMS error) comparable with supervised methods, such as support vector machine (SVM), followed by k-means and GMM (the latter being robust due to the fitted normal probability functions that resembles latent space in an autoencoder). Experimentally, quantified core and shell composition of Cu NPs using clustering, finding progressive Cu(0) oxidation in Cu(I) and then in Cu(II). For the AZO films, we have found a reduction of crystallinity of ~33% from FFTs patches analysis in the sample grown at 100 mTorr Ar pressure.

Conclusion
Principal component analysis and data clustering are relatively fast algorithms to perform data analysis and classification also in electron microscopy and spectroscopy. Together with the recent deep learning algorithms, they may contribute to progressively automate the analysis and experiments, and to reduce biases when different users perform the analyses [4].

Graphic
(a-d) EELS data clustering. a) Synthetic EELS dataset of a Cu core/shell NP on carbon film for data clustering tests. The integrated counts are shown together with the true labels and the results from KM and AGC. b) A single spectrum and the average spectrum from the whole dataset. c) Example of labelling in the latent space of the first 2 PCA components. d) Evolution of metallic Cu NPs grown on SixNy under post-growth oxygen plasma treatment (time in seconds) and followed using data clustering of EELS spectra (insets) and ADF imaging. After an initial Cu(II) shell formation at 30 s, even the core is oxidized to Cu(I) at 60 s, while at 120 s all NPs are oxidized to Cu(II) with only few cores still visible in the ADF image (bright spots).
(e-g) FFTs data clustering. e) HRTEM images from AZO cross-sectional films obtained at different Ar pressures during growth. f) A set of ~7.5k (128×128) FFTs from the HRTEM images were first clustered in 3 classes (insets) and the set of FFTs in the AZO class were analyzed to produce brightness/orientation maps. From the brightness, a reduction of 33% in crystallinity in the 100 mTorr AZO was found. g) Integrated SAED profiles from samples in plan-view, confirming the results from FFTs patch analysis.

In-situ TEM Investigations of the electrical Breakdown of Nanotubes made of Misfit-Layered Compounds

Simon Hettler[1,2], MB Sreedhara[3], Reshef Tenne[4], Raul Arenal[1,2,5]
[1]Instituto de Nanociencia y Materiales de Aragón (INMA), CSIC-Universidad de Zaragoza, Zaragoza, Spain, [2]Laboratorio de Microscopías Avanzadas (LMA), Universidad de Zaragoza, Zaragoza, Spain, [3]Solid State and Structural Chemistry Unit, Indian Institute of Science, Bengaluru, India, [4]Department of Molecular Chemistry and Materials Science, Weizmann Institute of Science, Rehovot, Israel, [5]Araid Foundation, Zaragoza, Spain

Poster Group 2

Background incl. aims
Misfit-layered compounds (MLCs) are complex material systems made up of two different layered materials [1]. The combination of the properties of both layered materials makes MLCs promising for numerous applications, e.g. in thermoelectricity. Due to the inherent asymmetry of MLCs, they tend to bend and form tubular structures. Micro- and nanotubes made of chalcogenide-based MLCs have been synthesized in copious amounts using the chemical vapour technique (CVT), for example for the MLC LaS-TaS_2 [2,3]. Transmission electron microscopy (TEM) characterization is crucial to study the structure and composition of MLC nanotubes in detail. In-situ TEM approaches can shed light on their behavior under external stimuli. Facilitated by the development of a sample preparation technique for electrical characterization by in-situ TEM with minimum damage and contamination [4,5], we studied the dynamic evolution of these MLC nanotubes under extremely high electrical currents.
Methods
Nanotubes made of LaS-TaS_2 were synthesized via the CVT technique [4]. To prepare an in-situ TEM sample for electrical studies, the nanotubes were first dispersed on a holey silicon nitride TEM grid. Suitable nanomaterials were selected in a conventional TEM analysis of the sample. The nanotubes sustained by the silicon nitride were subsequently transferred to an in-situ microchip assisted by focused ion beam (FIB) as described in [5]. Figure (a) shows a SEM image of one of the prepared devices consisting in a pair of MLC nanotubes. Using an in-situ sample holder (DENSsolutions Wildfire), the specimens were analyzed under the application of external heat and electrical currents in two aberration-corrected Titan microscopes (Thermo Fisher Scientific).
Results
Little changes in the nanotube specimens were observed when heating with an on-chip heating device and also for lower electrical currents. Only the application of considerable electrical currents, larger than 100 µA, led to structural modifications within the material. Electrical currents were applied as current ramps up to a maximum applied current followed by an abrupt stop of the current. During the ramps, the nanotubes are heated up smoothly to high temperatures followed by a rapid quenching to room temperature when the current was turned off. This rapid cooling led to fractures of the material, as seen exemplary in Figure (b), where two different breaking points for the inner and the outer part of the nanotube are observed. Already before the fracture, the LaS-TaS_2 MLC material starts to decompose and metallic tantalum is extracted, leaving La_2S_3 behind (Figure (c)). The investigations allow a detailed study of the chemical decomposition routes under extreme electrical currents. A clear difference between pure thermal annealing and electromigration is observed.
Conclusion

The conducted experiments allow an in-depth dynamical study of the behavior of micro- and nano-sized objects under high electrical currents. For example, for the investigated LaS-TaS_2 nanotubes, the TaS_2 first gets unstable and metallic Ta is extracted while released sulfur reacts with LaS to form La_2S_3. By specifically designing both the device geometry and the form of the applied electrical current, different chemical and physical processes can be studied at highest spatial resolution provided by the in-situ TEM approach.

Optimising a modern high performance FE-SEM for multimodal vEM

Dr Eudri Venter[1], Dr. Sonja Gürster[2]
[1]JEOL UK, Welwyn Garden City, United Kingdom, [2]JEOL (Germany) GmbH, Freising, Deutschland

Poster Group 1

The popularity of volume Electron Microscopy (vEM) has ballooned over the recent past. Noteworthy examples of the increased attention being paid to vEM include: large-scale funding investment initiatives (such as the Chan Zuckerberg Initiative's Imaging program(1)), influential opinion pieces in scientific journals (Seven technologies to watch in 2023 – Nature volume 613(2)) and the growing user base of informative community-run websites and discussion channels (such as the Volume EM community website(3), the Array Tomography community website(4), or the EMofCellsTissuesOrganisms Slack channel(5). One of the main advantages of the increased interest in vEM is the abundance of information to allow prospective vEM users to choose the workflow and methodology that best suits their needs, optimise their experimental approaches and interact with a rapidly expanding user base.

vEM can be accomplished in scanning electron microscopes (SEM), transmission electron microscopes (TEM) or with focused ion beam/ dual beam SEMs (FIB-SEM). This talk will focus on the two main techniques for vEM within a SEM; namely array tomography (AT) and serial block-face SEM (SBF-SEM). Each of these techniques has their own unique pros and cons in terms of the sample preparation requirements, achievable voxel resolution, and re-usability of sample material. Historically, one of the main drawbacks of vEM was that the requisite hardware often limited prospective vEM users to a single instrument choice, or worse yet, to a single vEM technique. Modern advances in hardware and software allows JEOL the ability to offer bespoke solutions for vEM workflows; whether the requirement is to choose a microscope best suited to the scientific questions, the flexibility to have access to both array tomography and serial block-face SEM within a single instrument, or both. The unique software and hardware advances, which allows multimodal vEM to be achieved, will be discussed in this talk.

Recent developments in FE gun and SEM column design makes it easy to optimize imaging conditions such as accelerating voltage, probe current, column mode and implementing beam deceleration. Hardware advances to allow this ease-of-use include an in-lens Schottky Plus FEG which integrates the electron gun with a low-aberration condenser lens improving brightness and reducing beam diameter, and an aperture angle control lens (ACL) (located beneath the condenser lens), that continuously suppresses the spread of the incident electrons maintaining the smallest possible probe size even when the probe current is increased.

Other hardware advances include the improved probe-forming capability of a field-free hybrid electromagnetic and electrostatic lens effect along with advancements in column optics for automated control and adjustment of the electron lenses and correction of electron trajectories in real time. Together these allow one to achieve optimized resolution under all imaging conditions. Another key to high quality data acquisition is a new scintillator-type back-scattered detector that is optimised for low kV imaging and allows high-resolution images to be acquired at fast speeds, perfect for the challenges faced by vEM sample preparation.

Transitioning our FEG-SEM from normal imaging mode to SBF-SEM mode is very straightforward through partnership with ConnectomX. All that is required is to vent the chamber, attach the stage-mounted Katana microtome, and pump down again; a process that can be done in just a few minutes. Capturing high quality 3D data has never been easier (Figure 1).

In addition to hardware advances, the evolution of software streamlines and simplifies automated data acquisition. For both AT and SBF-SEM experiments on JEOL microscopes, all of the hardware control (both microscope and microtome if in use), experiment setup and data acquisition is controlld through SEM Supporter software. Similar guided workflows exist for both techniques, which makes transitioning between the techniques straightforward. For example, the AT workflow complexity is easily condensed into three steps. First a low magnification montage is captured over the entire sample set. Then predictive ROI positioning is used to propagate the ROI over all serial sections. Finally image cross correlation is used to control image shift and scan rotation to keep the successive ROIs well aligned.
Following data acquisition significant advances have also been made to offer software solutions for image alignment, rendering and segmentation, to round out the solution for the whole vEM workflow.
In conclusion, JEOL offers bespoke solutions for different vEM applications, within a single SEM. Optimized solutions for all the steps in the vEM workflow – from high quality data collection, to easy to set up workflows, to intuitive and straightforward means for data processing and analyses, allow vEM to be within reach for researchers of any experience level.

TEM and photocurrent response of FE BTO thin films heterostructure on silicon for Neuromorphic applications

Myriam H. Aguirre[1,2,3], Miguel Rengifo[2], Diego Rubi[4]
[1]Departamento de Física de la Materia Condensada, Universidad de Zaragoza, Zaragoza, Spain, [2]INMA-Instituto de Nanociencia y Materiales de Aragón, Universidad de Zaragoza-CSIC, Zaragoza, Spain, [3]Laboratorio de Microscopías Avanzada, Universidad de Zaragoza, Zaragoza, Spain, [4]Instituto de Nanociencia y Nanotecnología (INN), Comisión Nacional de Energía Atómica-Consejo Nacional de Investigaciones Científicas y Técnicas (CNEA-CONICET), Buenos Aires, Argentina

Poster Group 2

Ferroelectric systems continue to be of great interest in applications related to photonics and neuromorphic systems [1][2] due to their memristive properties [3]. The rapid polarization response to electrical stress and the large miniaturization capacity of a few nanometers make them ideal candidates for the development of storage devices, processing and sensors.
In this work we successful obtained thin epitaxial films of $BaTiO3$ (BTO) on silicon (Si), by means of Pulse Laser Deposition (PLD). Yttria-stabilised zirconia (YSZ), CeO_2 and a very thin layer of $La0.5Ca0.5MnO_3$ ($LCMO$) were used as buffer-layers. Reflection High-Energy Electron Diffraction (RHEED) confirmed the epitaxial nature of the heterostructure. X-ray diffraction (XRD) measurements showed the unique presence of index peaks (00l) for all layers, indicating the high crystalline quality of the heterostructure. Scanning Transmission Electron Microscopy with High Angular Annular Dark Field images (STEM-HAADF) were used to identify and characterize the continuous thin layer of LCMO at ~2.5nm. Ferroelectricity measurements using the PUND method show a large remaining polarization of ~13$\mu C/cm^2$ and a coercive field of ±700 kV/cm, much higher than other similar systems and obtained at lower temperatures [4]. This large remaining polarization is attributed to the thin layer of lower $LCMO$ that generate negative stresses in the BTO layer increasing its tetragonal character.
Photocurrent measurements with 403 nm light, show a large photocurrent response of ~ 15 $\mu A/cm^2$ with small voltage values. These values are also considerably large compared to other reports [5]. The generation of load carriers due to light, modifies the barrier heights at the $LCMO/BTO$ and BTO/Pt interfaces and the photocurrent levels were also highly dependent on the bias voltage level. The large polarization and coercive field values obtained are attributed to the low leakage currents and high resistance of the $LCMO$ layer due to its low thickness. These features make this heterostructure a very robust system, with the ability to tolerate high field values with barely lost ferroelectric properties and high levels of electrical stress. Its excellent photocurrent response also contributed to its high intrinsic properties as a UV detector/sensor. All the above features make it a very good candidate for exploration of properties in neuromorphic systems.

Scanning electron diffraction reveals the molecular ordering of polysaccharides at the nanoscale

Mr. Mathias Nero[1], Dr. Tom Willhammar[1]
[1]Stockholm University, Stockholm, Sweden

PS-07 (2), Plenary, august 30, 2024, 10:30 - 12:30

Background

Cellulose is the most abundant biopolymer. Nature links glucan units to form polysaccharide chains which are organized in an intricate network of hydrogen bonds into crystalline cellulose fibers. These fibers are assembled into hierarchical structures that constitute the secondary cell wall of plants, forming the basis for their mechanical properties. The macroscopic attributes of these materials are determined by chemical interactions and mesoscopic organization spanning from the atomic scale to the macroscopic level. Understanding these assemblies is vital for grasping the properties of biological materials and for exploring ways to incorporate these naturally occurring components into hybrid materials.

Biopolymers are fundamentally challenging to study using electron microscopy due to their delicate and electron beam sensitive nature. Using scanning electron diffraction we can obtain unique nanoscale information about the molecular ordering of the polysaccharide chains, which can be used to understand e.g. their superior mechanical properties.

Methods

The strong interaction between an electron probe and matter enables the acquisition of scattering data from nanometer-sized volumes even from weakly scattering elements. Electron diffraction has proven to be an invaluable tool for the structural examination of a diverse range of nanomaterials. Scanning electron diffraction (SED) offers detailed maps that reveal the crystalline ordering at the nanometer scale, shedding light on the arrangement of polysaccharide chains within individual nanofibers and also their hierarchical assemblies in composite materials.

In this study, we are using a quasi-parallel electron beam, with a convergence angle of 0.1 mrad. The beam is scanned across the specimen to obtain a map containing information about the molecular scale ordering of the biomaterial. The high speed and sensitivity of hybrid detectors enable the acquisition of electron diffraction data from single cellulose nanofibers.

Results

Cellulose nanofibers (CNFs) can be extracted from various origins and stand out as a promising, sustainable building block with remarkable mechanical properties. Using SED data, the crystalline nanostructure within individual CNFs can be analyzed, offering insights into how the crystalline ordering persists. Data was obtained from twisted sections of the nanofibers and reveals that despite the strain this twisting introduces the crystalline structure remains intact.[1] Furthermore, SED data can be employed to investigate the hierarchical organization of cellulose fibrils within the plant cell walls as well as hybrid materials based on wood. One prominent example of this a composite mateial made from delignified and polymer-impregnated wood, the so-called transparent wood. SED data obtained from this material revealed the organization of cellulose fibrils into hierarchical helical structures across the various cell wall layers.[2] In most of the cell wall the cellulose fibers were organized along the extended dimension of the cells and towards the outermost part of the wall the fiber orientation gradually changed to a tangential orientation.

Conclusion
Using scanning electron diffraction we can for the first time reveal the molecular ordering of cellulose chains in twisting cellulose nanofibers as well as shed light on the mesoscale hierarchical ordering of cellulose fibers in hybrid materials and cell structures with nanometer resolution.

Two-photon line-scanning structured illumination microscopy (LIL-SIM) for super-resolution imaging in deep tissue

Patrick Byers[1,2], M.Sc. Thomas Kellerer[1], Prof. Dr. Thomas Huser[2], Prof. Dr. Thomas Hellerer[1]
[1]Multiphoton Imaging Lab, Munich University of Applied Sciences, Munich, Germany, [2]Biomolecular Photonics, Department of Physics, University of Bielefeld, Bielefeld, Germany

LS-03 (2), Lecture Theater 4, august 27, 2024, 10:30 - 12:30

Background incl. aims
In the field of cellular imaging, the demand for sub-cellular resolution and three-dimensional (3D) visualization of biological specimens has been a driving force behind the development of various microscopy techniques. This study explores a novel approach of combining structured illumination microscopy (SIM)1,2 and two-photon line scanning (2P-LS) microscopy to provide super-resolution imaging in thick biological tissue. We apply our method, named LIL-SIM, to cardiovascular artery tissue and tree trunk to demonstrate the penetration capability of our imaging system.

Methods
Structured Illumination Microscopy (SIM) is a well-established super-resolution method, breaking the diffraction limit by introducing a spatially modulated light pattern to the sample. However, SIM's performance traditionally decreases in highly scattering media typical of biological tissues. Conversely, Two-photon (2P) microscopy provides exceptional depth penetration due to its employment of near-infrared light, reducing scattering, and targeting excitation to the focal volume, thus limiting photodamage. Despite the advantages gained by combining 2P microscopy and SIM, the necessity for camera-based detection lowers the modulation contrast of the pattern in thick biological specimens and reduces the signal to background ratio (SBR) of the acquired SIM patterns. This leads to artefacts in the reconstructed images due to insufficient modulation contrast of the generated patterns. Interestingly, the SBR can be increased by confocalization of the emitted fluorescence emission, restricting out of focus contributions of scattered photons. This leads to increased SBR and high modulation depth of the generated SIM patterns in thick biological tissue, enabling volumetric super-resolution imaging.

Results
We validate the super-resolution capability of our microscope by imaging tissue samples composed of pine wood and tree trunk, with z-depths of around 40 µm. For all experiments, we generated SIM patterns with five phase shifts to acquire homogeneous illumination of the sample and three rotation angles for an isotropic resolution enhancement. This amounts to a total of 15 acquired images for one SIM frame. Averaging of the 15 acquired frames leads to a homogeneously illuminated intensity distribution, which we refer to as the 2P widefield image in the following. As seen in Fig. 1a), LIL-SIM increases the resolution compared to diffraction limited 2P widefield imaging while simultaneously obtaining better optical sectioning by line confocalization. The 2P widefield image is blurred by the contribution of excited fluorophores close to the focal plane due to scattering. By the application of LIL-SIM and following computation of the acquired images with fairSIM3 , the resolution is effectively doubled. LIL-SIM insets 1c) and e) show clear resolution improvement of nanostructures over the acquired 2P widefield structures 1b) and d). The line plot comparison in Fig. 1f) shows a FWHM distance of 384 nm in the 2P widefield image and 150 nm for 2P-LS-SIM.

Conclusion
Our results demonstrate that the fusion of SIM and 2P-LS microscopy leads to an imaging modality capable of resolving structures down to 150 nm in thick biological specimens. We provide data analyzing imaging parameters, e.g. penetration depth, modulation depth of the illumination grating and phase stability of the illumination patterns and present reconstructed super-resolution images of thick tissue samples, e.g. cardiovascular artery and pine trunk.

Fig. 1 a) 2P widefield and LIL-SIM comparison. b-e) insets and f) line graph demonstrate resolution improvement. g-h) 2P widefield and LIL-SIM with increasing z-depth (10, 20 and 30 µm). Scale bars a) 10 µm, b) 2 µm, g) 5 µm.

Study of nuclear materials for silicon carbide composite fuel claddings via STEM, EDX and EELS

Phd Student Hector Guerra Yanez[1], PhD Student Andrea Stinchelli[2,3], Doctor Fabio Di Fonzo[3], Professor Per O.Å. Persson[1]
[1]Department of Physics, Chemistry and Biology, University of Linköping, Linköping, Sweden, [2]Department of Energy, Politecnico di Milano, Milan, Italy, [3]X-nano s.r.l., Milan, Italy

PS-12, Lecture Theater 2, august 29, 2024, 10:30 - 12:30

Background incl. aims
Silicon carbide composites (SiC/SiC) are promising materials for fuel claddings in light-water reactors as their thermal, chemical and mechanical stability extend to very high temperatures, granting longer coping time in case of a loss-of-coolant accident. These materials would potentially allow to claim a power plant back even after many hours without active cooling of the core [1,2]. Despite their excellent performance under accidental conditions, during normal operating conditions, SiC/SiC composites are oxidized by the cooling water, forming silica (SiO_2). To prevent this, the application of a protective coating over the cladding is proposed. In this study, yttrium aluminum garnet (YAG) and chromium-doped yttrium oxide (Cr:Y_2O_3), deposited with pulsed laser deposition (PLD), were studied by scanning transmission electron microscopy (STEM). The coatings were observed before and after thermal treatment at temperatures resembling severe loss-of-coolant accidents.
Methods
Four samples were studied: 1) pristine YAG deposited on a silicon substrate; 2) YAG deposited on a stainless steel substrate that was annealed in air after deposition at 900 °C for 1 hour; 3) pristine Cr:Y_2O_3 deposited on a silicon substrate; and finally 4) Y_2O_3 with the same amount of Cr_2O_3 deposited on a zircalloy substrate and annealed at 1300 °C for 1 hour.
Electron-transparent samples for STEM were prepared by traditional low-angle Ar ion milling and by focused ion beam (FIB). The microstructure was investigated in the Linköping double corrected, monochromated FEI Titan3 60-300, operated at 300 kV. Energy dispersive x-ray spectroscopy (EDX) and electron energy loss spectroscopy (EELS) were employed to identify elements and density variations in the samples.
Results
STEM imaging of the samples shows that sample 1) is amorphous, however, apparent layering with an approximate period of 20 nm was observed in the sample. EELS spectrum imaging was performed to discern if the layering occurred as a consequence of elemental inhomogeneities or because of density variations within the coating, confirming the former. After annealing, the YAG assumed a crystalline nature with ~1 µm equiaxed grains (sample 2). The grain boundaries accommodate large voids and the original layers were removed, as can be observed in the graphic. The presence of these grain boundaries decorated by voids suggests that this material may not function as a diffusion barrier for water.
Sample 3) displays a predominantly amorphous structure, although crystalline nanoparticles are randomly distributed in the amorphous matrix. After annealing (sample 4), this coating presents different microstructures near the substrate and near the surface. The film has crystallized, and near the substrate, the film exhibits a dense structure. In contrast, the surface near region also exhibits a crystalline nature, although the grain boundaries appear to be porous and disordered. The origin of this presumably owes to chromium oxide segregating at the grain boundaries and evaporating during

the annealing process, leaving underdense boundaries behind that become swift routes for further chromium diffusion.
This is supported by the concentration of chromium, which is notably higher in the region near the substrate compared to near the surface, as measured by EDX. The interface between the two different microstructures shows apparent particles of segregated chromium. These presumably originate from migrating chromium that condenses into nanoparticles during the rapid cooldown. The gradual migration of chromium that occurs during annealing in the Cr:Y_2O_3 can help protect the integrity, or delay catastrophic failure, of the system as the inner phase maintains a diffusion barrier and effectively protects the fuel cladding.
Conclusion
This study shows that Cr:Y_2O_3 is a valid alternative material as a coating for SiC/SiC composites. This can be affirmed since the material acquires a microstructure that is gradually consumed during high-temperature processing.

Background incl. aims
The composition of organic matter (OM) in meteorites such as carbonaceous chondrites is a useful indicator for the type of organic matter present on early, prebiotic earth [1]. This OM can be extracted with solvents and analysed with mass spectrometers, but these techniques lose local petrographic context, and the sometimes harsh chemical processes involved in the extraction have the potentially to unintentionally alter the detailed functional chemistry of the OM. Here, careful preparation of thin lamellas using focused ion beam (FIB) techniques, and correlative analysis by high-resolution electron energy loss spectroscopy (EELS) and scanning transmission x-ray microscopy (STXM) of the very same samples, allow for a detailed OM characterization at the nanoscale [2] within the OM's native petrographic context and with minimal alteration.

Methods
Using a Hitachi Ethos NX5000 triple-beam FIB system, several lamellas were prepared containing OM from the meteorite Winchcombe, with special care taken to minimize the impact from sample preparation and enable the study of minimally altered OM. Steps taken to minimize alteration include minimizing the use of protection layers where possible to avoid carbon contamination, backside milling to ensure FIB-deposited material is downstream of the thinned area, and rocking milling to improve uniformity. Where FIB deposition was necessary, metal-containing deposits only (Pt, W) were used, ensuring that any redeposition could be easily identified. Most lamellas were thinned to ≤ 40 nm, a thickness optimised both for sufficient EELS signal at low kV as well as for complementary STXM analysis of the same lamella. To minimize surface damage, crucial for thin samples, Ga+ milling was followed by 1 kV Ar+ polishing using the 'third beam' of the NX5000. Careful, targeted broad-beam low-energy Ar+ polishing, with repeated short exposures and multiple incident angles proved highly effective at reducing surface amorphization and Ga-implantation-related damage. The application of Ar+ polishing directly in the FIB offers here an additional degree of control during the final thinning procedure while minimizing sample handling, thus further lowering any risk of alteration to the OM. SEM imaging of thin areas was also limited and performed at low beam energies to mitigate electron beam alteration of the OM.

Monochromated EELS was carried out at 60 kV in a Nion UltraSTEM100MC-Hermes equipped with a Nion IRIS spectrometer and a DECTRIS ELA direct electron detector. With the samples in ultra-high vacuum, a probe size of 0.1 nm with low beam current of < 5pA, together with an energy resolution of 50-90 meV, makes it possible to distinguish local variations in the different bonds in carbon- and nitrogen-containing OM. Both nanoglobules (~ 300 nm) and 'diffuse' carbon infiltrated into the phyllosilicate matrix (< 100 nm) were analysed. Complementary X-ray absorption near-edge structure (XANES) analysis in the STXM was carried out at the 108 beam-line of Diamond Light Source, UK with a nominal beam size of ~ 40 nm and energy step sizes of 0.1 to 0.5 eV. Where possible, both XANES and EELS were carried out on the same lamella, allowing for direct comparison and highlighting the complementarity of these related techniques.

Results

Both STXM-XANES and STEM-EELS reveal distinctive C K absorption bands at 285 and 286.5 eV across all lamellas, relating to aromatic carbon and aromatic ketone/aldehyde bonds. The superior spatial resolution of the STEM probe highlights local variations in the 285 eV aromaticity-linked peak, with a generally higher ratio of aromatic/aliphatic content compared to CM chondrites, indicative of higher alteration. The low noise of direct electron detector-based EELS also enables probing the functional chemistry of the less abundant nitrogen (atomic N/C ratios of only a few %). N K distinct bands are at 398.8 eV and 399.8 eV, associated with C-N double and triple bonds, respectively. Applying statistical denoising methods enables the detection of energy bands beyond those distinguishable in the STXM data, pointing to the presence in nanoscale areas of amino acids such as L-alanine, which had been previously detected by soluble OM studies [3]. Here, the variation of this 402-403 eV fine structure at small length scales, together with the care taken to provide as unaltered a view of the OM as possible within its petrographic context, suggest these functional groups can be linked unambiguously to fluid processes within the OM.

Conclusion

The combination of STXM-XANES and high-resolution STEM-EELS on carefully prepared, minimally altered FIB lamellas allows for the analysis of OM at the smallest length scales. Different nanoscale textures such as nanoglobules and diffuse OM can be distinguished and compared to learn about the evolution and alteration mechanics of organics in carbonaceous chondrites. The direct correlation and excellent match between STXM and 60 kV STEM-EELS results demonstrate how this approach provides a powerful characterization tool for complex extraterrestrial samples with a unique combination of high spatial and energy resolutions.

Figure: (a) scanning electron micrograph of an extracted FIB lamella. The top is thinned to electron transparency and exhibits both a bigger irregular OM grain and smaller patches of OM. (b-c) STEM-EELS + STXM data of the C-K and N-K edges. EELS – 1 and 2 correspond to regions indicated in (a). Subtle changes in the EELS spectrum can be observed for OM areas, even in close proximity.

Elucidation of Structure-catalytic Activity of Nickel-based Nanomaterial for Electrocatalytic Water Splitting

Dr. Jean Marie Vianney Nsanzimana[1], Charles Otieno Ogolla[1], Max Kasper[1], Prof. Manuela Killian[2], Prof. Butz Benjamin[1]
[1]Micro- and Nanoanalytics Group, University of Siegen, Siegen, Germany, [2]Chemistry and Structures of Novel Materials, University of Siegen, Siegen, Germany

Poster Group 2

Background

The lack of satisfactory and cheaper catalysts for hydrogen production by electrocatalytic water splitting and hydrogen utilization in fuel cells is the major challenge for this clean energy technology [1]. New advanced nanostructured materials with special properties for green H2 production by water splitting are needed to address this major and urgent challenge [2]. Nanostructured materials have shown promising catalytic performance that exceeds the sum of their individual components [3-4]. Thus, they contribute to the development of industrially applicable and sustainable materials for new alternative clean electrochemical energy technologies. For the discovery of novel advanced energy materials that meet the requirements of emerging clean electrochemical energy technologies, advanced tools for the elucidation of structural (electro)catalytic activity are at the heart of future and sustainable nanomaterial development. These advanced materials require advanced scale-bridge spectroscopic technics characterization to understand the chemistry and the elemental species of nanostructured materials at the nanoscale. We have developed a rational design of easily scalable nickel boride (NixB)-derived catalyst to correlate with optimized catalytic activity through metal elements incorporation in a one-pot synthesis method. Our method overcomes the challenge of conventional annealing-dependent processes which have limited applicability on a large scale since they also require an inert processing environment. Furthermore, we elucidate a structure-activity relationship by utilizing scale-bridging correlative microscopy techniques leveraging transmission electron microscopy coupled with electrochemical characterization.

Methods

To elucidate the structure-electrocatalytic activity functionality of these nanostructures, we conducted a thorough electrochemical and TEM investigation on binary nickel boride and quaternary nickel boride-derived catalysts.

Results & Conclusion

A one-pot synthesis method enabled a rational design of non-noble metal, highly efficient, and durable electrocatalysts for hydrogen production at low-temperature electrolysis in harsh alkaline solutions. This improved catalytic performance is further corroborated by microstructural investigations using TEM. The nanoparticles obtained have an improved porous structure compared to conventionally synthesized NixB (Figure 1), providing more available sites for surface reactions and catalytic performance of this nanostructured material. Furthermore, we demonstrate that activation enables morphological and structural changes, while some transition metal elements act as sacrificial elements to provide more accessible and stable sites for oxygen-forming centers. This paves the way for a better understanding of metal boride-derived electrocatalysts for electrocatalytic water splitting

and contributes to future discoveries of non-noble metal catalysts, yet with highly efficient and stable nanostructured materials.

Assessing the Accuracy of Strain Mapping using 4D-STEM

Petr Vacek[1], Paul Midgley[1]
[1]Department of Materials Science and Metallurgy, University of Cambridge, 27 Charles Babbage Road, Cambridge, United Kingdom

Poster Group 2

Background
With the advent of sensitive direct electron detectors, coupled with ever-greater computational power, 4D-STEM has grown rapidly in popularity [1,2]. In particular, scanning electron diffraction (SED), a variant of 4D-STEM, is based on acquiring a set of diffraction patterns with low convergence (near-parallel) probes for each scan position such that subsequent computational data processing can retrieve nanoscale information regarding phase identification, crystallographic orientation, internal electric and magnetic fields and strains. This work assesses the impact of different acquisition conditions to identify optimal imaging conditions for 2D strain mapping.

Methods
A simulated strain distribution (quantum well phantom with an (unstrained) primitive unit cell of 5Å) that included areas with uniaxial and biaxial normal strain, shear strain, lattice rotation, and their combination, was used to generate a SED dataset for strain mapping. The simulated diffraction patterns, 'recorded' on detectors with four different pixel sizes, were generated using the kinematical diffraction module in Py4DSTEM python library [3], and a custom plotting code based on the pyxem python library [4]. The maximum extent of the simulated diffraction pattern on each detector (with the origin at the detector centre) is +/- 1.25 Å-1. Kinematical simulations can be justified here because strain mapping often uses precession electron diffraction, providing integrated 'near-kinematical' intensities and, importantly, integrates over any contrast seen within the diffraction disk ('rocking curve' contrast); such contrast is known to have a deleterious impact on the accuracy of strain mapping [5]. Noise is added to the diffraction data accounting for the statistical nature of electron arrival and to account for a background noise that represents readout noise of the detector. Strain analysis was performed on the SED dataset using both cross-correlation (CC) and centre-of-mass (COM) algorithms and the results compared with the strain phantom (ground truth) to assess the effect of each parameter on the accuracy of strain mapping. A diagram of the workflow is illustrated in Figure 1(a).

Results
The effect of number of detector pixels, signal to noise ratio (SNR), order of reflection / magnitude of g-vector, and probe convergence was investigated. In general, as expected, the higher the number of detector pixels, the higher the strain mapping accuracy. This is illustrated in Figure 1(b), where we see a significant improvement in the sum of squares of errors in strain mapping between 128 and 256 detector pixels, while increasing the number of pixels still further is beneficial, in the case studied it has diminishing returns. Increasing the order of the reflection, and thus increasing the g-vector magnitude will, in general lead to a lower SNR for each disc. For strain mapping it is intuitively the case that we would wish to use reflections with high SNR and large g-vector magnitudes (reflections of high order). However, lower order reflections tend to have higher SNR and therefore it is important to find a balance between SNR and g-vector magnitudes. The effect of beam convergence depends on which peak-finding algorithm is used. It is advantageous to use COM algorithms for

probes with low convergence, where it is difficult to fit the peak position due to the lack of pixels to accurately represent a circle. CC works best for higher convergence angles where the pixelation of the detector does not affect the fitting precision. CC also requires lower SNR to work precisely compared to the COM algorithm. The optimised conditions taken from the simulation were used to acquire an experimental strain mapping dataset of SiGe quantum wells in a MAG*I*CAL sample using CMOS camera (ThermoFisher Ceta) and hybrid pixel direct electron camera (Quantum Detectors Merlin) to evaluate the findings from the simulations in an experimental setting, see Figure 1(c).

Conclusions
We have assessed the accuracy of strain mapping using SED, a 4D-STEM variant, by considering key parameters such as the number of detector pixels and the SNR of the reflection used for strain mapping. A clear optimum is found that balances the SNR and g-vector magnitude for a strain phantom. We find it is advantageous to use a centre of mass algorithm for low convergence probes and a cross correlation algorithm for larger convergence probes. Using these findings we were able to reconstruct a high fidelity experimental strain map from a SiGe quantum well data set. The authors thank the EPSRC for funding under grant numbers EP/V007785/1, and EP/R008779/1.

Cryogenic electron microscopy for native state analysis of soft- and nano-materials

Dario Luis Fernandez Ainaga[1], Teresa Roncal-Herrero[1], Martha Ilett[1], Stuart Micklethwaite[1], Zabeada Aslam[1], Eleena Naveed[1], James Hitchcock[1], Cheng Cheng[1], Benjamin Lobel[1], Olivier Cayre[1], Dr Nicole Hondow[1]
[1]University of Leeds, Leeds, UK

PS-07 (2), Plenary, august 30, 2024, 10:30 - 12:30

Background
Nanomaterials can potentially be used in a range of areas, including in consumer goods through to medical applications. In many areas, the nanomaterials are used while dispersed in a liquid, or contain hard-soft interfaces, which, while increasing their applicability to their end-use, can complicate characterisation and determination of structure-property relationships.
Electron microscopy, while ideally suited to the nanoscale imaging and analysis of these materials, can encounter limitations due to the vacuum requirements, which exclude many in situ or native state studies. In addition, necessary sample preparation can often lead to artefacts. A viable alternative is electron microscopy conducted on frozen hydrated samples, where the nanomaterials are 'captured' in the native state and any electron beam induced damage products are immobilised. This work aims to develop representative native state analysis of dispersed nanoparticles in soft materials using cryogenic electron microscopy approaches, with application shown here to a commercial sunblock sample containing metal oxide nanoparticles and Pickering emulsions (water-oil mixtures) designed to contain an active ingredient.

Methods
Results from two soft materials containing dispersed nanoparticles will be detailed. The first sample is a Pickering emulsion, comprised of oil in water droplets stabilised by ~5 nm platinum nanoparticles. The approaches are further developed by examining a commercial product, a sunscreen containing active ingredients of 4.5% of TiO_2 and 6.5% of ZnO nanoparticles.
All samples were prepared for cryo-TEM using an FEI Mark IV Vitrobot©. A 3.5 µl drop of suspension was loaded onto a lacey carbon-coated copper TEM grid (EM resolutions) before being blotted and then rapidly plunge frozen in liquid ethane. Transfer into the microscope was done using a Gatan-914 cryo TEM holder, and the temperature was maintained below −165 °C during analysis. Comparison was made to a static liquid cell (LC) commercially sold as a K-kit and supplied by Bio-Matek. S/TEM analysis was carried out using an FEI Titan3 Themis G2 equipped with a monochromator operating at 300 kV and fitted with 4 EDX silicon drift detectors and a Gatan One-View CMOS camera. The probe current was kept below 100 pA for all cryo and LC experiments. Samples were prepared for cryo-SEM using a Quorum Technologies PP3010 Cryo-SEM preparation system and examined in an FEI Helios G4 CX Dual beam FIB-SEM with a beam voltage of 1–10 kV and beam current 100 pA, while elemental mapping via an Oxford instruments EDX spectroscopy system was conducted at 15 kV.

Results
We have previously shown the advantage of cryogenic-EM approaches to the analysis of dispersed nanoparticles, including those in complex biological cell culture [1,2]. In this work we will show the advantages of using a cryogenic approach for more complex soft materials systems incorporating nanoparticles, with extension to the use of cryo-STEM-tomography and cryo-FIB-SEM.

Cryo preparation, transfer and analysis is essential for Pickering emulsions as the integrity of the sample is maintained as drying and the microscope vacuum results in bursting of the droplets. Undertaking higher magnification imaging with careful consideration of total electron fluence it is possible to examine the distribution of the nanoparticles using cryo-STEM [3], and we will show that utilising cryo-HAADF STEM over a ±60° tilt range permits 3D visualisation of the sample structure. This results in the confirmation of both the position of the stabilising nanoparticles and the overall droplet shape in 3D space. Using a combination of cryo-EDX and -EELS the elements in both the nanoparticles and oil droplets are confirmed.
Cryo-STEM and associated spectroscopies are also used to analyse the commercial sunscreen, with comparison to alternative in situ electron microscopy techniques – static liquid cell STEM and cryo-SEM [4]. While cryo-STEM does allow for higher resolution analysis, in this case both the concentration of dispersed particles and viscosity of the product causes complications with sample preparation. In analysis of a diluted product, both nanoparticle types are identified, something which was not possible in the static liquid cell due to electron beam artefacts causing dissolution of one nanoparticle type. Cryo-SEM was used to analyse the pure product without dilution but biased the characterisation to the larger fraction of nanoparticles and agglomerates.

Conclusions
Cryo electron microscopy offers route to the representative native state analysis of dispersed nanoparticles in soft materials. Complex systems, such as the soft hybrid inorganic-organic Pickering emulsions can be analysed by a combination of STEM-analytical techniques to provide nanoscale 3D information. Commercial products, with numerous components and required to be used at a set concentration can be more complicated, however with a combination of different in situ EM techniques an accurate, native state characterisation can be achieved.

PS-05 (2), Lecture Theater 1, august 28, 2024, 14:00 - 16:00

Background incl. aims
Chronic wounds are a healthcare problem both for patients and for society. They are often contaminated with bacteria, and the infection impacts the healing of the wounds. Therefore, a tremendous effort has been made to develop wound dressings supporting wound healing and preventing or even eliminating bacterial infection. Due to increasing bacterial resistance to antibiotics, other research approaches are used [1]. The aim of this study was to prepare polyvinyl alcohol (PVA)/polyethylene glycol (PEG) – based wound dressing doped with gold nanoparticles, to analyze their physical and chemical properties, cytocompatibility, and antibacterial properties.
Methods
Sputtering of Au for nanoparticle preparation was carried out at 20 °C by the sputter coater device SCD 050 (Baltec, argon pressure of 8 Pa), with the current of 30 mA, sputtering time of 500 s, and the electrode distance of 50 mm. Immediately after deposition of the metal nanoparticles into PEG (polyethylene glycol, Mw 600), the mixture was diluted with 18 mL of distilled water. The ratio of PEG/H2O in this case was 1:9. PVA-based nanofibrous materials were prepared by DC electrospinning. Solution of nanoparticles (AuNPs) was added into a 10 % PVA solution; the ratio of PVA:PEG was 9:1 or 6:4. Electrospinning was carried out on a needleless electrospinning device NS 1WS500U (Elmarco, CZ) using high voltage on electrodes 40 and 10 kV. The temperature was set to 21 °C and the relative humidity was of 21 %. Some of the samples underwent heat treatment (HT) at 150 °C for 1 h. The presence, size and homogeneity of the AuNPs in nanofibers was proven by JEOL JSM-IT800 scanning electron microscope by the analyses of backscattered electrons. The theoretical Au concentration was 111 and 666 µg/g for 9:1 and 6:4 PVA:PEG ratio, respectively. The nanofibers were analyzed by energy dispersive spectroscopy, atomic force microscopy, scanning electron microscopy (VEGA Easy Probe (TESCAN, CR) as well. The PVA:PEG membranes with/without Au, with/without heat treatment and at both ratios (9:1, 6:4), 1 cm2 in size, were added into the culture of normal human dermal fibroblasts (NHDFs) or human umbilical vein endothelial cells (HUVECs), which were seeded at the density of 20 000 cells/well in a glass-bottom 24-well dish. Cell morphology was assessed by immunofluorescence staining of vinculin and F-actin staining using phalloidin-TRITC. Cell metabolic activity/viability was analyzed using resazurin assay on days 1, 3, and 7 after seeding. HUVECs were stained for von Willebrand factor, and NHDFs for type I collagen production on day 7. Antimicrobial properties of the prepared materials were characterized by contact tests of the

materials with two environmental bacterial strains of Gram-positive S. epidermidis and Gram-negative E. coli. The number of colony-forming units of both bacterial strains after contact tests were calculated using ImageJ. As a control, bacteria incubated in a physiological solution were used.
Results
Scanning electron microscopy revealed different surface morphology of the prepared nanofibers for particular PVA:PEG mixtures, i.e. 6:4 and 9:1 as well as the presence and relatively homogeneous distribution of Au on/inside the nanofibers. The density of nanofibers, and more importantly the intensity of so-called “clusters”, were different; the PVA:PEG nanofibers had a narrow distribution of thickness with small or large drops inside membranes. The EDX analysis exhibited different surface chemistry of the prepared samples based on the amount of added nanoparticles and PEG in the solution. Atomic force microscopy was used for the determination of surface roughness, morphology and effective surface area both on the fiber (detailed scan), and also generally over the surface (larger scan above 30x30 µm). The heat treatment also affected both the surface morphology and chemistry of the prepared samples as was revealed by SEM, EDX and AFM techniques. Heat treatment decreased both the dissolution and shrinkage of the nanofibers in the cell culture medium. On day 1 after seeding, both HUVECs and NHDFs were well spread, and in the following days, they proliferated in the presence of all tested nanofibers with/without Au. Metabolic activity/cell viability of the cells was similar to that growing on the control tissue culture polystyrene surface. The HUVECs were positively stained for von Willebrand factor and NHDFs were proven to produce collagen on day 7. The analysis of material antimicrobial properties showed a partial inhibition of bacterial growth, presented as a lower number of colony-forming units.
Conclusions
The PVA:PEG–based nanofibers with homogeneously dispersed AuNPs at different Au concentrations were prepared and some of them were further stabilized by heat treatment.
The material physical and chemical properties were evaluated by various physical methods, their cytocompatibility was proven in vitro culture using both HUVECs and NHDFs cells. The materials with higher Au content seem to be promising for the treatment of chronic wounds with/without bacterial infection.

Fine-tuning the Size of ZIF-L Nanosheets Through Controlled Synthesis

Sara Talebi Deylamani[1], Dr. Giuseppe Di Palma[1], Dr. Pritam Banerjee[1], Prof. Kasper S. Pedersen[2], Prof. Joerg R. Jinschek[1]
[1]DTU Nanolab, Technical University of Denmark (DTU), Lyngby, , Denmark, [2]DTU Chemistry, Technical University of Denmark (DTU), Lyngby, , Denmark

PS-07 (1), Plenary, august 29, 2024, 15:00 - 16:00

Background incl. aims
To design novel hierarchical nanostructures with predefined properties and functionalities, e.g. for engineering and nanomedicine applications, we need to understand their bottom-up assembly processes as well as inherent structure-property relationships. This will open opportunities for precise synthesis of nanomaterials with targeted functionalities by simply controlling property-related structural characteristics in the bottom-up synthesis process, i.e. controlling size, morphology, crystallinity, etc. [1].
In this context, metal–organic frameworks (MOFs) have emerged as a customizable hierarchical material known for their high chemical and thermal stability. Controlled synthesis of these highly porous crystalline material is primarily about precise control of their chemistry, size, shape, and crystallinity. And, this ability has already been demonstrated, leading to controlled design of MOF structures with well-defined properties for various applications, such as gas storage & separation, wastewater treatment, and catalysis [2] [3]. For example, in catalysis applications where enhancing access of reactants to active sites is crucial, it is advantageous to design MOF nanosheets with precisely controlled thickness, as they offer a larger external surface area and decreased diffusion resistance [4].
Here, we investigate the synthesis process of zeolitic imidazolate frameworks (ZIF) with a leaf-like shape (ZIF-L nanosheets) to understand whether and how precisely we can control the nanosheet thickness (i.e. controlling the surface-to-volume ratio). We apply a series of photon- and electron-based characterization methods to understand the nucleation processes and growth mechanisms of ZIF-L nanosheets.

Methods
The ZIF-L nanosheets were prepared using a standard bottom-up synthesis method in which the synthesis parameters, including ligand-to-metal ratio, selection of additional ligands (modulators) as well as reaction time were systematically varied to synthesize uniformly thin nanosheets with controlled thickness.
A detailed structural characterization was conducted. Fourier-transform infrared spectroscopy (FTIR), scanning electron microscope (SEM), and X-ray diffraction (XRD) were used to confirm that ZIF-L was successfully synthesized. Crystallinity of the nanosheets was further determined by electron diffraction (ED). The size of the ZIF-L nanosheets (thickness and surface area) was determined using SEM and transmission electron microscopy (TEM).
ZIF-L are extremely sensitive to electron beams (critical dose <<100 e-/A2). Therefore, all TEM experiments were performed under low-dose conditions and/or using a Gatan cryo sample holder (cryo-TEM).

Results

ZIF-L nanosheets were synthesized by systematically varying the synthesis parameters to control their thicknesses. When the synthesis time was reduced from 4 hours to 2 hours at a constant ligand-to-metal ratio of <6, the nanosheet thickness decreased from ~ 135 nm to ~ 95 nm, as measured by SEM and TEM images. FTIR spectra, XRD as well as ED patterns confirmed that all nanosheets were ZIF-L single crystals. By further reducing the synthesis time to 20 minutes [5], the crystal thickness was further decreased to well below 90 nm. However, not all crystals exhibited nanosheet shapes. The particles showed nonuniform thickness and were agglomerated into flower-like shapes. Therefore, modulator ligands in various concentrations were added in the synthesis process to precisely control the balance between nucleation process and crystal growth. SEM imaging confirms that the addition of a modulator ligand resulted in formation of well-defined thin ZIF-L nanosheets even at low reaction times. Further (cryo) TEM experiments were performed to understand details of the ZIF-L growth kinetics.

Conclusion
The precise control of the morphology of a particular nanosheet MOF presented here is a great example of a promising strategy for designing nanostructures with predefined functionalities from the bottom up.
In detail, we provide an approach to design ZIF-L nanosheets with controllable size (i.e. thickness). The synthesis time as well as the concentration of modulator ligands were varied systematically. Their effects on nucleation, crystal formation, crystal growth, and the final leaf-like morphology were investigated by a detailed characterization study.

How to better understand ZrCu Thin Films Metallic Glasses recrystallization: a TEM in situ characterization?

Pr. Philippe Steyer[1]
[1]MateIS Laboratory, SNMS Microscopy group, INSA de Lyon, Villeurbanne, France

PS-01 (3), Lecture Theater 3, august 30, 2024, 14:00 - 16:00

Evolution of nanostructured thin films is closely related to their intrinsic small scale. Therefore, adapted characterization tools and techniques have to be developed, to highlight such relationships. The talk will focus on an advanced generation of surfaces: the thin film metallic glasses (TFMGs), obtained by magnetron sputtering. In this field, the Zr-Cu system does represent a model film, quite well-known at a meso/macro-scopic scale. In particular, its functional properties strongly depend on its crystallization dynamics, which is not clearly established, and needs to be better understood. The objective of the talk is then to demonstrate how specific research strategies involving, in particular, advanced TEM mode (in situ HT) were able to determine the evolution of the films' microstructural evolution.
Metallic glasses (MGs) have been intensively studied since the 60's, for their amorphous structure and associated properties. However, applications of MGs have stayed limited due to the fast quenching imposed to limit the crystallization process, and leading to small pieces of multicomponent materials. The condensation from the vapor phase to form a solid film in PVD process is another way to design metallic glasses. TFMGs indeed may show, for instance, particular interest in terms of physico-chemical and bactericide behaviors, coupled with an enhanced ductility [1]. Thermal stability of such amorphous metals nevertheless remains an issue. A non-conventional in situ technique, high-temperature scanning indentation (HTSI) [2], was first used to monitor the physical changes occurring in ZrCu-TFMGs during heat treatment. A complementary study was also done in parallel with the same film exposed to the same thermal conditions, at the TEM scale using specific heating chip equipped with the Wildfire sample-holder from Dens Solutions. This part will be developed within the framework of the talk. To correlate local transformation with a more global approach, all results acquired at the nanometer-scale were systematically compared with High-temperature XRD characterization, using the same thermal treatment. It was shown, for the first time, that crystallization initiates at ZrO2 nanoclusters as a transformation front, propagating throughout the film (Fig. 1). Acquired every 30 seconds, the front progression was measured, leading to thermodynamic and kinetic key-parameters as coefficients of diffusion. Behind the front, recrystallization results in the formation of bco- Zr7Cu10 intermetallics, identified by HRTEM. The transformation kinetics was also deduced from JMAK' modeling, giving rise to a well-documented new transformation mechanism [3].
From a quantitative point of view, really close crystallization kinetics were observed with our dual global-local approach, with close reaction rate (6.2·10-4 s-1 1 and 9.3·10-4 s-1, respectively) and Avrami exponents (1.9 and 2.2, respectively). Both measurements also give similar activation energies for crystallization (441 kJ.mol-1 and 445 kJ.mol-1, respectively). It suggests that crystallization mechanisms are the same for both investigated scales, despite the different sample configurations (micrometric thin film for XRD versus nanometric thin film for TEM).

Momentum resolved band gap measurement by high energy resolution electron energy loss spectroscopy

Dr Dileep Krishnan[1], Dr. Ioannis Iatrakkis
[1]Thermofisher Scientific, Eindhoven, Netherlands

PS-03 (3), Lecture Theater 2, august 30, 2024, 14:00 - 16:00

Techniques based on light optics have been traditionally used for studying optical properties of semiconductors. But there are 2 fundamental limitations of photon sources – 1. Its spatial resolutions are limited to µm range and 2. Photons cannot transfer any momentum (q) to the material. Electron energy loss spectroscopy (EELS) has been used to measure optical band gap for a few decades which compensates the aforementioned two shortcomings of UV-visible spectroscopy with nanometer range resolution and momentum transfer. But the limitation of EELS has been the energy resolution of the electron source; an X-FEG without mono was only 1 eV of resolution. With improvements of monochromator design on Thermo Fisher Scientific Spectra platform microscopes, energy resolution < 20 meV is now possible. Also, the 3-condensor lens system allows for a large range of momentum resolution possible with an upper limit <200 µrad in STEM mode.

In this report, momentum resolved band gap measurement has been performed with an excited monochromator (energy resolution < 25 meV) with a momentum resolution of < 800 µrad using the Thermofisher Scientific EELS filter and spectrometer. Effort is put to automate the acquisition of EELS across the momentum space. In the literature, the modelling of EELS in the low-loss region has been commonly done by simplistic free electron gas model [1].We are developing an effective tight binding model approach to approximate the band gap and extract the low loss spectral function. The final state in the double differential scattering cross section formula has been described suing mixed dynamic form factor (MDFF) [2].

Probing the Sensitive Reactions of Battery Cathodes Through (Cryogenic) Atom Probe Tomography

Dr. Mahander Pratap Singh[1], Mr. Eric V Woods, Prof. Baptiste Gault
[1]Max-Planck-Institute for Sustainable Materials, (formerly Max-Planck-Institute für Eisenforschung), Düsseldorf, Germany

PS-04 (4), Plenary, august 27, 2024, 14:00 - 16:00

Background incl. aims
Understanding battery materials and their interfaces (e.g., lithium-containing electrode materials, organic liquid electrolytes, solid electrolytes Interphase (SEI)), is central for advancing the development in Li-ion batteries (LIBs). However, characterizing these materials at the atomic scale presents challenges due to their sensitivity to reactions and electron-beam irradiation, leading to occasional inaccuracies in the precise quantification of elements like Li, C, and N. Atom probe tomography (APT) emerges as an effective materials characterization technique, complementary to electron microscopy, capable of generating 3D chemical maps by imaging the individual atoms with equal sensitivity to all elements[1]. Recent advancements in cryogenic APT workflows have further enhanced its capability to study LIBs with greater precision [2].
Our aim is to understand LIBs with utmost precision and confidence using cryo-APT protocols. APT of LIBs is plagued with multiple problems, including including field-induced delithiation (deintercalation), premature sample failures due to weak interfaces at the grain boundaries and porous structure. Additionally, preventing beam induced damage during sample preparations is a critical concern. Through the innovative design of experiments and novel cryogenic focused ion beam (FIB) sample preparation techniques, we have gained new insights into battery cathode material via. APT. In my presentation, I will discuss the challenges encountered, the solutions developed and the eventual results obtained while studying LIBs through APT.

Methods
In this work, commercial NMC811 ($LiNi_{0.8}Co_{0.1}Mn_{0.1}O_2$) was procured from Targray (Kirkland, Canada). Sample preparation involved the use of dual-beam Secondary electron microscopy-FIB instrument, Helios 5CX Ga (Thermo-Fischer Scientific, Hillsboro, OR, USA). The APT measurements were conducted using local electrode atom probe (LEAP, Cameca Instruments Inc.), either straight flight path (LEAP 5000XS) or reflectron (LEAP 5000XR). Measurements were done at different conditions depending on the samples. The reconstruction of the three-dimensional atom maps and data analysis was carried out using the commercial software AP Suite 6.1.

Results
We have developed an innovative cryogenic specimen preparation technique for battery materials, avoiding beam induced damage transformation from FIB. This involves a novel “redeposition welding” technique, enabling the secure attachment of APT specimens to Si micro-posts without the use of gas-injection system (GIS), see figure 1a [3]. We supplemented the technique with FIB-enabled, in-situ metal coating on the prepared APT specimens, see figure 1b [4]. These methods were applied successfully to study commercial materials like NMC811, LMO and cycled carbon fibers, with thin coatings proving effective in mitigating deintercalation, see figure 1c. This enabled the accurate Li quantification in battery materials using APT, serving as a valuable template for future battery investigation.

In the next study, we will explore how cryogenic APT workflows can easily study thin reactive layers formed on cathode particles exposed to ambient atmosphere, fig. 1d&e [5]. Similar technique can be utilized to study the thin secondary electrolyte interfaces (SEI) layers forms on the active materials of the cycled batteries.

Conclusion

Battery studies using APT offer atomic scale understanding of Li segregation at defects, interfaces and the diffusional behavior of Li in the cycled LIBs. All this will be of huge importance for the development of batteries. We have developed a novel, versatile and robust cryogenic APT workflow, involving whole sample transfer under vacuum and cryogenic FIB sample preparation, yielding relevant near-atomic scale microstructural information on battery samples. Cryo-preparation prevents beam damage, while metallic coating facilitates heat dissipation and provides mechanical support to the specimens against the Maxwell stresses generated by the applied field, a common cause of atom probe specimen failure. This approach provided high-yield, repetitive and precise compositional information across multiple samples. These procedures are further being used to study nanoscale compositional changes happening in the aged battery cathodes or anodes. Additionally, we successfully studied the formation of thin passive layers on the surface of Ni-rich cathodes (NMC811), laying the groundwork for further exploration of SEI layers on cycled materials.

LS-04 (1), Lecture Theater 4, august 29, 2024, 10:30 - 12:30

Liver sinusoidal endothelial cells (LSECs) are an excellent research target for developing high-resolution imaging methods due to their unique morphology [1]. LSEC membrane is perforated with multiple transcellular pores called fenestrations. Being in the range of 50-350 nm [2], fenestrations remain largely beyond the resolution limits of conventional optical microscopy, limited by light diffraction. LSECs play a crucial role in realizing the bidirectional transport of substances, especially lipoproteins, between blood and hepatocytes in the liver. Reduced LSEC porosity, called defenestration is often associated with ageing and chronic liver diseases such as hepatitis, steatosis, and cirrhosis. In vitro studies have shown that LSEC porosity can be altered pharmacologically [2,3]. These findings promise the development of a proper treatment allowing to reopen once closed fenestrations or to tune their diameters to achieve proper filtration properties within the liver [4]. Due to the great importance of fenestrations diameters, acting as a functional sieve for particles of a certain size into and out of the liver, the determination of the "true" fenestration size is extremely desirable.

Over the years various nanoscopy techniques have been challenged to disclose fenestrations in LSEC [5]. Obtained values of their diameters often significantly varied between the used techniques. The only way to understand these discrepancies was to visualise the exact same fenestrated areas using several techniques in a correlative manner. Each microscopy technique has its benefits and limitations originating e.g. from image acquisition, resolution, and level of sample preparation. We applied four different microscopy techniques, namely scanning electron microscopy (SEM), structured illumination microscopy (SIM), stimulated emission-depletion microscopy (STED), and atomic force microscopy (AFM), all to address the reported differences in fenestration size distribution.

A quantitative and qualitative description of the differences was made in a correlative manner [1]. Scanning electron microscopy (SEM) was combined with optical nanoscopy methods (STED, SIM). Additionally, atomic force microscopy (AFM) was used in combination with SEM (Figure) and STED, all in order to better understand the differences between literature reports on fenestration dimensions. The latter employed the prototype of a device in which AFM and STED were combined in one device, providing ease in directly overlaying obtained images. Finally, we showed the potential of correlative and comparative 4-dimensional imaging (3D + time) of living cells using AFM with fluorescence microscopy (conducted at the final stage of the experiment).
We concluded that dehydration needed in SEM causes fenestration enlargement, esspecially at the edges of so called sieve plates (Figure, arrowheads). Additionally, some fenestrations closed in hydrated samples, appear as opened after dehydration in SEM. An enlargement of fenestrations is observed when probing sample with an AFM tip if a sample is mildly fixed using formaldehyde. The effect vanishes after fixation using glutaraldehyde. The point of spread function (PSF) should be

considered when calculating fenestrations from images collected using optical nanoscopy. In our hands, smallest fenestrations, below 50 nm in diameter could not be disclosed with STED nor with SIM. Thanks to correlative studies and analysis of fenestrations in a one-to-one manner, we proposed the mathematical formula allowing for recalculation of fenestration size in order to compare data from LSEC imaged using different nanoscopy techniques. It will allow researchers to compare the results collected using different nanoscopy techniques. Finally, our results show promise of a better understanding of biological processes at the nanoscale, by combining the benefits of each method when used in a correlative way.

PS-04 (4), Plenary, august 27, 2024, 14:00 - 16:00

Background incl. aims
Lithium-ion batteries (LIB) are a key technology towards an emission-reduced transportation sector, in particular for electrical vehicles (EVs). One of the most promising cathode materials for LIBs are Ni-rich NMC cathode materials (LixNiyMnzCo1-y-zO2, with x > 0, y > 0.6). The main benefits of Ni-rich cathodes are an increased capacity, a high energy density and lower cost compared to conventional LIBs, which are needed to push the mileage limit and to make EVs more affordable. Although the advantages are great, Ni-rich NMC suffers from thermal and structural instabilities leading to a shorter life time and server capacity fading. The main degradation mechanisms occurring in NMC are: formation of surface reconstruction layer, formation of cathode-electrolyte interface (CEI), degradation of electrolyte and cracking of particles. [1,2]
This study focuses on the formation of surface reconstruction layer, specifically on the phase transition from layered structure (space group R-3m) to rocksalt phase (space group Fm-3m). [3] In the rocksalt phase the transition metals occupy the Li-positions and thus block the Li-diffusion paths. [4] A core-shell model describes the growth of this surface reconstruction layer, in which the degradation starts at the top of the surfaces and propagates into the bulk. [4] The aim of this study is to observe the phase change from layer structure to rocksalt structure and provide an answer to the questions: Does the rocksalt layer grow over time while the cell is kept under the harsh conditions of 4.5V and if so, is a trend in thickness growth of the rocksalt layer measurable?
Methods
A set of coin-half-cells against lithium was kept at high voltage of 4.5V for over 30 days. Every 2 days an electrochemical impedance spectroscopy (EIS) measurement was conducted. Afterwards, the cells were dissembled and the cathode sheets were rinsed with solvent. Using FIB-SEM allowed to cut very thin lamellas out of the cycled cathode sheets. However, preparing the sample for analysis presents several challenges. Firstly, the organic binder that surrounds the NMC particles melts faster under the ion-beam, leading to instabilities. Secondly, powder samples tend to redepositing and curtaining due to the pores in between. Finally, NMC is sensitive to the ion-beam, requiring lower voltages to be applied to reduce the amorphous layer on top. STEM was used to image the surface area of the particles down to atomic scale. Since the electron beam affects the NMC material and can lead to a phase transition from layered to rocksalt structure, it is very important to control the dose of the electron beam. [5] In addition, EEL spectra were acquired to provide a better understanding of the degradation process by monitoring the valance states of the transition metals. Moreover, further analytical methods such X-ray photoelectron spectroscopy (XPS) and secondary ion mass spectrometry (SIMS) were applied to investigate e.g. CEI formation.

Results
The EIS measurements showed an exponentially growing charge transfer resistance (Rct) which is an easily accessible indicator for degradation. Looking at the particles at atomic scale, the formation of rocksalt was present as depicted in Figure 1. The transition from layered to rocksalt appeared gradually and a typical transition region was visible. Interestingly, the variation of the thickness of rocksalt layer varied significantly within a lamella and even within one particle. It could be observed that the surrounding of the surface influenced the tendency to form rocksalt. A comparable, continuous trend in the growth of the surface reconstruction layer, as the Rct suggested, was not evident globally. However, the maximum thickness of degraded surface increased over time.
Conclusion
HRSTEM coupled with EELS provided a great insight into the rocksalt formation. The study indicates that while the core-shell model is generally a valid approximation for describing surface reconstruction in Ni-rich NMC, the real world is more complex. Therefore, it is crucial to comprehend the conditions under which a rocksalt structure is formed. Furthermore, understanding the time-correlation of different degradation mechanisms is crucial to improve battery materials.

IM-09, Lecture Theater 5, august 29, 2024, 14:00 - 16:00

Atomic Force Microscopy (AFM) has evolved into an indispensable characterization method as it provides quantitative 3D surface information with spatial nanometer resolution. It also enables access to electric, magnetic, optical and thermal properties using specialized functional AFM tips. However, achieving this functionality necessitates additional coating on AFM tips, resulting in increased tip apex size and thus limiting resolution. Moreover, coating introduces the risk of delamination, which could compromise or entirely diminish the functionality of the tip. The aim of our research is to surpass the limitations of functional image quality. To be more precise, it was of interest to achieve (1) higher resolution for functional AFM tips, (2) higher sensitivity for e.g. EFM/MFM phase signal, (3) good signal to noise ratio, and (4) higher wear resistance, compared to commercially available tips.
We have utilized the additive direct-write technology Focused Electron Beam Induced Deposition (FEBID), which enables fabrication of all-functional nano-probes that do not require additional coating. Depending on the application, different requirements become relevant such as tip design, type of precursor (elemental composition), spring constants, and so on. The 3D nano-printing process [1] and a variety of advanced, FEBID-based tip concepts for CAFM, EFM [2], and MFM [3] will be briefly discussed.
Ideal fabrication parameters were individually identified with subsequent determination of post-processing steps based on the required precursor, if needed. The FEBIP tips were then compared with commercially available products in terms of image quality, including resolution, signal-to-noise ratio, wear resistance, among others. After thorough testing of magnetic (M) and conductive tips (C), we give an outlook on further expanding AFM tip capabilities by combining both functionalities, produced with a single precursor. While in the past, MFM and CAFM measurements are operated via different modes, the here introduced MC fusion-probes contain unique possibilities, as both techniques can be performed in a single AFM-CAFM-MFM experiment. We present first results, which form the basis of this new type of nanoprobes.
FEBID presents an ideal technique for pushing boundaries in functional AFM measurements. All probes share the coating-free character, thereby mitigating the delamination risks during operation. Furthermore, tip apexes are consistently within the sub-10 nm range, enabling high-resolution imaging beyond alternative products.

Due to its excellent physical, chemical and electrochemical characteristics, pyrolytic carbon has emerged as a promising material for various technological applications [1]. Pyrolytic carbon can be obtained through the pyrolysis of a polymeric carbon precursor under controlled conditions at high temperatures and in inert atmosphere. By tuning the pyrolysis conditions, the hybridization of carbon atoms and thus the physicochemical properties of the derived carbon can be tailored. Although some researchers have attempted to investigate the graphitization process in atomic scale, a comprehensive understanding remains elusive. Transmission electron microscopy (TEM) is well-suited for investigating the graphitization of polymer thin films during the thermal treatment process at the nanoscale [2]. Indeed, TEM offers the advantages of in situ analysis capabilities which can reveal the nanostructure of pyrolytic carbon during the pyrolysis process. However, the preparation of polymer thin film samples for TEM remains a challenge. This work presents the microfabrication of suspended polymer thin film structures on MEMS-based TEM heating chips (DENSsolutions Wildfire), by two-photon polymerization (2PP) 3D printing technology [3]. We also report the results of the in situ TEM studies for tracing the graphitization of pyrolytic carbon.
A Nanoscribe Photonic Professional GT+ system from Nanoscribe was used to fabricate suspended polymer thin films using DENSsolutions chips as substrate. The microfabrication of thin films was done by direct laser writing of IP-Dip photoresist using 2PP with a Plan-APOCHROMAT 63×/1.40 Oil DIC objective. The optimized printing parameters were a laser power of 50%, a scan speed of 12000 µm/s, a hatching distance of 0.4 µm and a slicing distance of 0.1 µm. After printing, the samples were developed by a 20 min immersion in propylene glycol monomethyl ether acetate (PGMEA), followed by 20 min immersion in isopropanol. Finally, the structures were left to dry horizontally at room temperature.
TEM was performed with an FEI Titan 80–300 environmental transmission electron microscope. The microscope was operated at 300 kV at 10-8 Pa. In situ TEM was carried out with a TEM heating sample holder (Wildfire, DENSsolutions). Images were recorded on a Gatan OneView camera at an exposure time of 0.2 s. Images were post-processed using DigitalMicrograph (Gatan, Inc.).
To fabricate a thin film for visualizing the graphitization of carbon in the TEM, several designs and pyrolysis conditions were studied and optimized before selecting the optimal ones. The dimensions and integrity of the structure post-pyrolysis were assessed using SEM and the nanostructure of the resulting carbon was investigated by TEM. Based on these preliminary tests, we identified favorable parameters to resolve graphitic domain formation in the TEM. The identified conditions are a thin film with a thickness of around 700 nm pre-pyrolysis, a pyrolysis sequence reaching a maximum temperature of 1300°C and a minimum of 2 hours of dwell at this temperature. The final thin film design is presented in Figure 1a. The sample consists of a suspended ribbon with a center through-hole to facilitate imaging of the suspended thin film all around the edge of the ring. The central ring is 700 nm thick for TEM imaging (in dark grey in Figure1a) while the surrounding ribbon is thicker (900 nm) to provide support and strengthen the overall structure (in light grey in Figure1a).

Figure 1b & c show the structure after printing and after pyrolysis, respectively. From these images we see that the ribbon, the window, and the hole are well-defined both before and after pyrolysis. Three of the in situ TEM micrographs acquired during the dwell at 1300°C, are presented in Figure 1d to 1f. The images are acquired every 30 minutes, with the beam blanked between acquisitions. The formation of oriented carbon microdomains is visible, and their nature as graphitic carbon is affirmed by the measured inter-layer distance of 3.3 Å, a characteristic feature of graphitic materials. An increase in the number of graphene stacking layers was observed over dwell time. It is worth noting that since the beam is blanked in between acquisitions, these observations are valid independently of the beam influence.
To conclude, we demonstrated the successful 2PP fabrication of suspended polymer thin films for in situ TEM studies, as well as the visualization of graphitization on these films during in situ TEM heating studies.

Since its first construction by Gerd Binnig, Calvin F. Quate, and Christoph Gerber in 1986 [1], it took only a few years to disclose the tremendous potential of atomic force microscopy (AFM) in the research of biological objects [2]. It is mainly because AFM does not need sample modification and labelling. Freedom of selection of conditions, including performing measurements in culture media, control of pH, and temperature combined with large x,y, and z piezo-scanner ranges all have led to the rapid development of live cell imaging. Finally, novel AFM imaging modes, based on a fast acquisition of force-distance curves, such as Quantitative Imaging (QI), PeakForce Tapping, or PinPoint have enabled 4D (3D plus time) imaging of changes in biological samples.

Here, the results of the development of so-called in vitro pharmacology on a single cell will be presented [3-5]. Briefly, the methodology allows tracking the single-cell morphology and its nanomechanical properties over time. Then, a drug is injected into the culture medium and the cell response to the drug is further observed. It allows monitoring of morphological features and the cytoskeleton remodelling, including its effect on alterations in Young's modulus distribution. Depending on the area of interest single frame is collected in the range of minutes to several seconds allowing observation of drug-induced changes in the morpho-mechanics of cells.

The main focus will be devoted to primary murine liver sinusoidal endothelial cells (LSEC) in vitro. LSEC have transcellular pores, called fenestrations, that are indicators of the healthy phenotype of the liver. These nanostructures – 50-350 nm in diameter – participate in the transport of lipoproteins and solutes (e.g. hormones) between the vascular system and the liver parenchyma. AFM remains the exclusive tool allowing monitoring of drug response in living LSEC for up to 6 hours. Fenestration number, diameter, lifespan, migration range, and deformability can be quantified [3]. Moreover, Young's modulus distribution over the whole cell can be calculated [5]. We show that fenestration lifespan varies from minutes to hours. During this time fenestration changes their diameters and migrates within the cell as far as several micrometers. We employed so-called loading force-dependent tomography to assess the deformability of fenestrations. We test the established methodology in several pharmacological strategies aiming to restore fenestrations in LSEC originating from wild-type animals and genetic knockouts.

We conclude that novel AFM provides multiple parameters for quantifying drug responses in LSECs and their fenestrations in real time. Introducing in vitro pharmacology on LSEC fenestrations will enhance understanding of the mechanisms underlying fenestration formation and function.

PS-02 (2), Lecture Theater 5, august 28, 2024, 14:00 - 16:00

Nickel-base single crystal (SX) superalloys have long been served as indispensable materials for turbine blades in aerospace gas engines, owing to their outstanding creep properties. The unique mechanical resistance is attributed to the coherent γ/γ' microstructure in which the cuboidal γ' precipitates exhibit an ordered L12 crystal structure embedded in γ matrix channels, which is a solid solution with a face-centered cubic (FCC) structure. In severely harsh operation environments, the mechanical properties of superalloys are primarily controlled by the precipitate shearing events associated with elemental segregation to and away from dislocations and planar faults within the γ' phases [1].

The present work focuses on understanding the alloying segregation to dislocations and planar defects. Some key aspects under investigation are: a) Do the nano defect phases, formed through elemental segregation, contribute to the stabilizing defect phases within the γ' precipitate? b) Does the elemental segregation to defects result in a reduction of defect energy, thereby facilitating the cutting of the γ' precipitate by the defects? To address these aspects, we designed double creep shear specimens such that deformation takes place along a specific loading direction [11-2] to activate the slip system [11-2](111) with Schmid factor of 1. Local high-resolution energy dispersive X-ray (EDX) is used in scanning transmission electron microscopy (STEM) mode to measure the elemental segregation to planar defects as a function of creep strains (1% and 2%). Both creep-deformed sample states allow us to differentiate whether a compositional steady state, and consequently a nanophase, has formed in the vicinity of the crystal defects[2], or if transient states are measured. Transient states would indicate ongoing diffusion processes that potentially control the kinetics of shear processes [3].

Microstructural characterization post creep deformation with the low magnification high-angle annular dark-field (HAADF) STEM micrograph of the 1% crept sample in Figure 1(A), and the conventional dark field two-beam condition image of the 2% crept sample in Figure 1(C) both depict the termination of planar fault motion inside the precipitate, indicating a leading partial dislocation shearing segment within the γ' phase. High-resolution HAADF images in Figure 1(B) and (D), elucidate that along these leading segments, the nature of the largest stacking fault is a superlattice extrinsic stacking fault (SESF), while at the very tip, in front of SESF we observe a short complex intrinsic stacking fault (CISF). Both faults show the same defect configuration: a closely spaced pair of Shockley partial dislocations with identical Burgers vector1/6[11-2] glide on adjacent (111) planes. This process creates two energetically unfavourable CISFs, which are known to subsequently reshuffle Al-Al atom positions to convert the high-energy fault structure into a stable SESF with low planar fault energy [4].

The chemical distributions across the SESFs in Figure 2 illustrate almost identical segregation tendencies for 1% and 2% crept samples. The γ forming elements such as Cr, Co, W, or Re are enriched in the vicinity of the SESF, while γ' alloying elements Ni and Al are depleted. Quantitatively comparing the local alloying element concentration magnitudes at the SESFs show that the 1% crept sample exhibits the same local composition as the 2% crept sample, even though it experienced a longer creep time. This observation concludes that the segregation to the SESF has reached a steady state and establishes a stabilized nano-defect phase within the SESF after 1% creep strain. This result suggests that with a longer creep time, alloying elements do not further diffuse to the SESF.

Poster Group 1

Background incl. aims
Over the last few decades, the properties of ferroelectrics and their polar arrangements have been extensively studied in thin films or bulk systems. However, it is only recently that ferroelectric-based superlattices (SLs), i.e. an alternation of two layers with a chemical period Λ, have emerged and leaded for example to the discovery of exotic polar textures such as skyrmionic states or vortices in PbTiO3/SrTiO3 SLs. [1,2] Thus, SLs offer a unique and promising new platform to study these novel polar states which result mainly from the effects of strain, confinement, and competing interactions between the degrees of freedom (polar displacements, oxygen tilts) of these perovskite layers. BiFeO3/LaFeO3 (BFO/LFO) SLs, have also showed interesting features in recent work.[3] BFO is, in essence, the model multiferroic material which exhibits in its bulk form ferroelectric polar states coexisting with a complex magnetic state. However, when it's incorporated in such SLs, an unusual antiferroelectric like-state is observed. Here, the aim of our study is to understand, through scanning transmission electron microscopy (STEM) characterization, how the buffer (LaFeO3 or NdFeO3) layers influence the polar states of BFO.
Methods
BFO/LFO (or NFO) SLs were grown on cubic single crystal (001) STO substrate by pulsed laser deposition (MECA 2000 chamber) using a KrF laser (248 nm). BFO and LFO (or NFO) layers were grown at the same conditions under 0.5 mbar of oxygen pressure (PO2) at 740°C at 6 Hz repetition rate. Cross-section transmission electron microscopy (TEM) samples were prepared on an FEI ThermoFisher Helios Nanolab 660 by using the standard lift-out technique. The annular bright field (ABF) and high angle annular dark field (HAADF) STEM images were acquired by a FEI Titan3 G2 80-300 microscope, operated at 300 kV and equipped with a Cs probe corrector. The analysis of atomic displacements has been performed by the Python open-source library Atomap and Temul-Toolkit library for visualization.[4,5] In complement, STEM images were also analyzed by a "render-and-compare" (RAC) method based on Principle Component Analysis (PCA).
Results
We analyzed several BFO/LFO and BFO/NFO SLs, with various periods Λ (3, 6, 12 and 20 nm) and same BFO/LFO (or NFO) thickness ratio, deposited on STO substrates. We were able to reveal various polar textures within the BFO layers by analyzing the relative atomic displacements as well as the Fourier components with Atomap and RAC respectively. Among them, we unexpectedly observed in-plane and ~45° ferroelectric displacements, but also step-like polar arrangements resulting in a quadrupling of the unit cell confirmed by fast Fourier transform (FFT) images. While Atomap indicates an (up-up-right-right)-like shifts (see Figure), RAC rather suggests a more complex polar distribution with 4 different types of displacements. Moreover, some polar singularities showing hedgehog-like, i.e. skyrmionic textures, were also observed revealing the wild variety of the polarization in BFO.
Conclusions

STEM analysis shows that introducing BFO in SLs systems induces drastic changes of its polar textures, mainly by strain and confinement effects, thus showing the high potential for modulating its polarization. Besides, the comparison of data analysis methods shows that Atomap and RAC are complementary into revealing the nature of the observed displacements.

Poster Group 2

Background and aims:
Food colorants are applied to enhance the appearance of food. To obtain specific hues, inorganic food additives containing (nano)particles are mixed in varying concentrations, and pearlescent pigments, consisting of mica platelets coated with a layer of titanium dioxide and/or iron oxide particles, are applied to provide glitter effects [1]. For assessing potential risks of multi-constituent substances and mixtures, characterisation of the fraction of small particles, including the particle size distribution, is needed for each single constituent or each component in the mixture [2]. This is challenging for control laboratories and only limited guidance is currently available [3].
This study developed electron microscopy-based methods to identify and characterize the particles of individual components in 8 commercially available food-decoration sprays of different colours, containing mixtures of food additives and pearlescent pigments.

Methods:
To avoid altering the properties of the particles consumers are exposed to, no extensive dispersion protocols or purifications steps were applied. Samples were prepared by spraying 5 mL in a glass vial and coated on EM-grids using the grid-on-drop method. Scanning transmission electron microscopy (STEM) combined with energy dispersive X-ray spectroscopy (EDX) and EDX-tomography were applied to image the various components. Subsequently, image processing using the ImageJ software was performed to obtain quantitative results.

Results:
The various components were identified based on their elemental composition, including potassium aluminum silicate-based pearlescent pigments, vegetable carbon, rutile titanium dioxide, iron oxide and aluminum containing (nano)particles. Their presence, size, and relative concentration varied among the different spray colours. Often the layer of titanium dioxide particles detached from the mica substrate, and titanium dioxide particles were also observed forming near-spherical aggregates. STEM-EDX tomography allowed identifying particles of overlapping components and examining the structure of the pearlescent pigments in 3D. This way, all components in the mixtures could be successfully identified, and the particle size distributions of each components in all but the most challenging mixtures could be obtained.

Conclusion:
The developed electron microscopy-based methods allowed identifying the different components in the mixtures, and the presence of a fraction of nanoparticles in each component was demonstrated based on their number-based particle size distributions. The methods and findings support regulatory bodies in assessing the potential health risks of mixtures of (nano)particles used in food-related applications.

Optimizing data acquisition and interpretation in atomically resolved STEM spectrum imaging

Yi Wang[1]
[1]Center for Microscopy and Analysis, Nanjing University of Aeronautics and Astronautics, Nanjing, China

Poster Group 1

Recent advances in instrumentation hardware have made chemical analysis, i.e. electron energy-loss spectroscopy (EELS) and energy-dispersive X-ray spectroscopy (EDXS), at atomic resolution readily possible. However, the acquisition and interpretation of atomically resolved spectra can still be problematic due to, for instance, image distortions or poor signal-to-noise ratio (SNR) spectra, especially for investigating energy-loss near-edge fine structures. To achieve a decent SNR, STEM spectrum imaging (SI) requires much higher electron doses and longer dwell times (pixel exposure times) than for STEM imaging. Consequently, these distortions become more serious in SI data. Instabilities combined with long dwell times may create substantial image distortions, i.e. expansion, compression, and/or shearing of the lattice that limit the interpretability of the results.

In this contribution, we report the development of on/off-the-fly methods for optimizing atomically resolved STEM SI. The first technique is used to post correct (off-the-fly) image distortions in atomically resolved SI and diffraction imaging [1]. We demonstrate the correction of linear and nonlinear distortions, the feasibility of this tool for 4D-STEM diffraction imaging, and the application for maximizing the elemental mapping area. In the second technique, by combining multi-frame spectrum imaging and automatic energy-offset correction, we report an on-the-fly SI technique for minimizing image distortions and improving the SNR of EELS spectra [2]. The energy-offset correction technique significantly reduces correlated noise [3], as for successive spectra different camera pixels are exposed which precludes amplification of small gain normalization errors. We have implemented these techniques into STEM SI for atomically resolved EELS elemental and fine-structure mapping. Using practical examples, we demonstrate that multi-frame SI and post-alignment can effectively suppress image distortions and improve the final elemental-map quality. The energy-offset correction method reduces the correlated noise and helps to resolve weak features of the near-edge fine structures. The final SI with improved SNR enables the extraction of individual component maps of the Ti-L2,3 near-edge fine structure and of a Ti-O-Ti bonding direction map at atomic resolution in SrTiO3 (Figure 1), which has been theoretically predicted but extremely difficult to detect experimentally due to the poor SNR of the spectrum [4]. Combining multi-frame SI and automated energy-offset correction, we demonstrate that these techniques will open new opportunities for atomically-resolved EELS fine-structure mapping. Moreover, this multi-frame SI technique also paves the way for low-electron-dose imaging techniques to reduce damaging of the sample [5], as well as the possibility for atomically resolved imaging and SI at cryogenic temperatures. In the last, their application in battery and catalysis materials will be discussed.

Background incl. Aims

Magnons, the quanta of spin waves, play a pivotal role in various solid-state phenomena, including memory and information processing [1]. Understanding their behavior at the nanoscale is crucial for advancing magnetic technologies. Electron energy loss spectroscopy (EELS) holds promise for probing these excitations with high spatial resolution [2, 3], potentially enabling the exploration of magnon dispersions down to the atomic scale. However, experiments face substantial challenges due to the overlap in excitation energy ranges between phonons and magnons, with phonon signals typically overshadowing magnon signals significantly [3]. Hence, elucidating optimal conditions for discerning magnon EELS signals remains crucial.

In this work, we present our progress in simulating inelastic electron scattering signals of magnons in Scanning Transmission Electron Microscopy, discussing the feasibility of Magnon EELS detection.

Methods

We implement a new methodology [4] to compute magnon EELS from Pauli-multislice simulations. In particular, this methodology integrates state-of-the-art simulation techniques to model magnon spectra, including the Frozen Magnon Multislice Method with absorptive-potential-based phonon scattering [3].

Results

We present findings suggesting the potential for detecting statistically significant magnon signals by selecting combinations of temperature and sample thickness [3]. Additionally, we show the capabilities of our methodology by presenting angle-resolved magnon EELS simulations.

Conclusion

Our simulations suggest the existence of feasible conditions to differentiate magnon inelastic signals from phonon signals. Also, we show the potential of our developed methodology to simulate angle-resolved magnon EELS signals.

Poster Group 2

Lithium-ion (LIB) batteries' technology has evolved rapidly to be on par to the increasing demands of the market. The EV (Electric Vehicle) market requires batteries presenting high safety, higher energy density and duration. For instances, one of the cathode materials suitable for EV application is NMC 811, however, its accelerated degradation leads to a short battery life. For the further development of EV suited batteries, the understanding of NMC 811 degradation dynamics is crucial.
For a proper study of the dynamics of (de)lithiation in NMC 811 cathode material, an in-situ analysis at the primary particle scale is proposed. The electrochemical liquid TEM analysis configuration [1] allows the performance of battery cycling inside the TEM for imaging at different SoC (state of charge), inducing less of perturbations during data acquisition and imaging analysis. The information obtained could reveal the behavior of lithium inside the crystallographic, as well as other phenomena that lead to battery degradation.
One of the main causes of degradation in NMC 811 is due to the formation of a passivation layer during cycling, the CEI (cathode electrolyte interface) [2]. The CEI formation take place during the first cycles of the batterie, at the interface between the active material and the electrolyte, organic and inorganic compounds (LiF, LiOH, Li2Co3, etc.) are formed, consuming active Li which leads to the reduction of the batter capacity and degradation of the electrolyte. The CEI layer is not stable, dissolution and reformation of it occurs during each cycle, reducing the batterie life. STEM-EDX and 4D-STEM microscopy technics can be used to follow the formation of the CEI.
4D-STEM technique allows us to obtain structural information based on electron diffraction pattern collections (50k patterns) with a spatial resolution of 1-2 nm. [3-5]. Using this method, it is possible to reconstruct it via pattern matching, a phase mapping of the present inorganic components in a CEI as has already being done for ex situ analysis of NMC 811 (figure 1) [2]. Coupling 4D-STEM and STEM-EDX analysis for different SoC (State of Charge) will allow us to follow the behavior of the CEI layer and determine the dynamics behind it.
The obtained information could lead to the comprehension of the strains present at the primary particle level that could eventually lead to the fracture of secondary particles and the degradation of the material as reported several times in literature.

Poster Group 1

Background incl. aims

Liquid phase transmission electron microscopy (LPTEM) has emerged as a powerful tool, presenting enormous potential for understanding the electrochemical processes behind electrolysis, batteries, and other technologies [1]. However, obtaining high-resolution structural and chemical information during these electrochemical processes remains a challenge due to the issue of liquid thickness. While utilizing a monolithic MEMS-based nanoreactor with integrated electrodes can be a potential solution, it too faces limitations from an electrochemical perspective. To ensure proper ion conduction to mirror processes occurring in macroscopic cells, LPTEM studies require a thicker liquid layer, which directly contradicts the need for high-resolution information. On the other hand, obtaining high-resolution information through post-mortem studies, by disassembling a typical two-chip nanoreactor, too is not a viable solution due to possible changes due to absence of the native liquid environment. Furthermore, ideally high-resolution information is required at different stages of in situ experiments. These necessitate the ability to dynamically control the liquid thickness. novel method that enables high-resolution and analytical electron microscopy studies within a liquid flow cell [2].

Methods

Smart micro electrical mechanical systems (MEMS) and holder designs have enabled us to control liquid flow and thickness, allowing us to create a stable and reproducible environment that is ideal for investigating the electrochemical processes of interest [2,3]. In particular thanks to the on-chip flow capability, the liquid in the field of view can be efficiently reduced by flowing gas, which is termed “purging” [4]. This purging method enables the acquisition of high-resolution TEM images, chemical composition and valence analysis through energy-dispersive X-ray spectroscopy (EDX) mapping and electron energy-loss spectroscopy (EELS). In addition, the purging approach is both reversible and reproducible, which therefore enables the alternation between a thick and a thin liquid configuration. This provide us the necessary dynamic control over the liquid thickness to perform the electrochemical experiments in a thick liquid configuration and then perform anlytical studies including 4D STEM at the thin liquid configuration to enable the best resolution without changing the state of the sample. This coupled with simple image processing that has allowed us to extract 3D information from the in-situ image series and a step towards live 4D STEM provides the pathway to developing new and more efficient energy technologies.

Results

Dendrite growth during cycling is one severe problem to harm durability and safety of energy applications, so many efforts have been studied to inhibit the dendrite growth. One example case is aqueous zinc (Zn) based battery chemistry, including redox flow battery, which has recently generated significant interest as an alternative battery technology for stationary applications beyond Li-ion batteries. The main driving force is the high volumetric capacity of aqueous zinc batteries, low cost, safety, and abundance of Zn metal. Despite these advantages, alongside electrode passivation, anode shape change, and H2 evolution, the problems of Zn dendrite growth cause premature battery failure and safety hazards, severely limiting the progress and further commercial exploitation of aqueous Zn batteries. Direct visualization of dendrites under operando conditions can lead to an in-depth understanding and the development of the most effective mitigation routes toward achieving a compact plating and smooth stripping of Zn during battery cycling, which is a prerequisite for battery safety, longevity, and viability. Thus we apply the developed method for dynamic control of liquid thickness and image processing to gain 3D growth along with crystallographic orientation information of the Zn deposits during electrodeposition using 0.1 M ZnSO4. Figure 1. Showcase dendrite formation and extracted 3D information from the in-situ image series.

Conclusion

The 3D visualization of electrodeposition at the nanoscale enabled us to study how different electrolyte additives affect growth across all three planes (XY, YZ, and XZ) and thus establish a workflow that researchers can utilize to optimize electrolytes to promote compact deposition and mitigate unwanted features like dendritic growth for Zn and other battery chemistries and electrodeposition processes in general.

Figure Caption

Figure 1: Investigation of Zn dendritic growth during plating in static 0.1M ZnSO4. (a-c) STEM images obtained at 7th, 8th and 9th seconds. (d) The plated Zn volume vs. time. (e-g) Processed images show the Zn dendritic growth between 7-8, 8-9, and 9-10 seconds. A color map on (g) represents the thickness [µm] at that second.

LS-06, Lecture Theater 4, august 30, 2024, 10:30 - 12:30

Background incl. aims
The Gammacoronavirus Infectious Bronchitis Virus (IBV) is a highly contagious pathogen of poultry and can be used as a model coronavirus (CoV) to study the formation and structure of CoV replication organelles (ROs). CoVs rearrange host cell membranes into ROs which act as platforms for the viral replication-transcription complex and are the sites of RNA genome replication. Conserved RO structures exist including double membrane vesicles (DMVs) and double membrane spherules (DMSs). The mechanisms of RO formation and the function of DMSs have not yet been elucidated. Using fluorescent recombinant viruses and correlative cryo-bioimaging, ROs will be marked and directly targeted for imaging using X-rays and electrons. These techniques will reveal RO structures over multiple scales, in 3D, to high resolution, and under near-native conditions. The aims are to develop a correlative workflow to observe the RO network in whole cells, RO formation events, and DMSs under cryogenic conditions. Subvolume averaging of electron tomograms will reveal membrane associated proteins which may give clues to RO formation mechanisms and functions.
Methods
Fluorescent tags were inserted at the N-terminus of nonstructural protein 2 (nsp2) using reverse genetics. The growth kinetics of recombinant IBVs were characterised in comparison to wild type. Viral stocks were concentrated to optimise the number of sites of nascent viral RNA synthesis able to be detected by immunofluorescence imaging. Resin-embedded correlative light and electron microscopy (CLEM) was used to confirm RO formation by the recombinant virus. Cryo-sample preparation by plunge freezing has been used to make grids for cryo-correlative light and soft X-ray tomography (SXT, B24, Diamond Light Source), correlative cryo-focused ion beam (FIB) milling, and cryo-electron tomography (ET, eBIC, Diamond Light Source).
Results
Recombinant GFP-nsp2-IBV does not significantly attenuate viral replication. GFP-nsp2 colocalises with sites of nascent viral RNA synthesis as seen by immunofluorescence imaging. GFP-nsp2 marks known IBV RO structures as seen by CLEM. Correlative cryo-SXT has revealed RO networks in whole cells to 30nm resolution. Plus, correlative fluorescence microscopy, FIB milling, and cryo-ET has resolved the structure of the DMS bilayer. Sub-volume averaging on cryo-electron tomograms will gives clues to the DMS protein composition and their functions.
Conclusion
Fluorescent-tagged viruses are being used in combination with advanced imaging to further understand CoV ROs. This work will significantly improve our knowledge about the sites of CoV RNA synthesis and this critical stage of the virus lifecycle. Consequently, novel replication mechanisms of current and emerging positive-sense single-strand RNA viruses may be revealed.

Enhancing tool performance with complex microscopy investigation of additively manufactured M2 steel and composites

Ing. Ph.d. Martina Koukolíková[1], Mr. Pavel Podaný[1], Mr. Miroslav Urbánek[1], Mr. Michal Brázda[1], Mrs. Ivana Poláková[1], Mr. Josef Hodek[1]
[1]COMTES FHT a.s., Dobrany, Czech Republic

Poster Group 2

Background incl. aims
The study explores the application of complex microscopy and imaging techniques to investigate the microstructure of M2 steel and carbide-reinforced composites additively manufactured (AM) using powder-based Directed Energy Deposition (DED). Aiming to understand the material's properties and behaviour under various conditions, the research emphasizes the role of microscopic analysis in enhancing tool and material performance. The emergence of additive manufacturing techniques, such as DED using powder feedstock, has opened new avenues for fabricating components with intricate geometries, complex material variations, and tailored properties. M2 steel is renowned for its exceptional mechanical properties, making it a preferred choice for high-speed steels. Carbide-reinforced composites investigate the impact of incorporating different concentrations of tungsten carbide (WC) particles into a high-temperature nickel-based superalloy Nimonic 80A for applications requiring improved wear resistance, such as forming tools. The role of microscopic analyses in the enhancement of manufacturing processes and material performance is emphasized by the research. These insights will serve as a basis for the digitalization of material testing and the development of material models using finite element methods.
Materials and Methods
The materials were fabricated by DED using a INSSTEK MX-600 system, which is equipped with a 2-kW yttrium fibre laser, under a protective atmosphere of argon 5.0 in a direct metal tooling (DMT) mode. By continuously monitoring and adjusting the laser power multiple times per second, the DMT system ensures a consistent layer by automatically reducing or increasing the laser power. The 800 and 1600 modules (laser-beam spot size: 800 µm and 1600µm) were applied. The powders were fed from separate feeders to the nozzle. The average particle size of the powders was declared by the producer to be 50-150 µm. Nevertheless, powder analyses were conducted adhering to the ISO 13320 standard. This methodology facilitated the precise quantification of particle size and particle fraction across designated particle size ranges through the utilization of laser scattering techniques. The metallographic analyses involved a detailed examination and comprehensive evaluation of the microstructural characteristics inherent in the as-built condition. The study delves into the utilization of advanced microscopy and imaging techniques, encompassing both light and electron microscopy techniques coupled with Energy Dispersive X-ray Spectroscopy (EDX) and Electron Backscatter Diffraction (EBSD). These sophisticated techniques were employed to scrutinize the intricate microstructure of additively manufactured tools, particularly with M2 steel and carbide-reinforced composites, enabling detailed analysis of microstructure, potential defects and phase distribution. The evaluation of the WC phase was conducted in accordance with ASTM E562 (2019) standard. Furthermore, confocal laser microscopy was applied to meticulously assess the wear rate.
Results
The microscopic and imaging analyses revealed significant insights into the correlation between the DED fabrication parameters and the resulting material microstructure. Key findings include the identification of optimal processing conditions for achieving desired mechanical properties and the

detection of critical microstructural features that influence the material's performance in engineering applications. The incorporation of M2 steel onto the operational surfaces of tools manifests a notable enhancement in tool longevity, predominantly ascribed to its exceptional hardness, resistance to wear, and capacity to endure mechanical stresses encountered during cold working cutting tools activities. Microstructural examination unveils a martensitic matrix with the presence of complex carbide particles containing Mo, V, Cr and W. Remarkably, these particles faithfully replicate the characteristic cellular structure inherent in additively manufactured materials in as-built states, i.e. after deposition. The resultant hardness attains a formidable 63 HRC.
The research also demonstrates a substantial improvement in tool life, wear resistance, mechanical properties, and microstructural stability with additively manufactured carbide-reinforced Nimonic 80A layer as a functional coating onto the tool steel. The gradual addition of particles (5%, 10%, 15%, and 20%) highlights the potential for WC-doped Nimonic 80A in multimaterial components, particularly in challenging environments of hot forming operations where wear resistance and mechanical strength are critical. The integration of WC into the Nimonic 80A matrix proved successful, yielding significant advantages for the material, while no defects were detected. Additionally, it was observed that the WC particles were uniformly dispersed within the matrix, contributing to the overall homogeneity of the material.
Conclusion
Microscopy and imaging techniques have proven to be pivotal in advancing the understanding of the microstructural characteristics of M2 high-speed steel and WC-doped Nimonic 80A produced via DED. This study not only highlights the importance of these techniques in material science but also sets the groundwork for future research aimed at optimizing metallic materials for various engineering applications. The investigation into the additively manufactured materials highlights its potential for high-performance applications. The findings not only contribute to the digitalization of material testing and the development of predictive material models but also pave the way for optimizing the manufacturing processes of high-performance tools, showcasing the role of microscopy in advancing materials design and application.

Poster Group 2

Background
Environmental catalysis has long been a subject of significant interest, particularly given the pressing need for renewable, eco-friendly energy sources amid the current energy crisis. O2 and/or H2 are commonly involved in these processes, either as reactants or products, with redox reactions playing a pivotal role in understanding the reaction pathways and their mechanisms. The performance of catalysts is closely linked to these mechanisms, making an in-depth study of these systems vital for enhancing catalytic activity and selectivity. However, catalysts are dynamic entities prone to undergoing structural and chemical transformations during reactions. Traditional electron microscopy techniques are limited in their ability to capture these changes, typically providing insights only into the catalyst's initial and final states1. In response to this challenge, gas-cell in situ electron microscopy has emerged as a crucial tool. This cutting-edge technique allows for the direct visualization of phenomena occurring at the nano and even atomic scale during catalytic reactions. A better understanding of the materials and their functionality during reaction will aid in designing rational catalysts with improved performance.
Yet, there is a big scale gap between conventional catalytic reactors and the in situ nanoreactor affecting phenomena such as mass or heat transport that should be given more consideration2,3. Aiming to investigate the potential disparities emerging between the macro and nano scales, we propose to in situ characterize the chemical behavior of reducible oxides, while contrasting it with the results obtained in regular catalytic reactors.
Methods
To this end, two families of model catalysts have been picked to track their evolution during reduction/oxidation reactions. The systems consist of CeO2 and Cu2O oxides with nanocubes morphology. A well-defined surface crystallography will contribute to generalizing about the phenomena taking place. These samples have been submitted to temperature-programmed reductions/oxidations (TPR and TPO) monitoring their reducibility.
Similarly, in situ redox reactions under H2 or O2 atmospheres have been carried out in a DENS Solutions Climate holder, using a double-corrected FEI Titan Cubed at 200 kV. Pressure inside the nanoreactor was about 950 mbar and gas flow was set to 0.01 ml/min with 50% of reactive gas (either H2 or O2) balanced with N2. The phase transformations related to temperature and gas flow in electron-transfer reactions entail chemical changes, like a shift in the valence state, and structural changes triggering a modification in the crystal lattice. Electron diffraction and electron energy loss spectroscopy (Gatan Quantum 966 ERS) have allowed us therefore to trace the modifications on the model Cu2O and CeO2 catalysts.
Results
Prior to investigate controlled-morphology Cu2O and CeO2 catalysts, a reference CuO sample has been tested to compare reduction degree and temperature between in situ and ex situ redox cycles. Their correlation determines a shift of about 50 ºC towards higher temperatures in the reduction at

the nano scale, spanning as well over a wider range. Deviations in the actual conditions of both experiments may point out differences in their kinetics that should be further considered. From a structural point of view, Figure 1A shows the drastic change suffered in commercial CuO crystals after interaction with H2, splitting apart into way smaller nanoparticles. The interpretation of electron diffraction patterns unveils that, in line with the TPR results, the morphological transformation is linked with the transition to metallic Cu.
Moving forward with our target systems, we have first explored the reduction of CeO2 nanocubes, where the ex situ TPR is mainly defined by two reduction events separated by at least 300 ºC. Figure 1B follows the evolution of ceria nanocubes under H2 when the temperature increases up to 950 ºC. The elemental mapping has been extracted from Ce-M4,5 EELS fine structure, showing the spatial distribution of Ce3+ (red color) and Ce4+ (green color) at 450 ºC and 950 ºC. The in situ reduction triggers the formation of a reduced cerium-based shell which propagates towards the core of the nanocubes at elevated temperatures. The presence of two reduction peaks muddles the direct correlation between the ex situ and in situ experiments, demanding therefore a quantitative analysis of both processes to match the temperatures and defined each of the two reduction events.
To clear out the roots of these and further experiments, a deeper investigation on the reduction/oxidation of these oxides is required. In addition, the Cu2O nanocubes will also be addressed comparing the results with the CuO reference and the details determined in the reduction of the CeO2 nanocubes approach.
Conclusion
The relationship between conventional quartz reactors and Si3N4-membrane nanoreactors has inferred a temperature deviation in the in situ measurement, although further experiments are mandatory to determine if this departure is material-related or just a fixed value. Despite the reduction of CeO2 nanocubes has been captured with the surface-to-core spreading of a reduced phase, the nature of this shell still remains unclear. Future experiments based on Cu2O nanocubes will be used to cross-check this singular observation.

PS-05 (3), Lecture Theater 3, august 30, 2024, 10:30 - 12:30

Background incl. aims
Titanium dioxide (TiO2) nanoparticles (NPs) are extensively studied due to their versatile applications ranging from photocatalysis [1] and photovoltaics [2] to incorporation into food items as additives [3] . The reduction of these NPs to sub-stoichiometric TiO2-x, e.g., by solar light irradiation, exposure to inert or reducing atmospheres, or doping is garnering significant interest due to the reaction products superior physical properties compared to the unprocessed NPs. For instance, the introduction of Ti3+ species has been shown to prevent the recombination of photogenerated electron-hole pairs in TiO2 resulting in improved photoelectric properties. Similarly, Magneli TixOy based phases are highly desirable as electron transport layer (ETL) in dye-sensitised solar cells thanks to their high electrical conductivity, and chemical stability [4]. Here, we use state of the art in-situ electron microscopy to elucidate the evolution of the atomic structure, chemistry, and electronic structure of TiO2 anatase nanoparticles for ETL and photocatalysis applications.

Methods
We investigate at the atomic scale, the evolution of the microstructure in single-crystal anatase NPs, under variable temperature and in ultra-high vacuum environment, in an aberration-corrected monochromated Nion UltraSTEM100MC – Hermes Scanning Transmission Electron Microscope (STEM) operated at 60kV. The instrument is equipped with a cold field emission source, and can be monochromated down to an energy spread of around 6meV. STEM bright field (BF) and high-angle annular dark field (HAADF) images were acquired by rastering a 1Å corrected probe with a beam convergence half-angle of 30 mrad across the interfaces. The electron energy loss spectroscopy (EELS) spectrum images (SI) were acquired with a probe with an energy spread of 150 meV with a collection half-angle of 22 mrad using a Nion EEL spectrometer equipped with a Dectris ELA hybrid-pixel direct electron detector optimized for EELS acquisition at low acceleration voltages. The in-situ heating experiments were performed using a Protochips Fusion in-situ heating biasing adapter for Nion, and the temperature calibrated thermal E-chips from Protochips.

Results
STEM BF and HAADF imaging was used to observe the formation of extended defects during the annealing process of [111] oriented TiO2 NPs for which the {111} facets are known to exhibit high photocatalytic activity [5]. We observe the continuous growth of Ti2O3 trigonal structures (Fig.1) forming via Σ3 grain boundaries (yellow line) in the three corners of the {111} TiO2 anatase facet and between the Ti2O3 grains at a temperature as low as 300 ^{o}C. The formation of the Ti2O3 trigonal structures was further confirmed by spatially resolved monochromated electron energy loss

spectroscopy (EELS) measurements of the Ti L2,3 and O K edges at each stage of the annealing process. Specifically, we observed the change on the Ti L2,3 fine structure in the new domains, with the four characteristic multiplet peaks of the anatase near-edge structure (ELNES) broadening into two peaks more characteristic of a Ti2O3 trigonal structure alongside a shift toward a lower energy loss position: see Fig.(1,d-e). This ELNES change is known as a fingerprint of a Ti4+ to Ti3+ transition, confirming the imaging observations and the assignment of the newly formed domains to a Ti2O3 phase.

Conclusion
These observations are used to create realistic atomic models of the reduced and anatase phases, and of transitional structures observed during the experiments, which will be critical to develop a more fundamental understanding of possible unique electronic states forming at the Σ3 boundaries and their effect on the electron transport, including charge trapping, and other phenomena.

Poster Group 2

Aluminum alloys are notorious for the many phase transitions that can occur during precipitation heat treatment. Distinguishing these phases is challenging because many of them have only slight variations of their composition and lattice parameters. In this work, we characterized by TEM the evolution of the precipitation state during overageing (>1000h) of 2xxx series aluminium alloys. To identify the phases, a combination of automated crystal orientation mapping (ACOM) and energy dispersive X-ray spectroscopy (EDX) is implemented. Using standard ACOM setting (external CCD camera filming the phosphorescent screen) only one phase is identified in the heat-treated samples (the S phase), while using a direct electron detector, two phases are identified (the S and Q). The identification with the direct electron detector is consistent with the EDX observation. The potential benefit of direct electron detector cameras for phase recognition is discussed. We finally discuss how these observations improve the interpretation of complementary characterizations performed on this material, such as small angle X-ray scattering and hardness measurements.

Simulations of phonon and magnon EELS/EEGS including dynamical effects and multiple inelastic excitations

José Ángel Castellanos-Reyes[1], Paul Zeiger[1], Jan Rusz[1]
[1]Department of Physics and Astronomy, Uppsala University, Uppsala, Sweden

IM-05 (2), Lecture Theater 3, august 26, 2024, 14:00 - 16:00

Background incl. aims
Phonons and magnons play important roles in various technological applications. Phonons are essential for understanding heat flow at the nanoscale, while magnons hold promise as an information carrier (quasi-)particle for a new generation of hardware in information technologies. Instrumental advances, bringing high spatial resolution offered by scanning transmission electron microscopes (STEMs) together with high energy resolution and high dynamic range offered by direct electron detectors, offer an exciting route for studying these quasiparticles down to atomic scale [1-2].
However, the strong interaction between the electron beam and the sample, resulting in multiple elastic and inelastic scattering events, complicates the interpretation of experimental data and reliable theoretical predictions are thus of high importance.

Methods
We extend the quantum excitation of phonons method [3] to the spectroscopic domain. This is achieved by deriving a time-autocorrelation function of the so-called auxiliary wave-function and showing that it represents the desired spectral information. The exact quantum-mechanical evolution of the auxiliary wave-functions is approximated by scattering on a structure model with the atomic coordinates (or magnetic moment directions in the case of magnon EELS) evolving classically. Motion of atoms or precession of magnetic moments is simulated by molecular dynamics or atomistic spin dynamics, respectively.

Results
We present a derivation of a new theoretical framework that treats elastic and inelastic scattering on equal footing, including energy loss and gain processes, and effects of multiple elastic and inelastic scattering events [4]. The resulting simulation method remains flexible and efficient, and in comparison with recently introduced frequency-resolved frozen phonon multislice method (FRFPMS; [5]) it includes multiple inelastic scattering, doesn't require knowledge of Debye-Waller factors, and effectively includes anisotropic vibrations (or precession of magnetic moments) and non-local absorption effects of the elastic channel. We present the method on simulations of phonon EELS/EEGS on crystalline silicon and magnon EELS/EEGS for bcc iron and compare them to available data.

Conclusion
A new approach to simulations of phonon and magnon EELS has been presented. Comparison with FRFPMS and adiabatic magnon spectra from spin dynamics shows good agreement.

Background incl. aims
Very recently, bimetallic nanoparticles (NPs) are getting a lot of attentions due to their superior efficiency in heterogeneous catalysis and potential to replace conventional fossil fuels. Bimetallic systems showed superior stability, and superior activity compared to any of their individual metallic counterpart. In this aspect, Au@Pd core@shell NPs and recently Au-Pd nano-alloys has been used for electrocatalytic production hydrogen peroxide (H2O2), ethanol oxidation reactions and they observed to show much better catalytic activity compared to bare Pd nanoparticles. However, Au NPs are less efficient for oxygen reduction but highly efficient for conversion of alcohols to aldehyde, which is completely opposite to the catalytic activity of Pd. These limitations were repressed by alloying both systems (Au and Pd), but the lower electrochemical potential of the metal alloy contrast to the individual metals decreases its efficiency towards alcohol to aldehyde conversion reaction. Thus, it should be highly beneficial to construct a bi-metallic Au-Pd system where both the phases are separated from each other in a single nanoparticle. In such systems, the oxidation and reduction reactions will take place at totally different locations of the same nanoparticle, leading to more superior catalytic activity and stability. Such systems are unique in this sense, as they retain the individual properties of separate constituents and also provide physical, chemical, optical interaction between them due to the presence of a common interface [1]. However, obtaining bi-metallic nanoparticle based on phase separation method depends on the fact that the lattice mismatch between two constituent metals must be large (>5%, ex. Au-Ni, Au-Cu). Metals with lower lattice mismatch tend to create an alloy system due to complete miscibility in their all composition range at all the temperatures according to their bulk phase diagram (i.e. Au-Pd) [2]. Though theoretical researchers predicted a miscibility gap of an Au-Pd bimetallic system, the conversion of Au-Pd nanoalloy to phase separated Au/Pd bi-metallic system with annealing could not be observed till now. Okamoto et. Al. observed Au-Pd alloy formation in face centered cubic (fcc) structure at high temperature for all Pd composition range [3]. Wu et. Al. observed formation of an alloyed nanoparticle upon in-situ heating of a core@shell Au@Pd nanostructure up to 600°C [4]. Precot et. al. studied the annealing effect of Au-Pd nanoparticles deposited on amorphous carbon at 873K and observed bi-modal distribution of nanoparticle upon annealing, where small nanoparticle and big nanoparticles became Au-rich and Pd-rich, resulting a bi-modal distribution of nanoparticles driven by Ostwald ripening mechanism [5].
We have shown by in-situ vacuum annealing high-resolution transmission electron microscopy (HRTEM) study of the generation of phase separated Au-Pd bimetallic nanoparticles from an initial Au nanotriangle (AuNT)@Pd core@shell nanoparticle system. We have observed through extensive aberration-corrected HRTEM, high-resolution scanning TEM (HRSTEM) and energy-dispersive X-ray spectroscopy (EDS) that the core@shell Au@Pd nanostructure forms an Au-Pd alloy during in-situ heating at 400°C and is very much stable up to 800°C, which is a completely normal behavior. Upon further heating at 900°C-1000°C range, the Au and Pd phase surprisingly got separated from each

other and the separation is observed to be much prominent for initial core@shell NPs with higher Pd loading.

Methods

Au nanotriangles (AuNT) were produced by a previously described seedless method. Thickness of Pd layer was controlled by controlling the amount of H2PdCl4 in the AuNT solutions. The nanoparticles were initially identified by UV-Visible and X-ray photoelectron spectroscopy (XPS) technique. The in-situ HRTEM and selected area diffraction (SAD) studies were performed in an image-corrected FEI TITAN operated at 300 kV. HRSTEM, energy dispersive X-ray spectroscopy (EDS) analyses were carried out in a probe-corrected FEI TITAN TEM equipped with high-brightness gun and an Oxford Instruments Ultim X-MaxN 100TLE detector for EDS measurements. A DENSsolutions Wildfire MEMS based double-tilt heating holders was used for the in-situ heating measurements. The heating circuits were fabricated on a SixNy membrane and it can measure temperature until 1300 °C. A very dilute solutions of the AuNT nanoparticles were drop casted on the heating chips and kept overnight for drying.

Results

We have extensively studied the interface and surface of bare AuNT and AuNT@Pd core@shell nanostructures and identified presence of number of defects at the Au/Pd interfaces (i.e. stacking-faults, dislocation pair etc.). Also, the melting point of bare AuNT is observed to be lower compared to the Pd doped sample and the melting point seemed to be increasing with increase in Pd content. Besides that, the relative change in lattice parameter with in-situ heating was also studied for bare NT and AuNT@Pd with different Pd thickness using fast Fourier transform (FFT) method and we observed the change in lattice parameter of (220) plane is much lesser for Au-Pd alloy compared to bare AuNT. However, the most important observation was the phase separation of Au-Pd alloy triangular nanostructure producing distinctive Au and Pd region at higher temperature which was verified by HRTEM and EDS measurement. The Pd region increased in size with higher Pd loading. The in-situ microscopy reveals the Pd atoms outward movement from the core due to their higher mobility at high temperature while Au atoms move inwards to finally produce a phase separated structure. This structure was also observed to be very stable as the EDS spectra taken from the sample at room temperature after 7 days revealed that the nanoparticle still remains in the phase separated form.

Conclusion

We have done in-situ heating experiment on bare AuNT and AuNT@Pd core@shell nanostructure up to 1000°C. The Pd deposited AuNT showed much more stability in terms of structure and thermal resistance as observed. Most importantly, though Au and Pd are miscible in all temperature range and all compositions. We observed when Pd content is higher, it can produce phase separated region at High temperature which was observed to be very much stable in ambient atmosphere over a month. This result will be of very much important to understand not only the catalytic activity of Au-Pd alloy but also to produce phase separated bi-metallic nanostructure consisted of separated Au and Pd region for superior catalytic activity.

4D-STEM Post measurement machine learning enhanced aberration correction for amorphous and magnetic samples

Maximilian Töllner[1], Xiaoke Mu[3], Di Wang[1], Christian Kübel[1,2]
[1]Institute of Nanotechnology - KIT, Karlsruhe, Germany, [2]KNMFi, Karlsruhe, Germany, [3]School of Materials and Energy and Electron Microscopy Centre, Lanzhou University, Lanzhou, China

Poster Group 2

High-resolution transmission electron microscopy is one technique to resolve the atomic structure of materials. However, the phase information of the exit-wave is lost. Therefore, 4D-STEM techniques such as ptychography were developed to retrieve the phase information and enhance the resolution. Even so electron ptychography is used frequently on different material systems, imaging the domain structure of magnetic samples remains challenging. This is due to the fact that for magnetic imaging the objective lens needs to be switched off and the aberration corrector becomes obsolete. This would decrease the resolution limit.
This work is a first step to achieve aberration free high-resolution imaging of magnetic domains in the field-free mode (objective lens is off). This is needed to avoid the interaction between the strong magnetic field of the objective lens with the magnetic sample.
It has been previously shown that 4D-STEM datasets can be used to remove residual aberrations in high resolution images of crystalline samples[1]. This work builds on the previous work and transfers it to objective lens free operations in which the probe corrector cannot be used. The largest issue in lens-free operations is that the spherical aberrations cannot be corrected. Additionally to field free measurements, this method can also be used for post processing 4D-data on amorphous samples like polymers or metallic glasses in which the probe correction was not ideal.
For the reconstruction of the aberrations, the Single-Side Band(SSB) ptychography method is used for gaining information about the aberrations. The SSB method is a direct reconstruction method, which is performed by making a Fourier transform of the real space. It should be noted that in the field-free mode, the Fourier transform of a brightfield image does not show sharp spots, but a more diffusely spread intensity distribution. As an example, a gold cross grating imaged at low magnification is shown in figure 1a and its Fourier transform in 1d. In order to remove the higher-order aberrations to improve the phase reconstruction, more SSB patterns need to be selected, in comparison to the method that relies on crystalline samples. This is due to the previously mentioned diffuse distribution of the intensity in the Fourier space which is then visible as noise in the SSB-patterns as shown in figure 1b. A minimum number of 20-30 patterns are needed to achieve good results. To index these patterns the knowledge of the position of the discs needs to be known see figure 1b. The position was accurately indexed by using artificial intelligence (AI), which measures the angle and the distance between the discs. The training data of the artificial intelligence was simulated to look as close as possible to real measurements. Since the amount of data for training an AI needs to be large and it needs a large amount of computational power to simulate thousands of 4D-STEM datasets. The SSB datasets have been calculated directly without running a full simulation. For this a list of object function was created, the distances, the angles between the discs and the aberrations were selected randomly. After the indexing of the patterns the aberrations are calculated in the same way as previously shown by Ning et al. in [1]. The resulting SSB phase images show that the aberrations have been corrected compare figure 1c and 1e. The resulting data can then be used to be further processed by an iterative ptychography method like the extended ptychographic iterative engine(ePIE).

PS-11, Lecture Theater 2, august 28, 2024, 14:00 - 16:00

Background: The optical properties of luminescent materials are intricately tied to their structural and chemical characteristics at the nanometric, or even atomic scale. Understanding this relationship has long relied on the combination of scanning transmission electron microscopy (STEM) with external optical techniques such as absorption or photoluminescence spectroscopies, probing the excitation and emission mechanisms at the micrometric scale. However, the significant gap in spatial resolution between these methods and phenomena of interest often leads to ambiguous or even impossible interpretations of the measurements. Recent advancements in nano-optics seek to address this resolution disparity by enabling observation of luminescent material properties at nanometric scales. In that sense, STEM has undergone substantial instrumental and theoretical progress, providing valuable insights into optical properties through conventional inelastic electron scattering (electron energy loss spectroscopy, EELS) and photon emission (cathodoluminescence, CL) spectroscopies [1]. However, both techniques are hindered by spectral resolution limitations and the broadband excitation process of the electron beam. This contribution investigates the possibilities presented by the latest advancements in STEM techniques, specifically focusing on electron-photon time-correlations.
Methods: To overcome these challenges, two techniques currently in development will be highlighted in this contribution:

- Cathodoluminescence Excitation Spectroscopy (CLE, Figure 1b), based on coincidence measurements between EELS and CL events. CLE offers insights into energy transfer pathways and excitation lifetimes at the nanometer scale, as previously reported [2,3].
- Electron Energy Gain Spectroscopy (EEGS, Figure 1c), an extension of the photon-induced near-field electron microscopy (PINEM) technique, investigates primary electron acceleration when the beam interacts with a strong optical field generated by a laser. By changing the energy of the photons, this technique can resolve ultra-fine optical resonances in the sub-meV range, revealing novel physical properties below the energy resolution achievable with state-of-the-art monochromated electron beams. So far, it has only been applied to photonic excitations, such as plasmons or surface polaritons [4].

Results and Conclusion: These techniques, with their distinct excitation and deexcitation processes (Figure 1a), are expected to be highly complementary, offering deeper insights into optical mechanisms at the nanometer scale. The present contribution focuses on using transition metal dichalcogenides (TMDs) as a model system of functional luminescent material to explore the insights provided by these correlated techniques.

Laser particle acceleration in an ultrafast scanning electron microscope

Leon Brückner[1], Tomas Chlouba[1], Roy Shiloh[1], Stefanie Kraus[1], Julian Litzel[1], Peter Hommelhoff[1]
[1]Physics Department, Friedrich-Alexander-Universität Erlangen-Nürnberg, Erlangen, Germany

Poster Group 2

Background incl. aims

Ultrafast electron microscopy is rapidly approaching the limits of electron microscopes in terms of electron pulse length (typically hundreds of femtoseconds) and beam energy (up to 30 keV for a SEM and about 300 keV for a TEM). A miniaturized particle accelerator inside a microscope could overcome these limits by providing a beam of high-energy, ultrashort electron bunches. Dielectric laser acceleration (DLA) aims to achieve this by utilizing pulsed laser light for generating the accelerating field. The high damage threshold of dielectric materials could exceptionally high acceleration gradients of up to several GeV/m [1].
A DLA nanostructure typically consists of two rows of silicon pillars that are illuminated with an infrared laser pulse, which creates an oscillating nearfield mode with a phase velocity given by the period of the structure. Electrons are then injected into the channel in between the pillars with velocity (energy) corresponding to the phase velocity of the nearfield mode which ensures phase-matching and thus efficient energy transfer. By adding a buncher stage, additionally attosecond bunch trains can be generated over very short distances [2].

To allow acceleration over long distances, it is necessary to confine the particle beam transversally in order to prevent particle losses. This is realized by exploiting the transverse forces exerted by the nearfield. By incorporating periodic gaps in the structure design, we can instantly change the phase of the propagating electrons and thus alternate at will between transversally focusing and defocusing forces. With this scheme, beam transport over a distance of 78 µm has been demonstrated [3]. Combining guiding with a tapering of the structure period and the periodic gaps, we demonstrated coherent, phase-matched acceleration over long distances [4,5]. This enables significant energy gains, opening the door towards useful applications of these miniaturized accelerators.

Methods

We have designed and fabricated a 500 µm long acceleration structure with an average gradient of 22.7 MeV/m [4]. In the experiment, an ultrafast SEM serves as the electron source. Ultraviolet laser pulses with a duration of 150 fs are focused onto the SEM tip cathode, emitting electron pulses with a mean energy of 28.4 keV and a pulse length of the order of 700 fs at the sample. The DLA structure is illuminated with a 1.93 µm, 250 fs long laser pulse with a pulse energy of 2.2 µJ that is focused to an elongated spot of 640 µm beam waist along and 13 µm transverse to the structure, creating the design peak field strength of around 600 MV/m. The laser pulse front is tilted by 71° to ensure optimal temporal overlap between electrons and the light field along the propagation. The electron energy is measured with a magnetic spectrometer.

Results

The accelerator demonstrates successful capture, confinement and acceleration of electron bunches. The 500 µm long acceleration structure shows an energy gain of the accelerated bunch of 12.3 keV, meaning a relative gain of 43% and a total energy of 40.7 keV, as predicted by simulation [4].

Conclusion

With careful design and extension of the interaction length, this energy gain could be increased much further, potentially enabling high-energy TEM imaging or electron diffraction in SEMs, for example. Exploring different combinations of dielectric materials with high damage thresholds and excitation wavelengths, particularly in the mid-infrared, will give access to acceleration gradients far in excess of those demonstrated here.

Background incl. aims
Very recently, bimetallic nanoparticles (NPs) are getting a lot of attentions due to their superior efficiency in heterogeneous catalysis and potential to replace conventional fossil fuels. Bimetallic systems showed superior stability, and superior activity compared to any of their individual metallic counterpart. In this aspect, Au@Pd core@shell NPs and recently Au-Pd nano-alloys has been used for electrocatalytic production hydrogen peroxide (H2O2), ethanol oxidation reactions and they observed to show much better catalytic activity compared to bare Pd nanoparticles. However, Au NPs are less efficient for oxygen reduction but highly efficient for conversion of alcohols to aldehyde, which is completely opposite to the catalytic activity of Pd. These limitations were repressed by alloying both systems (Au and Pd), but the lower electrochemical potential of the metal alloy contrast to the individual metals decreases its efficiency towards alcohol to aldehyde conversion reaction. Thus, it should be highly beneficial to construct a bi-metallic Au-Pd system where both the phases are separated from each other in a single nanoparticle. In such systems, the oxidation and reduction reactions will take place at totally different locations of the same nanoparticle, leading to more superior catalytic activity and stability. Such systems are unique in this sense, as they retain the individual properties of separate constituents and also provide physical, chemical, optical interaction between them due to the presence of a common interface [1]. However, obtaining bi-metallic nanoparticle based on phase separation method depends on the fact that the lattice mismatch between two constituent metals must be large (>5%, ex. Au-Ni, Au-Cu). Metals with lower lattice mismatch tend to create an alloy system due to complete miscibility in their all composition range at all the temperatures according to their bulk phase diagram (i.e. Au-Pd) [2]. Though theoretical researchers predicted a miscibility gap of an Au-Pd bimetallic system, the conversion of Au-Pd nanoalloy to phase separated Au/Pd bi-metallic system with annealing could not be observed till now. Okamoto et. Al. observed Au-Pd alloy formation in face centered cubic (fcc) structure at high temperature for all Pd composition range [3]. Wu et. Al. observed formation of an alloyed nanoparticle upon in-situ heating of a core@shell Au@Pd nanostructure up to 600°C [4]. Precot et. al. studied the annealing effect of Au-Pd nanoparticles deposited on amorphous carbon at 873K and observed bi-modal distribution of nanoparticle upon annealing, where small nanoparticle and big nanoparticles became Au-rich and Pd-rich, resulting a bi-modal distribution of nanoparticles driven by Ostwald ripening mechanism [5].
We have shown by in-situ vacuum annealing high-resolution transmission electron microscopy (HRTEM) study of the generation of phase separated Au-Pd bimetallic nanoparticles from an initial Au nanotriangle (AuNT)@Pd core@shell nanoparticle system. We have observed through extensive aberration-corrected HRTEM, high-resolution scanning TEM (HRSTEM) and energy-dispersive X-ray spectroscopy (EDS) that the core@shell Au@Pd nanostructure forms an Au-Pd alloy during in-situ heating at 400°C and is very much stable up to 800°C, which is a completely normal behavior. Upon further heating at 900°C-1000°C range, the Au and Pd phase surprisingly got separated from each

other and the separation is observed to be much prominent for initial core@shell NPs with higher Pd loading.

Methods

Au nanotriangles (AuNT) were produced by a previously described seedless method. Thickness of Pd layer was controlled by controlling the amount of H2PdCl4 in the AuNT solutions. The nanoparticles were initially identified by UV-Visible and X-ray photoelectron spectroscopy (XPS) technique. The in-situ HRTEM and selected area diffraction (SAD) studies were performed in an image-corrected FEI TITAN operated at 300 kV. HRSTEM, energy dispersive X-ray spectroscopy (EDS) analyses were carried out in a probe-corrected FEI TITAN TEM equipped with high-brightness gun and an Oxford Instruments Ultim X-MaxN 100TLE detector for EDS measurements. A DENSsolutions Wildfire MEMS based double-tilt heating holders was used for the in-situ heating measurements. The heating circuits were fabricated on a SixNy membrane and it can measure temperature until 1300 °C. A very dilute solutions of the AuNT nanoparticles were drop casted on the heating chips and kept overnight for drying.

Results

We have extensively studied the interface and surface of bare AuNT and AuNT@Pd core@shell nanostructures and identified presence of number of defects at the Au/Pd interfaces (i.e. stacking-faulst, dislocation pair etc.). Also, the melting point of bare AuNT is observed to be lower compared to the Pd doped sample and the melting point seemed to be increasing with increase in Pd content. Besides that, the relative change in lattice parameter with in-situ heating was also studied for bare NT and AuNT@Pd with different Pd thickness using fast Fourier transform (FFT) method and we observed the change in lattice parameter of (220) plane is much lesser for Au-Pd alloy compared to bare AuNT. However, the most important observation was the phase separation of Au-Pd alloy triangular nanostructure producing distinctive Au and Pd region at higher temperature which was verified by HRTEM and EDS measurement. The Pd region increased in size with higher Pd loading. The in-situ microscopy reveals the Pd atoms outward movement from the core due to their higher mobility at high temperature while Au atoms move inwards to finally produce a phase separated structure. This structure was also observed to be very stable as the EDS spectra taken from the sample at room temperature after 7 days revealed that the nanoparticle still remains in the phase separated form.

Conclusion

We have done in-situ heating experiment on bare AuNT and AuNT@Pd core@shell nanostructure up to 1000°C. The Pd deposited AuNT showed much more stability in terms of structure and thermal resistance as observed. Most importantly, though Au and Pd are miscible in all temperature range and all compositions. We observed when Pd content is higher, it can produce phase separated region at High temperature which was observed to be very much stable in ambient atmosphere over a month. This result will be of very much important to understand not only the catalytic activity of Au-Pd alloy but also to produce phase separated bi-metallic nanostructure consisted of separated Au and Pd region for superior catalytic activity.

Background incl. aims
The noise model of a detector's counting process is known as Poisson shot noise. However, direct reconstruction algorithms like single-sideband (SSB) or Wigner-distribution deconvolution (WDD) do not assume a specific noise model. This is not the case for gradient descent-based iterative methods that allow the free choice of the loss function and, therefore, the underlying noise model. In practice the mean square error (MSE), also known as L2 loss, is often used, which assumes Gaussian white noise. This is a good approximation for the Poissonian statistics for high counts.
In contrast, the (extended) iterative engine (e)PIE assumes no specific noise model. However, Melnyk showed that ePIE can be seen as a particular case of stochastic gradient descent using the MSE Loss on the amplitudes instead of the intensities [1], which we will call the Amplitude loss function in the following. The amplitude loss can be derived from the Poisson loss function via a Taylor expansion, assuming that the specimen guess is close to the original specimen [2] and, therefore, an approximation of the Poisson loss.
The interest in using STEM for low-dose applications has grown in recent years, e.g., to examine dose-sensitive, weakly scattering specimens like covalent or metal organic frameworks (COFs/MOFs), or 2D materials. Moreover, the interest rises to explore STEM for imaging proteins and lamellae of cells [3, 4, 5], which are very dose-sensitive. Therefore, we perform a detailed analysis of the influence of the loss function on the reconstruction accuracy using a gradient descent approach for the L1, MSE, amplitude and Poisson losses.
Methods
We used a MoS_2 monolayer as a test case to perform STEM simulations and experiments. Simulations were conducted with an acceleration voltage of 60 kV and 300 kV with a convergence semi-angle of 18 mrad, in focus with a dose of 10^6 electrons per diffraction pattern. The high-dose case is of particular interest because the dark field (DF) contains very few counts.
To better understand the loss functions, we compare different virtual detector geometries. Firstly, we compare the results of the full pixelated detector for 300 kV and 60 kV. Subsequently, only an acceleration voltage of 300 kV is used. Secondly, we use the pixelated bright field (BF) disc in combination with virtual ring detectors for the dark field. Thirdly, we use only the BF disc. The results suggest that the choice of the loss function makes a difference if a wide dynamic range of electron counts is measured. Therefore, we explore the BF disc again, but this time with more features in the BF disc introduced by an under-focused electron probe of 25 nm. Finally, we go back to the first case using 300 kV and stepwise reduce the dose to 10000 and 100 electrons per diffraction pattern for sparse-count dark field studies.
Results
Figure 1 depicts reconstruction results using different loss functions and high (left) as well as low (right panels) dose. The differences between the reconstructed objects using various loss functions are significant if the signal involves a wide dynamic range of electron counts. This applies to the high-

dose case (left) in which the signal levels of the BF disc and the DF differ significantly. It is best seen in the power spectra (c) where Poisson and Amplitude losses lead to reconstructed object transmission functions containing the highest spatial frequencies, followed by the L1 loss result. Note that only the Poisson loss leads to a flat spatial frequency transfer, whereas the other methods pronounce Fourier coefficients within a band of twice the probe-formin aperture radius. The line profile in (d) exhibits the sharpest peaks for the Poisson loss. Chemical contrast between a Mo monomer and S dimer is only represented in the phase of the Poisson and amplitude loss functions, respectively.
An electron dose of 100 electrons per diffraction pattern on the right of Fig. 1 appears as a limiting case for all losses considered here, with the Poisson loss still performing best. However, the difference to the MSE loss becomes smaller than for the high-dose case.
The counts in the DF are sparse, so we used virtual ring detectors for the DF to perform an azimuthal integration to get a more robust measurement. In this case, the differences between the loss functions became smaller and the chemical contrast accessible. Excluding the dark field counts and only using the BF, all loss functions lead to comparable reconstructions because the dynamic intensity range in the BF itself is rather small. Moreover, the introduction of more features into the BF disc by an under-focus increases the dynamic range slightly, but the variation is too small to pronounce one of the loss concepts against others.
Conclusion
Our results show that the differences between the loss functions become large for a broad dynamic range of electron counts, which is the case for high-dose measurements when the BF and DF are of interest at the same time, is relevant for chemical contrast found accurately represented in the phase of the Poisson loss based reconstruction. The MSE loss assumes a constant Gaussian noise distribution and the same standard deviation for all pixels. In contrast, the standard deviation of the Poisson loss scales with the square root of the number of counts. This makes a difference for a wide dynamic range in measurements and is consistent with our results. Our results suggest that the differences between the MSE and Poisson loss become small for dose-sensitive materials because sparse counts are measured and, as a result, a very low dynamic range. However, the Poisson loss is still beneficial at high frequencies and shows a lower variance of the reconstruction. In addition to the simulations, our study includes dose-dependent MoS_2 measuremts as well, which will be used to demonstrate the reliability of the theoretical findings in practice.

Background incl. aims
The colorful patterns displayed by longhorn beetles Doliops similis (Cerambycidae: Laminae) are formed by opalescent photonic structures confined within their cuticular scales [1]. The layers of packed nanospheres produce opalescent green colour. The morphogenesis of the nanoparticles in each scale and their self-assembly into opal-structures are unknown. We wish to employ correlative and multimodal imaging in our workflow that combines FIB/SEM volume imaging with super resolution microscopy of intact scales in order to monitoring the organic molecules distribution in the scale and in the photonic crystals.

Methods
Focus Ion Beam Scanning Electron Microscope (FIBSEM) was used to collect sequential images with voxel size of 5 nm. 3D model of 3580x 840x 270 voxels FIB-SEM stack at 5 nm resolution. Data were segmented by binarization after denoising (n2v [2]) and oriented domains were extracted using customized pipeline derived from the open source bmmltools [3].
With Fourier-transform Infrared Spectroscopy (FTIR), Small/Wide Angle X-ray Scattering and X-ray Fluorescence (SAXS/WAXS/XRF), we are able to measure the compositions in the scale, in the skin of the scale, and in the photonic crystals. Complemented with Depth-profiling Time-of-Flight SIMS (TOF-SIMS), X-ray Photoelectron Spectroscopy (XPS, NEXA G2, Thermofisher Scientific), we can understand the distribution and binding states of components with high resolution (<10 nm) in axial direction of an intact scale (60 x 40 x 5 um).

Results
We demonstrate that these needle-like scales contain a core-shell structure with a thin cuticular skin and an inner core of agglutinated amorphous calcium phosphate nanospheres (ACP, diameter of 160 nm). The spheres assemble into hexagonally close-packed layers along the surface normal of the scale, producing hence a uniform and intense green reflection colour. We successfully located the chitin fibers in the skin by applying chitin-binding proteins on sections of scales and visualized the distribution of chitin/proteins in the skin of the scales [4].

Conclusion
Our results show the D.similis longhorn beetles are able to produce highly-orderred arranged ACP nanoparticles within every micrometer-sized scale. From our preliminary results of IR, TOFSIMS, XPS, and super resolution microscope (Zeiss Elyra Sim2), we observed the co-existence of short chain lipids with the ACP nanoparticles in the core of the scale. Such observation seems an agreement with one of the hypotheses in biomineralization that the arrangement of chitin and (lipo-)protein at the interface of the cuticular shell and mineraloid core mediates the packing of the nanospheres [5]. To

address this hypothesis, we wish to employ tissue clearing methods with correlative imaging to observe the networks and conformations of organic molecules in the intact scale and their association with the ACP opal photonic crystals.

IM-03 (2), Plenary, august 28, 2024, 14:00 - 16:00

Structural biology, which primarily focuses on the tertiary structure of biological molecules, has played a pivotal role in disease research, drug development, and the investigation of fundamental biological processes. Recently, the growing demand for more precise determination of three-dimensional biological structures using single particle analysis (SPA) or electron tomography (ET) necessitates high-quality two-dimensional projection images with both strong contrast and high resolution. Nevertheless, due to the fact that unstained biological samples are primarily composed of light elements and their structures are extremely radiation sensitive, which means that the electron dose used for imaging is limited, the contrast of biological samples in electron microscope images is very weak. To address this issue, phase contrast imaging at high defocus or novel phase plates is commonly employed. However, using high defocus corrupts information transfer at high spatial frequencies and the applications of phase plate attenuate signals from biological samples at high frequencies. Therefore, there is currently no technological means available to achieve imaging of non-stained biological samples with both strong contrast and high resolution simultaneously.
Electron ptychography has gained considerable interest in materials science and bioimaging, which has been recently reviewed1. However, the contrast transfer function of electron ptychography strongly relies on the selected convergence angles. In materials science, by employing a large convergence angle, ptychography has been demonstrated to achieve deep sub-angstrom resolution, whereas in the field of bioimaging, a small convergence angle tends to be used to enhance contrast of unstained biological samples at the expense of resolution2,3. In other words, conventional electron ptychography still fails to provide images with simultaneous strong contrast and high resolution.
Here, we introduce a novel ptychographic method, Multi-Convergence-Angle (MCA) Ptychography4. Our research addresses the current limitations of conventional ptychography and presents a promising approach for achieving high-quality two-dimensional images with improved clarity and precision.

The schematic experimental setup of MCA-ptychography is illustrated in Fig. 1(a). In contrast to conventional electron ptychography, which employs a single convergence angle (hereafter referred to as single-convergence-angle ptychography or SCA-ptychography), MCA-ptychography utilizes multiple condenser apertures with varying diameters to modify the convergence angles of the electron probe during the scanning process. However, such a device with the aperture-switching

capability is not currently available for electron microscopes. Therefore, as a proof of concept, we performed MCA-ptychography in series by acquiring the first dataset with one aperture for the entire scanning area and subsequently switching to the other aperture to acquire the second dataset for the same area. The two SCA-ptychographic datasets are mixed before reconstructing the object wavefunction via MCA-ptychography reconstruction algorithm.

A model of GroEL protein (PDB: 2eu1) suspended on a monolayer graphene substrate was simulated using the multislice method5. Two ptychographic datasets were generated at an accelerating voltage of 300 kV and convergence semi-angles of 3 mrad and 15 mrad, respectively. These two datasets were combined into a single dataset (mixed-angle dataset) and subsequently subjected to MCA-ptychographic reconstruction. The SCA-ptychographic reconstructed results at 3 mrad and 15 mrad, together with the MCA-ptychographic reconstructed result at different electron doses, are presented in Fig. 2. It is evident from the graph that SCA-ptychography at a smaller convergence angle provides strong contrast but limited resolution, while SCA-ptychography at a larger convergence angle achieves higher resolution albeit with weaker contrast. In contrast, MCA-ptychography not only provides strong contrast but also achieves high resolution. Furthermore, we found that even when the electron dose drops to as low as 11 e-/Å2, MCA-ptychography still maintain its robustness while providing simultaneous strong contrast and high resolution.

In conclusion, we propose a novel ptychographic method, MCA-ptychography, which incorporates multiple convergence angles during the data acquisition process and demonstrate its capability to provide simultaneous strong contrast and high resolution. Our research addresses the current limitations of conventional ptychography and in the future, we anticipate the integration of MCA-ptychography with cryo-electron microscopy, which will further enhance 2D projection images, leading to improved 3D reconstruction methods.

STEM-EELS unveils atomic stacking in 2D MoSe2 ECM memristors.

Dr Khalil El Hajraoui[1,2], Dr Andrea Capasso[3], Mr Guilherme Araújo[3], Dr Demie Kepaptsoglou[1,2], Prof Quentin. M Ramasse[1,4]

Poster Group 2

Background incl. aims
Memristors, short for 'memory resistors', are two-terminal electronic devices whose resistance can be modulated by previous voltage and current inputs. As such, memristors can act as both processing and storage units, enabling computation within the memory subsystem itself, with high-speed switching and low power consumption [1],[2]. An electro-chemical metallization (ECM) memristor consists of a solid electrolyte layer (acting as an ion conductor) sandwiched between an electrochemically active electrode (usually Cu or Ag) and an inert electrode (such as Au or Pt) [3]. The device switches to an ON state when a positive voltage induces the formation of a metallic filament between the electrodes (SET), maintaining this state until a negative voltage dissolves the filament (RESET) [4]. Recently, 2D materials such as hexagonal boron nitride (h-BN) and transition metal dichalcogenides (TMDs, e.g.,MoSe2) have been integrated into memristor designs [5]. With their atomic thickness and suitable electrical/electronic properties, these materials have the potential to enable ultra-low switching voltages, a critical feature for neuromorphic computing and artificial synapses. In this work, we study a vertical ECM cell composed of chemical vapor deposited (CVD) few-layers MoSe2 sandwiched between a Au bottom electrode (BE) and a Cu top electrode (TE) in a cross-bar configuration (5×5 µm2). The metallic electrodes were patterned by ultra-violet (UV) lithography, while the MoSe2 film was transferred to the device and selectively etched by O2 plasma prior to the TE deposition. I-V measurements, performed using a two-terminal configuration, demonstrated bipolar resistive switching with SET and RESET voltages of 0.75V and - 0.95V, respectively, corresponding to the low and high resistive states (LRS, HRS) (see Fig. 1a). This macroscopic observation suggests the successful formation of conductive filaments (CFs) between the two electrodes.

Methods
To visualise the CFs formed in the cross-bar device, focused ion beam (FIB) lamellae were prepared from the operated devices (that demonstrated electrical switching) in a Hitachi Ethos NX5000 dual FIB-SEM instrument. Standard FIB protocol for low-kV STEM observations was followed to prepare these lamellae with extra care on reducing the ion milling time at 30kV to limit Ga+ damage on the MoSe2 film. Final 1kV argon (Ar+) polishing was applied for 4 min directly within the FIB-SEM instrument using a dedicated 'third beam' Ar+ source to remove remnant surface damage from the low-kV milling. These lamellae were investigated at atomic resolution in an aberration-corrected Nion UltraSTEM100 dedicated Scanning Transmission Electron Microscope (STEM) operated at 60kV. The instrument is equipped with a cold field emission source with a nominal energy spread of 0.3 eV. STEM High-angle annular dark field (HAADF) images were acquired by rastering a 1Å corrected probe with a beam convergence half-angle of 30 mrad across the interfaces. The EELS spectrum images (SI)

were acquired with a collection half-angle of 44 mrad using an Enfina EEL spectrometer retro-fitted with a MerlinEM direct electron detector optimized for EELS acquisition at low acceleration voltages.

Results

The HAADF images of the devices confirmed the presence of clean Cu/MoSe2/Au interfaces in most of the investigated regions, as displayed in Fig. 1b-d, where the atomic-scale crystalline structure of each material is apparent. This confirms the successful fabrication process and the absence of residues at the interfaces, resulting in the expected electrical contact between the layers [5]. Furthermore, the HAADF image in Fig. 1d shows the hexagonal order confirming the semiconducting character of the CVD-grown MoSe2 film, essential for a good ohmic-contact at the TE/MoSe2 interface in HRS. However, a number of sections of the interface between the MoSe2 and the respective BE and TE showed a non-perfect adhesion, resulting in 'gaps' seen as darker contrast along the interface between the materials (see Fig. 1b-d). EELS maps were acquired across the interfaces to clarify their chemistry at the atomic scale, and to identify the location of Cu after the biasing cycles undergone by the devices. The Cu and Se EELS maps in Fig. 1f, obtained from integration of the Cu and Se L2,3 edges, show that Cu appears to have diffused into the MoSe2 layers and beyond. A continuous Cu layer is observed at the BE surface, filling the 'gap' between the MoSe2 and the BE. The presence of Cu in MoSe2 layer could be linked to the formation of Cu CFs during the HRS and LRS cycles, while the Cu layer at the BE surface might be ascribed to the fabrication process. For the latter, the presence of discontinuities in the MoSe2 film (possibly connected to its morphology and/or transfer process) could allow the infiltration of Cu during the TE sputtering process.

Conclusion

Cu diffusivity is a big hurdle in device fabrication. Our results highlight its presence at the atomic scale, even in macroscopically functional devices. A number of solutions could be proposed to limit its effect starting by using a less energetic deposition process such as electron-beam deposition process, a low-cost process compatible with industrial large production. Furthermore, our findings show that atomic STEM-EELS characterisation of 'real-life' 2D MoSe2 based memristor devices is possible, providing new insights and paving the way towards a better understanding of memristor's working mechanisms and a potential optimisation in the device fabrication process.

Study of metal powders oxidation by means of Energy Dispersion Spectroscopy (EDS)

Dr. Matteo Giardino[1,2], Dr. Federico Simone Gobber[1,2], Mr. Antonio Pennacchio[1], Prof. Marco Actis Grande[1,2]
[1]Department of Applied Science and Technology (DISAT), Politecnico di Torino, Alessandria, Italy, [2]RU Torino Politecnico, Consorzio INSTM, Firenze, Italy

Poster Group 2

Background incl. aims
Energy Dispersion Spectroscopy (EDS) is a very common technique for elemental composition characterization based on the capacity of specimens to produce characteristic X-rays when illuminated by an electron beam.
Different works have already described the possibility of using EDS for the determination of the thickness of metal and oxide thin film. Such approaches usually rely on the simulation of EDS spectra by means of Monte Carlo method-based algorithms.
The aim of this work is to apply EDS for the determination of the thickness of the oxide layer formed onto the surface of copper alloy powder during its storage in order to provide a tool to rapidly assess the “goodness” of the powder and its compatibility with the laser-based additive manufacturing processes.

Methods
Powder of CuAg 3.4 alloy was prepared via a gas atomization process (VIGA) and sieved to obtain a size distribution compatible with additive manufacturing processes by laser bed powder fusion (LBPF) technique.
The powder was then divided into two batches and stored for 1 month under different conditions. In particular, the first batch was stored under dry Argon whereas the second was stored at room conditions.
The chemical composition of the surface of a CuAg 3.4 alloy powder was investigated by means of Raman spectroscopy using a Renishaw InVia Raman confocal microscope using an excitation wavelength of 633 nm. The optical response of the powder was recorded in diffuse reflectance mode (incidence at 0°) using a Shimadzu UV-2600 UV-visible spectrophotometer equipped with an ISR2700 plus integration sphere.
EDS spectra were recorded using a Zeiss EVO 15 SEM equipped with a Peltier-cooled Oxford Ultim Max 40 EDS detector.
EDS spectra of CuAg 3.4 particles coated with different thicknesses of cupric oxide (CuO) layer were simulated using the WinMCXRay.

Results
From UV-Vis and Raman spectra, it was concluded that the inert sample developed a mixed Cu2O/CuO oxide layer of 5.4 nm thickness whereas the oxidized sample exhibited a thicker layer (15.3 nm) composed mainly of CuO.
Using the WinMCXRay tool, the EDS spectra of CuAg 3.4 particles coated with an oxide layer of different was simulated, and the γ was defined as the ratio between the x-ray count at 0.525 keV (Cu Kα) and 0.931 keV (Cu Lα).

EDX spectra of the two samples were collected under different beam acceleration tension conditions in the range from 3 kV to 12 kV, using a beam current of 800 pA.
After background removal, the value γ was calculated on the experimental spectra and the obtained value was compared with the simulated data to determine the oxide layer thickness t_CuO. For simplicity, we assumed that the oxide layer is composed of CuO only.
We obtained a value of t_CuO=4.6 nm and t_CuO=16.1 nm for the inert and oxidized samples, respectively.

Conclusion

Energy dispersion spectroscopy was revealed to be a very useful and effective tool for assessing the extent of surface oxidation on metal powder. The oxide layer thickness evaluated by EDS are in good agreement with the estimation obtained from the UV-visible measurements and confirm the validity of the adopted procedure.
The possibility of measuring the oxide thickness without the need for more expensive and complicated instruments is of utmost importance in both academic and industrial contexts.

Transition metal oxides are excellent catalysts for the industrially relevant selective oxidation reactions, particularly of alcohols,[1] In the selectively catalyzed oxidation of 2-propanol to form acetone, the spinel cobalt(II, III) oxide (Co_3O_4) exhibits a peculiar behavior, which is expressed by changing the catalytic properties significantly. The changes depend on the temperature: below 200 °C, the catalyst shows high acetone selectivity, but deactivates rapidly, while above 200 °C, stable conversions and steady-state conditions can be reached, at the expense of lowered selectivity due to total oxidation (to form H_2O and CO_2).[2] In addition, once the high-temperature regime has been reached, the low-temperature region gets deactivated completely, but can be recovered by re-oxidation. Thus, it would be beneficial to stabilize the low-temperature regime. However, a prerequisite for being able to accomplish this challenging task is gaining an understanding of the underlying processes. As many phases and states formed during the reaction are metastable, this understanding can only be obtained when the sample is investigated under reaction conditions, i.e. operando methodologies are of great importance. In an operando experiment, the system is exposed to reaction conditions and its performance is measured simultaneously.[3]
Here, we use a combination of operando TEM (OTEM), as well as (operando) near-ambient pressure X-ray photoelectron spectroscopy (NAP-XPS) and near-edge X-ray absorption fine structure (NEXAFS) spectroscopy, combining the spatial resolving power of OTEM with the surface-sensitivity and energy-resolution of X-ray techniques. We employ this multimodal approach to elucidate a network of interconnected diffusional solid-state processes governing the catalytic activity of Co_3O_4 in the selective oxidation of 2-propanol towards acetone.
OTEM was performed on an image-corrected ThermoFisher Scientific Titan 80-300 instrument operated at 300 keV, equipped with a TVIPS TemCam-XF 416R CMOS camera. A DENSsolutions climate in situ holder, connected to a custom gas feeding and detection system,[4] was used. Using a gas saturator filled with anhydrous 2-propanol, and subsequent mixing it with oxygen in a 1:1 ratio, a total reactant pressure of 13.5 hPa was obtained inside the nanoreactor, which was, filled to 450 hPa with helium.
NAP-XPS and NEXAFS measurements were performed at the CAT endstation at the BESSY II electron storage ring operated by the Helmholtz-Zentrum Berlin für Materialien und Energie using the UE48-PGM (soft X-ray) and CPMU17-DCM (tender X-ray) branches of the EMIL beamline.[5] The chamber was backfilled with a 1:1 mixture of 2-propanol and O_2 to a total pressure of 0.5 hPa and photoelectrons were detected using a differentially pumped Specs Phoibos 150 NAP hemispherical analyzer.
The reductive chemical potential of the reaction feed (isopropanol/O2 1:1) induces the exsolution of amorphous CoOx nanoparticles from the spinel, which is already significantly reduced at room temperature. This leaves behind cation vacancies, which cause strong distortions of the Co_3O_4 lattice.

The exsolution is self-limiting as both the number of nanoparticles and the lattice parameter remain constant above 100 °C.
Increasing the temperature further causes the vacancies to collapse to voids inside the spinel particles, restoring the (mostly) undistorted lattice, as seen by the linear behavior of the lattice parameter above 200 °C. The exsolved nanoparticles also start crystallizing as rock-salt-structured CoO at temperatures above 200 °C, as evidenced by SAED and HRTEM. Furthermore, NAP-XPS and NEXAFS measurements reveal a maximum in the cobalt oxidation state at this temperature. Thus, the catalyst is in a frustrated state at 200 °C: at this temperature, the system transits from the low-temperature to the high-temperature activity regime and exhibits the highest selectivity towards acetone. Moreover, cobalt is in its highest oxidation state, the exsolved particles start to crystallize and the cation vacancies coalesce to voids. If the system is cooled down again and a second catalytic run is started, the exsolved and crystallized particles remain, but they are dissolved again during reoxidation.
Using a combined operando microscopic and spectroscopic investigation, it could be shown that the selective oxidation of 2-propanol on Co_3O_4 is accompanied by severe morphological changes and restructuring, which already start at room temperature. Furthermore, the catalyst is strongly controlled by solid state processes such as exsolution, vacancy agglomeration and crystallization. All together, they determine the catalytic properties and are responsible for the transition between the low and high temperature activity regimes.

Poster Group 2

Background:
Rotaviruses are enteric pathogens responsible for life threatening diarrhea in children. Despite several globally distributed vaccine programs, rotavirus-related deaths still number in the hundreds of thousands. Given the burden of these pathogens, the development of vaccine alternatives or direct-acting therapeutics is a necessity. Understanding rotavirus particle structure is fundamental to this pursuit. The rotavirus virion, ~90 nm in diameter, is comprised of three concentric protein layers each exhibiting icosahedral symmetry. The outermost layer is shed during cell entry, yielding a double-layered particle (DLP) of ~70 nm that initiates the infectious cycle. VP6 makes up the exposed T=13 layer of the DLP, which surrounds a T=1 core shell comprised of VP2. VP1 polymerases are encapsidated beneath the VP2 core shell, just off-center from each 5-fold axis. A virus-like particle (VLP) system is regularly used to study protein interactions critical for DLP assembly. In this system, recombinant VP2 and VP6 are expressed in insect cells using baculovirus vectors. These capsid proteins self-assemble into “double-layered” 2/6-VLPs, which can be purified from the culture media. Co-expression of VP1 along with VP2 and VP6 yields 1/2/6-VLPs. There are currently no high-resolution structures of rotavirus VLPs, hampering understanding of whether they truly mimic native DLPs. Therefore, we employed cryo-electron microscopy (cryo-EM) and single particle analysis (SPA) to solve high-resolution structures of rotavirus strain SA11 2/6-VLPs and 1/2/6-VLPs.
Methods:
Rotavirus strain SA11 VLPs were designed for expression using an established and well-characterized baculoviral vector system and subsequently expressed in SF9 cells. The VLPs were separated from cells by ultracentrifugation against a 35% sucrose cushion, and the resulting pellet was further purified using isopycnic ultracentrifugation in a cesium chloride (CsCl) gradient. The rotavirus SA11 DLP was produced by infection of MA104 cells with native rotavirus, followed by separation of virus particles from cell debris via centrifugation. Native triple-layered particles (TLPs) were rendered non-infectious by stripping of the outer capsid in ethylenediaminetetraacetic acid (EDTA), producing media containing DLPs. DLP particles were then purified under the same conditions as VLPs, using a sucrose cushion followed by isopycnic centrifugation in CsCl. Purified particles were frozen by plunge-freezing on copper (Cu) 200 mesh Quantifoil® grids, with 2µm holes and a hole-spacing of 1µm, using a Thermo Scientifc Vitrobot Mark IV. Particles were then imaged at 59,000 magnification using a Titan Krios cryo-EM and a Falcon 4 direct electron detector (DED). The resulting images were then processed using SPA workflows in the CryoSPARC v4.1.2 software package, where individual particles were isolated and computationally averaged to solve the 3D structures of each VLP. Atomic modeling of the rotavirus asymmetric unit was done using Phenix v1.21 and Coot v0.9.8.4 software.
Results:
Without icosahedral symmetry enforcement, 3D structures of 2/6- and 1/2/6-VLPs were solved to resolutions of 4.9Å and 4.6Å, respectively. Icosahedral symmetry (I1) enforcement allowed for improved structural resolution of 2/6- and 1/2/6-VLPs to 4.0Å and 2.7Å, respectively. The 2.7Å structure of the 1/2/6-VLP further allowed for isolation and de novo atomic modeling of the rotavirus

asymmetric unit as well as direct comparison to the rotavirus strain UK DLP X-ray crystal structure (3KZ4), demonstrating remarkable similarity and structural fidelity. The rotavirus SA11 DLP was resolved, without symmetry enforcement, to a resolution of 6.12Å. Icosahedral symmetry enforcement was not appropriate for the DLP structure, which contains asymmetric enzymes and genomic material.
Conclusions:
In achievement of the project aims, not only were the first high resolution structures of rotavirus VLPs produced, but also the first atomic model of a rotavirus VLP. This success significantly validates the rotavirus VLP system as an appropriate research tool, mimicking native rotavirus structure, and contributes to structural knowledge of the rotavirus VLP which is currently in development as a potential vaccine platform. Ongoing work seeks to (i) improve the 2/6-VLP structural resolution to ~2.7Å and (ii) to map structural differences, if any, between the particle types (i.e., 2/6-VLPs v. 1/2/6-VLPs v. DLPs).

Scale-bridging microscopic characterization of complex energy devices enabled by novel cross-sectional preparation routines

Marco Hepp[1], Charles Ogolla[1], Dominik Stepien[2], Dominik Bresser[2], Benjamin Butz[1], Tristan Zemke[1]
[1]Micro- and Nanoanalytics Group, University of Siegen, Siegen, Germany, [2]Helmholtz Institute Ulm, Ulm, Germany

Poster Group 1

Background incl. aims
Energy devices like batteries, fuel cells and solar cells are assembled from multiple functional components with different material properties. To gain a fundamental understanding of structure property relations, to systematically contribute to performance enhancement and to unravel device degradation and failure mechanisms, high quality cross-sections of entire devices or of as large regions as possible are required for complementary microscopic analysis.
Methods
Since many devices not only consist of different classes of materials but also of liquid and/or air sensitive components, working under cryogenic and/or inert conditions is essential to conserve their pristine state. To enable scale-bridging cross-sectional characterization of those devices all the way down to the atomic level, we utilize different preparation tools. A novel self-built cryo-cutter allows us to produce cross-sections of entire devices like pouch-cells in a one-step process and thus to investigate the inner structure in their pristine state by OM from the macroscopic scale to the optical resolution limitations. For characterization down to the atomic scale (cryo)ultramicrotomy is employed to generate high-quality and large-area cross-sections, e.g., of PEM-FCs and even highly reactive battery electrodes not only for investigation by OM/SEM (microtomic blockface) but also for (atomic resolution) TEM, as high-quality thin samples with thicknesses below 50 nm are provided.
Results
In this contribution, we demonstrate the scale-bridging capabilities of those preparation techniques applied to various devices and their components in conjunction with advanced (electron) microscopic and spectroscopic methods. Examples include devices like batteries (Fig. 1 a) and components thereof (Fig. 1 b) as well as complex fuel cells.
Conclusion
The applied techniques and developed routines are ideally suited to investigate even complete devices, individual components as well as materials. Aspects range from interfaces of individual layers and components in terms of their morphology and contact to the systematic identification of their composition and chemical bonding states.

Poster Group 2

Background incl. aims:
The Isua Supracrustal Belt in Southwest Greenland contains rocks which are at least 3.7 billion years old, and are among the oldest rocks on Earth. Sediments found here display contiguous horizons of carbonaceous material parallel with sedimentary bedding planes (Rosing 1999). This material, present as graphitic carbon, has been proposed to be some of the oldest remnants of life on Earth, inferred based on its mode of occurrence, carbon isotope ratios, its association with heteroatoms such as nitrogen, oxygen, phosphorous and iron, and from the nanoscale crystal structure (Ohtomo et al. 2014, Hassenkam et al. 2017), evidence which is all compatible and together suggestive of an origin of the graphitic material as biogenic pelagic detritus.
In certain places, the graphite is enclosed in secondary metamorphic minerals such as garnets. This graphite occurring as inclusions has been targeted by previous studies, which also identified certain viscous fluid inclusions. The study presented attempts to characterize the chemistry of these fluid inclusions occurring alongside the graphitic material within garnet porphyroblasts.
Methods:
In this study, the liquid inclusions are accessed by breaking open the garnets and their residues are subsequently characterized using atomic force microscopy (AFM), as well as infrared spectroscopy coupled to AFM (NanoIR). Optical photothermal infrared spectroscopy (O-PTIR) and time-of-flight secondary ion mass spectrometry (ToF-SIMS) are also used to characterize the chemistry of the inclusion residues and to assess their association with the solid graphitic inclusions.
Results:
Using AFM-based infrared spectroscopy, we obtain infrared absorption spectra from just the inclusion at a high spatial resolution. The liquid inclusion residues are ubiquitously characterized by infrared absorption at wavenumbers 1280 cm-1 and 1660 cm-1, interpreted as the C-N and C=O vibrational absorption from amide-like functional groups. Similarly, ToF-SIMS shows secondary species containing C, N and O from the inclusion residues. O-PTIR shows how the amide-like infrared absorption signal can be traced along horizons of graphitic material.
Conclusion:
This study shows how infrared spectroscopical methods coupled to optical and scanning probe microscopy methods can be used to characterize the chemistry of minute domains of ancient carbonaceous material occurring as inclusions in garnet porphyroblasts. The observations from NanoIR were corroborated by ToF-SIMS analyses. Together, these methods indicate that the carbonaceous material consists of C, N, and O-rich material in an amide-like configuration.
The chemistry of the inclusions is consistent with that which would be expected from degraded biogenic matter. Together with previous studies, this is highly suggestive of a biological origin for the carbonaceous material found in the oldest sediments on Earth.

Poster Group 1

Background incl. aims:
Chiral ferrimagnets emerge as promising candidates for spintronics, especially for skyrmion-based device applications1,2. This ferrimagnet class lacks long-range crystalline-like structural order. Still, it exhibits a diverse set of appealing material properties, including bulk DMI of Néel type2, perpendicular magnetic anisotropy of bulk origin, and vanishing stray fields. Such characteristics of rare earth transition metal ferrimagnets contribute to a distinctive dual nature that integrates features from ferromagnets and antiferromagnets3. We aim to utilize advanced electron microscopy techniques to overcome the challenge of a volume-sensitive method for quantifying the strength of bulk DMI, particularly considering the crucial parameter of thickness.
Methods:
Ferrimagnetic Dy/Co-based multilayer films were prepared using the RF/DC Magnetron Sputtering technique for thin-film deposition techniques, ensuring precise control over film thickness and composition. In this study, we utilise JEOL NEOARM 200F in the LOW-MAG mode for Fresnel Lorentz Transmission Electron Microscopy (L-TEM) imaging, leveraging the objective lens as a magnetic field source. This facilitated to resolution of the chirality and topology of spin textures in thick ferrimagnetic Dy/Co multilayer films and quantification of the strength of Néel-type bulk DMI.
Results:
Under varying conditions, involving field cycling and tilting in the L-TEM microscope, we observe the coexistence of both skyrmions and topologically trivial bubbles within the material, indicating an intricate balance of micromagnetic interactions. In addition, we have encountered a fascinating underlying worm domain pattern that remains stable even after the saturation of chiral spin textures. In our exploration of DyCo monolayers, we encountered intriguing domains through high-precision MFM imaging, revealing a host layer beneath the normal domain pattern that guides the as-grown domain pattern. A similar background pattern, even higher periodic modulation appears during the L-TEM imaging, seemingly functions as a guiding pathway for normal domains, suggesting its potential role in influencing their behavior (see Fig. 1).
Conclusion:
Overall, the study highlights the crucial role of local real-space probes in comprehending the chirality of bulk DMI ferrimagnets. Furthermore, it demonstrates the capability of the Fresnel L-TEM technique in determining local saturation magnetization and revealing the imprinted

phenomenological structural phase under the magnetic domains with high resolution. Ultimately, these findings pave the way for further exploration and exploitation of these materials.

Poster Group 1

Background
Over recent decades, scanning transmission electron microscopy (STEM) has become widely used for matierals charaterizations, achieving atomic-level detail in structural analysis across various scientific disciplines, including physical, chemical, and biological studies. With the recent development of high-acquisition-speed pixelated detectors and advanced computational methodologies, 4D-STEM is progressively transforming into a standardized modality in high-resolution EM. This method integrates a range of applications, from orientation mapping and strain measurement to electric and magnetic field mapping. Furthermore, it transcends the boundaries of conventional STEM imaging to include super-resolution techniques and to provide phase-based imaging, such as ptychography.
Methods
Ptychography, a technique for phase retrieval that extends from the concept of scanning in-line holography introduced by Hoppe, involves shining a light source on a specimen. It captures a sequence of diffraction patterns based on the position of the light source and utilizes iterative algorithms to reconstruct the wavefunction of the sample's exit plane.. Ptychography has attracted considerable interest from both X-ray and electron communities for its potential applications in super-resolution imaging, reaching a resolution of 0.39 ångströms. Electron ptychography has proven to have high-contrast light-element detection detection, high dose-efficiency efficient and 3D imaging [1,2]. Recently we have shown its potential to yield high-contrast image and high sensitivity in capturing phase information from biological samples [3,4]. The significance of phase imaging extends beyond the ability to detect light elements at super-resolution and minimal dosage, as it also promises to provide unique information associated with local variations in magnetic and electrostatic fields.
Results
In this paper, we explore the established multidimensional applications of electron ptychography, such as 3D tilted tomography [2], and single-particle analysis [4], conducted under both room and cryogenic temperatures. Specifically, we introduce a new STEM configuration illustrated in Fig. 1. This setup features an advanced hollow detector that is adeptly coupled with an EELS spectrometer [1]. The design facilitate simulatious, complementary analysis, leveraging the capabilities of sensitive phase and Z-contrast detection alongside comprehensive chemical mapping.
Conclusions
In ptychography, the image-forming optics of traditional imaging modes are replaced by computational methods that utilize a series of electron diffractions collected by rapid detectors. This technique has exhibited great potential in various important applications, including the high-contrast detection of light elements and low-dose imaging. The concept of multidimensional ptychography expands upon this by recording data more than the two dimensions. This expansion may involve capturing changes in the third dimension, electron energy loss, or time.

Simulating electron energy-loss spectroscopy and cathodoluminescence for nanoparticles located on substrates

Alexander Kichigin[1], Mingjian Wu[1], Stefanie Rechberger[1], Benjamin Apeleo Zubiri[1], Maxim Yurkin[2], Erdmann Spiecker[1]
[1]Institute of Micro- and Nanostructure Research (IMN) & Center for Nanoanalysis and Electron Microscopy (CENEM), Friedrich-Alexander-Universität Erlangen-Nürnberg, IZNF, Erlangen, Germany, [2]CNRS, INSA Rouen Normandie, Univ Rouen Normandie, Normandie Univ, CORIA UMR 6614, Rouen, France

Poster Group 2

Background
Electron energy-loss spectroscopy (EELS) and cathodoluminescence (CL) are widely used to study the plasmonic properties of individual nanoparticles. In the experiment, the sample is irradiated with relativistic electrons having energy of about 100 keV. After the interaction with the sample, electrons' energies are measured to obtain the energy loss spectrum (EELS spectrum). When interacting, the sample itself begins to emit photons. This light is collected by a parabolic mirror to obtain CL spectrum. The main advantage of EELS/CL over light scattering methods is the ability to study plasmonic properties with a spatial resolution of less than 1 nm (at wavelengths of visible light and infra-red).

Methods
We extended the capabilities of the discrete dipole approximation (DDA) to simulate EELS and CL. Until recently, there was only a theory for simulating the case of particles located in vacuum, which is never true in the experiment. In an electron microscope, the particle is always placed inside or on top of the substrate medium, which redshifts the plasmonic response of the sample. We extended our previously published DDA theory for particles inside an infinite medium[1] to simulate EELS and CL for particles on top of a semi-infinite medium, which successfully reproduces experimental results for particles deposited on TEM membranes of finite thickness.

Results
With the extended theory, the simulations successfully reproduce the results of EELS experiment where a gold nanoprism (209 nm side length, 10 nm thickness) was deposited on 30-nm-thick Si3N4 substrate.[2] A straightforward workaround for such simulations (with any DDA code) is to discretize a finite volume of the substrate below the particle, which would take 1 645 070 dipoles for both prism and the substrate (Fig. 1a), making it a heavy computational task. In the extended theory, however, the presence of substrate is accounted in the DDA formulation of the problem (by adjusting the dipole-dipole interaction function) requiring only 66 206 dipoles to discretize only the prism itself (Fig. 1b). This requires much less computational resources, leading to about 10 times faster simulations.
In the simulations of the prism, the Si3N4 refractive index was set to a constant 2.15 for all energies, and the refractive index of gold was taken from the data by Babar et al.[3] The redshift caused by the semi-infinite substrate in the simulated plasmon energy peaks matches the ones observed in the experiment by Griffin et al.[2]. Moreover, the simulated plasmon maps (Fig. 1c) also match the experimental ones,[2] in contrast to the simulations for a particle in vacuum in that paper.

The extended theory also successfully reproduces the CL experiment where a gold nanorod was placed on top of SiO2 membrane,[4] and even the CL experiment where a gold nanorod-shaped antenna was on top of gold substrate.[5]

Conclusion
Simulations with the semi-infinite substrate theory successfully reproduce experimental spectra and plasmon maps for both EELS and CL for samples on top of dielectric substrates, and for CL even in the case of a metallic substrate. Brief theory overview followed by simulation results in comparison with previously published and our own experiments will be presented at the conference.

IM-11 (1), Lecture Theater 5, august 29, 2024, 10:30 - 12:30

Background
Rapid advances in cryo-electron microscopy (cryo-EM) have made it possible to visualize three-dimensional structures of a wide range of biological macromolecules at near-atomic resolution in a close-to-native, frozen-hydrated state 1. However, the high electron irradiation sensitivity inherent in biological samples leads to a low signal-to-noise ratio and low contrast in EM images. While cryo-EM single particle analysis (SPA) usually records microscopic movies with high defocus to improve contrast, high-defocus condition attenuates low-frequency information and rapidly reverses high-frequency information in the phase contrast transfer function (PCTF), which causes difficulties in accurate identification, classification and alignment of particles to a common reference. Ptychographic diffractive imaging, a technique capable of reconstructing phase information from diffraction patterns using an iterative algorithm known as ePIE (Fig. 1a), holds great promise for achieving super-resolution, high-contrast, low-dose, and 3D imaging of biological samples in vitreous ice at low doses2. Moreover, ptychography utilizes the entire diffraction pattern , making it particularly dose efficient, especially when using direct electron detector data with a high signal-to-noise ratio at a low electron dose 3. Using cryogenic electron ptychography (cryo-EPty) [4], we have successfully reconstructed the 2D phase images of rotavirus double-layer particles (DLPs) measuring 76.5 nm in diameter at doses of 20 e/Å2, corresponding to a convergence semi-angle (CSA) of 4.83 mrad, employing approximately 300 particles. Additionally, we have demonstrated the visualization of 3D structures by integrating SPA 4. The resolution of the 3D map was estimated to be 1.86 nm at the nanometer level. These advancements underscore the potential for combining cryo-EPty and single-particle analysis to reach atomic-level resolution in imaging . We aim to increase the resolution achieved by not only increasing the number of particles used as is done in traditional SPA but by increasing the optically limited resolution with a larger convergence semi-angle.

Methods
We used apoferritin embedded in vitreous ice as a benchmark sample. Experimental cryo-EPty SPA datasets (Fig. 1b) were acquired in a scanning diffraction configuration, in which a defocused probe is scanned over a sample at cryogenic temperatures for probe overlap and information redundancy of approximately 85% as is commonly employed for defocused cryo-EPty 5. The use of a defocused probe enables a lower electron fluence than employed in physical sciences while maintaining full coverage of the scanned specimen area.

Results
We reconstructed 2D ptychographic phases of apoferritin particles with varied CSAs (i.e., 4.64 and 8.01 mrad) as shown in Fig. 2a-b to obtain information transfer over a greater range of spatial frequencies. We will demonstrate that using the SPA pipeline with the ptychographic phase, high-resolution 3D density maps of apoferritin can be reconstructed from the stack of particle phases.

Using a Fourier Shell Correlation, we anticipate that the 3D density maps will approach a resolution of a few angstroms with a greater number of particles. Our findings show that larger convergence angle datasets produce higher-resolution information that can be combined with essential lower spatial frequency information for data across a greater range of spatial frequency.

Conclusion
Our findings suggest that the promise of cryo-EPty combination with SPA will pave an alternative method for high-resolution 3D reconstructions of biological samples, potentially reaching atomic resolution .

eCHORD crystalline orientation maps: channeling contrast at interfaces

Dr. Hdr Cyril Langlois[1], Dr. Gabriel Denhez L'Hôte[1], M. Thierry Douillard[1], Dr. Matthieu Bugnet[1], Dr. Claire Maurice[2]
[1]INSA Lyon, MATEIS laboratory, Lyon, France, [2]Ecole des Mines Saint-Etienne, LGF laboratory, Saint Etienne, France

Poster Group 2

Background incl. aims
Every signal acquired by a scanning electron microscope (SEM) originates from a certain interaction volume below the surface, making localization of the received information challenging. For orientation maps obtained by EBSD, the Kikuchi patterns acquired at the interface between two grains contain contributions from both crystals. This impacts the precise localization of the interfaces on the generated map and thus, influences the spatial resolution when dealing with objects of a size comparable to the interaction volume [1]. For EBSD, this interaction volume can be hardly reduced, as Kikuchi patterns significantly weaken at accelerating voltages of 5kV and lower.
The same “blending” effects are expected in eCHORD orientation maps obtained using SEM since the channeling contrast also arises from a certain interaction volume beneath the sample surface [2, 3]. However, at such low accelerating voltages, electron channeling contrast can still be accomplished, hence orientation maps with a reduced interaction volume could potentially be obtained via the eCHORD approach.

Methods
When considering the orientation maps obtained using the eCHORD approach [2, 3], the raw data comprises of an image series captured by rotating the region of interest (ROI) within the SEM, with the sample being tilted at approximately 10-15°. Such an image series constitutes a datacube from which intensity profiles can be extracted, one for each beam position on the ROI, representing the variation of the backscattered electron (BSE) signal as the sample rotates. Similar to Kikuchi patterns, these intensity profiles are also influenced by the respective contributions of two neighbouring crystals. To evaluate how this effect affects the eCHORD orientation maps, acquisitions were carried out on a copper thin film of 3 µm thickness exhibiting submicronic twins with 80 nm in thickness. The acquisition conditions are outlined as follows: 120 images (2048*1536) were captured using a frame time of 20.3s per image, at an accelerating voltage of 5kV, with a sample tilt of 15°, and utilizing a below-the-lens BSE detector. It is worth noting that an accelerating voltage of 5kV is now a routine condition for eCHORD experiments.

Results
Experimental evidences of a hybridisation effect are presented, showing that the intensity profile at a given interface is a blend between the intensity profiles of the two neighbouring grains. In addition to the interaction volume, various other factors explaining these hybridisation effects are presented and discussed: CHORD geometrical setup, image alignment, denoising, and indexing by pattern matching. Numerical simulations were also performed to quantitatively assess the effect of this hybridisation on the results of indexing intensity profiles, leading to a proposed adjustment in the indexing algorithm for the eCHORD method. This adjustment involves deriving the experimental as well as the theoretical profiles of the CHORD database prior to indexation, aiming to limit the effect of hybridisation on the final orientation maps. We demonstrate that this new algorithm has beneficial

effects on indexation quality in general, compensating for differences between simulated and experimental profiles.

Conclusion
An effect of hybridization at interfaces has been observed in eCHORD orientation maps, which is limited by the adjustment of the indexing algorithm, thus demonstrating its robustness against degraded data.
This work represents an intermediary step in a more comprehensive approach aiming to enhance the spatial resolution in orientation maps obtained by eCHORD. This is achieved through the reduction of the accelerating voltage, improving the acquisition procedure, and by enhancing the post-treatment operations.

Coupling Clustering and Channeling Contrast in the Scanning Electron Microscope

Dr. Sudeep Kumar Sahoo[1,2], M. Thierry Douillard[1], Dr. Bianca Frincu[2], Mme Christine Nardin[2], Dr. Hdr Cyril Langlois[1]
[1]INSA Lyon, MATEIS Laboratory, Lyon, France, [2]Constellium Technology Center (C-TEC), , France

Poster Group 2

Background incl. aims
Channeling contrast in the Scanning Electron Microscope (SEM) facilitates the imaging of crystals and their defects. A name for this approach has been coined as ECCI for “Electron Channeling Contrast Imaging”. This contrast arises from the diffraction of the electron beam as it traverses through the crystalline sample, and is intricately linked to the crystalline orientation of the underlying crystal. Within a grain, the channeling contrast hence aids in the recognition of crystalline defect. In a polycrystalline sample, neighbouring grains can be differentiated by the channeling contrast due to their difference in orientation. However, obtaining multiple ECCI images with different angles of electron beam incidence on the crystal is necessary: (i) to identify the defect character (such as screw or edge dislocations) and (ii) to ensure that all grains are detected within a polycrystalline region of interest. Eventually, the acquired ECCI image series have to be treated quantitatively to extract valuable information about the microstructure. In this context, machine learning, particularly clustering algorithms, is extremely beneficial for analyzing ECCI data. As an example, defects like dislocations and stacking faults can be detected in an ECCI image series by clustering [1-2]. In the present work, the idea is to process ECCI image series by clustering: (i) to extract the grain size distribution rapidly in an automatic and reproducible manner, (ii) to extract meaningful information about the microstructure, i.e., recrystallized fraction in an aluminum alloy [3], and (iii) to reduce dramatically the computation time of orientation maps using the eCHORD approach [4].

Methods
The raw dataset consists of a series of ECCI images acquired by rotating the region of interest (ROI) in the SEM, with the sample being tilted to~10-15°. Such an image series constitutes a datacube from which intensity profiles can be extracted at each ROI position, reflecting the variation of the backscattered electron (BSE) signal due to the sample rotation. To demonstrate the effectiveness of clustering algorithms for estimating grain size distributions, a copper thin film of 3 µm thickness exhibiting submicronic twins as thin as 80 nm in thickness is employed as a test sample. For determining the recrystallisation fraction, a 6XXX aluminum sample is considered and subjected to heat treatment to achieve a ~75% recrystallised microstructure. Finally, to explore the possibilities for fast-indexing within the framework of the eCHORD approach, duplex steel with coexisting austenite and ferrite phases is adopted.

Results
The intensity profiles defined at each place in the ROI will be used to cluster the data for grain size distribution calculations. The HDBSCAN algorithm [5] was selected for clustering, as it does not require the number of clusters (i.e., of grains) as an input. Furthermore, the algorithm automatically determines a reasonable criterion for defining a cluster. The influence of the intensity profiles pre-treatments is discussed, as well as the minimal number of images required for the clustering is explored, which is found to be between 10 to 20 ECCI images only.

For the recrystallisation fraction, it appears that the non-recrystallised area in the ROI corresponds to pixels that are left apart within the “noisy” class during the clustering using HDBSCAN. The results show good agreement with the recrystallised fractions as determined by EBSD on the same ROI. Concerning eCHORD orientation mapping, the approach involves grouping similar intensity profiles into clusters, computing the mean profile for each cluster, and subsequently indexing it by comparing it to an eCHORD database. In this case, over-clustering is not a problem, and the KMEANS algorithm has been used with a significantly higher number of clusters than the apparent grain count, ensuring a reasonable spatial resolution is maintained. If some clusters belong to the same grain, the indexing operation will yield the same crystallographic orientation in the final map. This approach has been applied to the image series of duplex steel, allowing it to discriminate between the austenite and ferrite phases. Due to the tremendous GPU-computed indexing speed, it is possible to compare all the cluster profiles to both austenite and ferrite databases in order to perform phase mapping and retrieve the correct orientations.

Conclusion
This work demonstrates that clustering the ECCI image series using several types of clustering algorithms (HDBSCAN, KMEANS) can be extremely beneficial for several applications such as grain size distribution calculation, recrystallization fraction determination, phase discrimination, and orientation map computation.

Poster Group 2

Background incl. aims
Superhydrophobic, omniphobic, icephobic and self-cleaning mean advanced properties of a surface when precise control of the roughness combining different levels of topography, from micro- to-nanostructures for the called hierarchical surface [1-4]. Particularly one-dimensional nanostructured matrix allows the integration of nanowires with dimensions around several micrometers with the nanofiber surface roughness at the nanoscale. We study here hierarchical photoactive core-shell nanostructured surfaces, which wetting behaviour can be easily tuned. Understanding the mechanism of water condensation on such nanofibers at the nanoscale is crucial to design efficient systems. In this presentation, we identify their hydrophobic/hydrophilic behaviour and discuss the water condensation mechanisms using multiscale environmental electron microscopy.
Methods
Liquid-phase electron microscopy can be carried out with different systems. We used a dedicated environmental scanning electron microscope (ESEM) and an environmental transmission electron microscope (ETEM), in which different hydration states can be reached by controlling the sample temperature and the water vapor pressure.
TiO_2 core-shell nanowires were fabricated by vacuum and plasma assisted deposition techniques according to the soft template method [5]. In order to obtain the water repellent character, surface functionalization by fluorine-based grafting of the oxide surface has been employed [1]. Hydrophobic nanowires were collected by scratching the substrate and were dry-deposited onto a grid with a holey carbon membrane. The fibers were either analyzed as such, or plasma-treated to become hydrophilic. During the experiments, care was taken to minimize irradiation damage and preserve the hydrophilic/hydrophobic nature. An image processing method was developed to highlight the changes brought about by water condensation.
Results
Experiments in ESEM were performed in the STEM mode (see Figures 1a and d). Under similar conditions, where water condensates on the holey carbon membrane, the hydrophilic nature of the plasma-treated nanowires can clearly be evidenced: they are systematically surrounded by water. On the contrary, water droplets are visible on the carbon membrane but not on hydrophobic nanostructures. The presence of water onto hydrophilic surfaces but not on hydrophobic ones could be confirmed at the nanoscale using similar thermodynamic conditions in ETEM (see Figures 1b and e). The experiments were continued until water was visible around both types of nanowires (see Figures 1c and f).
Conclusion
ESEM images, obtained on a large number of core-shell nanowires, enable us to assess the reproducibility of results obtained at nanometric scale in ETEM on isolated fibers. Irradiation of the

nanostructures with the electron beam during the experiments did not modify their hydrophilic/hydrophobic character. In fact, clear differences in behavior towards water condensation are revealed at the nanometric scale. These differences will be discussed as a function of nanostructure and chemistry.

Poster Group 2

Background incl. aims

Cryo-EM has significantly impacted the field of structural biology due to its capabilities to resolve the three-dimensional structure of proteins, protein complexes and other biological macromolecules at high or even atomic resolution. However, acquiring high-quality data still largely depends on the expertise of the microscope operator. This limits the speed of adoption as researchers must invest considerable time into understanding microscopy and the technicalities of the workflow. Here, we show how the Thermo Scientific™ Glacios 2™ cryo transmission electron microscope (Cryo-TEM) with low-energy-spread Cold Field Emission Gun (E-CFEG) and combined with Thermo Scientific™ Smart EPU Software enables users of all expertise levels to acquire high-quality cryo-EM data.

Methods
In collaboration with the Greber lab (Institute for Cancer Research), several high-resolution structures of the 85 kDa Human CDK-activating kinase (CAK) were determined. CAK is a master regulator of cell growth and division and is a promising target for cancer therapeutics.

Results
Structures of CAK were rapidly determine in free and nucleotide-bound states as well as in complex with 14 inhibitors(1). In addition to achieving high-resolution structures from large datasets, ~4 Å and ~3 Å-resolution structures of ligand-bound complexes were determined using from only 1 hour and 4 hours of data collection respectively. Furthermore, in combination with an E-CFEG we have been able to generate a 1.5 A reconstruction of Apoferritin; the highest resolution 200 kV structure to date.

Conclusion
These results show the use of cryo-EM to enable structure-based drug design.

Poster Group 1

Background and Aims:
Silicon offers an extremely high gravimetric capacity of 3579 mAh /g, about 10 times greater than graphite. Making it a promising next-generation anode material for lithium-ion batteries (LiB). However, throughout charge-discharge cycles, silicon experiences significant volume fluctuations, leading to material cracking and pulverization. This leads to solid electrolyte interphase (SEI) layer breaking, necessitating the formation of a new SEI layer, which results in capacity loss and poor cycle performance. Partial lithiation or capacity-limited charging presents a promising strategy for addressing the challenges associated with severe volume expansion in lithium-ion batteries. [1,2] Nonetheless, further investigation into the morphology of the silicon particles is necessary to enhance battery performance and durability. This study aims to delve deeper into the morphology of partially lithiated porous and non-porous silicon microparticles, as little literature exists on the subject. [3,4]

Methods:
The samples were prepared by Focused Ion Beam (FIB). Employing post-mortem analysis, we examined the morphology of partially lithiated silicon microparticles after being cycled. Selected area electron diffraction (SAED) and energy dispersive X-ray spectroscopy (EDX) allow distinguishing between amorphous and crystalline silicon phases present after the lithiation, resulting in a very valuable tool. Furthermore, Techniques like computed tomography and in-situ transmission electron microscopy (TEM) experiments shed further light on porous silicon microparticles and their behaviour upon lithiation.

Results:
Lithiation of the non-porous microparticles leads to the amorphization of the pristine crystalline silicon, leading to changes detectable with TEM. TEM analysis revealed the absence of particle pulverization across all samples despite evidence of lithiation within the particle interiors This highlights the positive influence of lower cutoff potentials upon morphological changes. In-situ studies performed on both the porous and non-porous Si samples further show the reason for long-term stability.

Conclusions:
Our findings provide insights into the complex interplay between silicon and lithium during partial lithiation shedding light on the morphology of silicon microparticles used in anodes crucial for anode applications in lithium-ion battery technology . Furthermore, using capacity-controlled charging with porous silicon microparticles has demonstrated the potential for achieving high long-term capacity, paving the way for realizing the full potential of lithium-ion batteries.

Figure caption:

Analyzing conformational and compositional heterogeneity of macromolecular complexes by cryo Electron Microscopy: Zernike3Deep and HetSIREN

Dr. David Herreros Calero[1], Carlos Óscar Sánchez Sorzano[1], José María Carazo[1]
[1]National Centre for Biotechnology CNB-CSIC, Madrid, Spain

IM-11 (1), Lecture Theater 5, august 29, 2024, 10:30 - 12:30

BACKGROUND INCL. AIMS
Biological macromolecules have varying degrees of conformational flexibility and compositional heterogeneity that complicates the image processing of large sets of cryo Electron Microscopy images, especially when flexibility is continuous or there are many compositional options. New approaches like HetSIREN (1) and the Zernike3D family of algorithms (2) are capable to generate conformational landscapes representing complex heterogeneity cases while also producing higher resolution maps of the different states. Additionally, novel meta-approaches, like the ones pioneered by Scipion Flexibility Hub (3,4), start bringing consistency and reliability to this emerging field of flexibility analysis and map quality improvement.

METHODS
HetSIREN and Zernike3Deep are two cutting-edge deep learning algorithms meticulously designed to address the analysis of structural heterogeneity in cryoEM single particle analysis. These new algorithms not only excel at segregating particles into distinct 3D conformational states but also places special focus on the representation of structural features and map quality to enhance the biological interpretability. These new algorithms are distributed as part of the Scipion Flexibility Hub (4), together with new tools designed to analyze and integrate findings across different conformational landscapes.

HetSIREN performs a constrained heterogeneous reconstruction or refinement, relying on a structural prior in real space. This approach decodes high-resolution stable and non-stable structural states, providing a more sensible picture of the structural landscape explored by a biomolecule.

In contrast, Zernike3Deep relies on a semi-classical neural network that is specifically designed to learn mathematically meaningful latent spaces. These spaces are to be used in conjunction with the Zernike3D basis to accurately expand molecular motions. The decoded motions are suitable not only for modeling high-resolution structural states captured in the conformational landscape but also for applying as a correction for motion blur artifacts during the reconstruction process. This application increases the resolution of molecular regions that are moving and difficult to resolve.

RESULTS
HetSIREN and Zernike3Deep have proven themselves as versatile tools for the heterogeneity analysis of cryoEM particle datasets with varying characteristics, emphasizing the importance of accurately representing structural features to enhance biological interpretation. To illustrate the capabilities of these methods, we present an analysis of the Gr-HsP90-FKBP51 complex, a highly dynamic and biologically significant biomolecule. Its understanding is hindered by motion blurring, which obscures both its structural characteristics and dynamic behavior.

The accompanying graphic summarizes the analysis conducted by Zernike3Deep, depicting the PCA representation of the conformational landscape, along with the primary motion described along the first principal component. Additionally, the graphic also compares the motion-corrected map derived from Zernike3Deep heterogeneity analysis with the one obtained without correction by a classical method in the field (CryoSPARC (5)). The results underscore the importance of incorporating advanced heterogeneity analysis into cryoEM workflows, enabling the recovery of structural information that would otherwise be overlooked by the conventional assumptions of more traditional methods regarding reduced and discrete structural heterogeneity.

CONCLUSION

CryoEM structural analysis is undergoing a revolutionary shift towards extracting richer and more accurate conformational landscapes. The advent of new heterogeneity algorithms moves beyond the limiting assumptions of classical methods, significantly reducing the amount of structural information discarded during estimation processes. In this work, we introduce two innovative deep learning methods for advanced heterogeneity analysis, named HetSIREN and Zernike3Deep, as well as a meta-analysis environment named Scipion Flexibility Hub. These methods are designed not only to accurately estimate conformational landscapes and structural states but also to place a strong emphasis on the representation of structural features. These approaches aim to enhance the biological interpretability of the estimated structural states and improve the resolvability of highly dynamic molecular regions.

Poster Group 1

Background incl. aims
Gypsum has been traditionally used as a building material, but can also be a model for the development of injectable biomaterials for bone substitution. Set plaster, or gypsum ($CaSO_4.2H_2O$), is prepared by mixing dry hemihydrate powder ($CaSO_4.0.5H_2O$) with water. Its properties as a solid binder are largely influenced by the setting reaction occurring when $CaSO_4.0.5H_2O$ dissolve and crystals of gypsum precipitate. It is well known that the resulting solid is formed by an interlocked network of gypsum needles and platelets, but the exact setting process is not well understood yet. The objective of our study is therefore to monitor the evolution of crystals and understand the entire setting process, using operando observations [1], using Liquid-phase scanning electron microscopy.
Methods
For Scanning Electron Microscopy (SEM) experiments, the hemihydrate powder is manually mixed with an aqueous solution containing 5.2 mM citric acid. Plaster paste is then deposited onto the window of a Quantomix cell placed in a Zeiss Supra 55VP SEM microscope. Such cells are indeed water - and airtight, and therefore plaster evolves under the same conditions as in real use, especially in terms of water-to-plaster ratio. Gypsum crystallization is followed by taking SE and BSE images every 30 s.
In situ Environmental Transmission Electron Microscopy (ETEM) experiments are performed on a Titan ETEM from FEI/TFS. The hemihydrate powder is dry deposited onto a grid covered with a holey carbon membrane, then placed on a cryo-holder from Gatan/Ametek. The temperature is slowly decreased to 0°C and once stabilized, the partial pressure of H_2O is increased until liquid water covers the hemihydrate particles.
Results
The dissolution of hemihydrates and crystallization of gypsum is followed operando in SEM. Image processing and analysis procedures are developed to segment the gypsum crystals and follow their growth vs time. Based on geometric information and the knowledge of the equilibrium morphologies [2], we propose an indexation of the crystal facets (see example in Figure 1). The growth rates of the different planes, including unstable ones, is measured.
In situ experiments in ETEM give a more precise view of the onset of gypsum nucleation, with the formation and evolution of facets at the nanometer scale.
Conclusion
The use of liquid-phase electron microscopy at different scales allows the investigation of gypsum growth in a real plaster mixture. The formation of unstable facets and their transformation into stable ones are evidenced from the onset to full plaster setting. Moreover, the growth rates for all types of facets can be measured and compared with the few values found in the literature. The influence of several parameters is discussed (addition of a retardant, presence of a membrane, image acquisition conditions and irradiation damage) [3].

Background
Understanding high-resolution protein structure in the context of the whole cellular environment is the vision of visual proteomics. With the advent of high-throughput cryo-FIB and cryo-electron tomography (CryoET), paired with cutting-edge computational techniques, achieving such an ambitious goal is no longer a far-reaching dream. The new generation of cryo-FIB from Thermo Fisher Scientific uses plasma ions, which reduce redeposition and ion beam damage, substantially improving throughput. In preparation for a large-scale effort towards visual proteomics of the model organism Chlamydomonas reinhardtii, we have prepared enough lamellae to allow for acquisition of more than 1800 tomograms of different cellular compartments. Initial results demonstrate that the data is of sufficient quality to achieve sub-nanometer resolution (6Å) for the 80S ribosome using a fraction of the dataset (six tomograms). Together with collaborators, multiple proteins were selected as targets for sub-tomogram averaging (STA). One of these proteins required the development of a novel workflow. Photosystem II (PSII), which is present in very high abundance in the chloroplast, proved to be a challenging target as it is a membrane embedded protein with only a small region protruding into the lumen of the thylakoid membrane. The denoising neural network cryoCARE was implemented on all tomograms in the dataset to increase template matching accuracy. Unfortunately, in the case of PSII, denoising tended to blur or erase the small density that projects from the membrane which led to significant under picking when template matching was performed.
Methods
An alternative strategy that paired a regression denoising UNet with a semantic segmentation UNet was employed to generate candidate coordinates for further averaging and classification. Regression denoising: Synthetic training data for regression UNet was generated using CryoTomoSim. Using a box of 400x400x50 pixels, a mixture of medium and small proteins were modeled in four layers at 7.84 Å /pixel, exact protein identity is not important to training. 10 membrane vesicles were modeled. Iterations for each layer were 500, 500, 4000, 8000, and particle density was 0.8. Finally, the vitreous ice option was used. The output or ideal tomogram was simulated at -1 micron defocus, -89 to 89 tilt, 0.5 degree tilt increment and total dose = 0. The input or noisy tomogram was simulated at -3 micron defocus, -60 to 60 tilt, 3 degree tilt increment, total dose 80. Both datasets are loaded into Dragonfly 2022.2 (Object Research Systems) and used as training input and output for a regression 2.5D UNet with architecture: depth level 5, initial filter count 64, slice count 5, patch size 128, Loss function ORSMixedGradientLoss. Training proceeded for 46 epochs using a total of 15,840 patches. Segmentation: 2.5D Segmentation UNet for PSII was trained using Dragonfly 2022.2 according to protocol. In brief, Segmentation Wizard was used for manual annotation of 5-6 training slices and a generic UNet of the following architecture was trained: (2.5D: 3 slice, depth level: 5,

initial filter count: 64, patch size: 128). Training data included slices from tomogram numbers: 24, 373, 473, and 900. Aside from patch size, all hyperparameters are left as default. Training labels were Membrane, ATP Synthase, Ribosomes, PSII and Background. Post segmentation, PSII class was extracted for each tomogram, split into connected components, and center of mass X, Y, Z coordinates were calculated for each label and exported to CSV for subtomogram extraction.
Once trained, both UNets are applied to 41 tomograms to generate 52,000 PSII candidates which can be extracted for the STA workflow.

Results

With the initial set of 52,000 candidate coordinates, one high-quality class emerged during classification and as of the writing of this abstract an 18Å structure has been achieved (Fig 1). Ongoing work is in progress to apply this workflow to an additional 200 tomograms. With more candidate coordinates, optimized alignment of sub-tomograms, and further post-processing, we are confident we can improve the resolution of the in situ structure of PSII.

Conclusion

The scale of this dataset is exciting, but the huge number of molecular complexes within living cells makes it difficult to identify, confirm the identity of, and determine each structure by just one group. Achieving a full visual proteome of C. reinhardtii will necessitate a large collaborative effort. Challenging targets such as PSII demonstrate the need for new, creative methods or combinations of techniques to facilitate in situ structural determination. To that end, we would like to create an open access database for C. reinhardtii to accelerate annotation and curation, enable further cell biology research, and develop new computational tools for in situ cryo-ET. Along with sharing the raw data, reconstructed tomograms, denoised datasets, and structural determinations, we will provide high quality segmentations of selected datasets created using 2.5D (Dragonfly) and 3D (MemBrain Seg) UNets. This project has the potential to provide invaluable insights into cellular processes and will hopefully lay the foundation for future large-scale studies of other species.

Cryogenic large volume 3D and TEM sample preparation with multiple ion species plasma FIB

Dr. Min Wu, Haifeng Gao, Devin Wu
[1]Thermo Fisher Scientific, Eindhoven, The Netherlands

Poster Group 2

Direct quantitative investigation of the inner morphology and structure of soft materials is of critical importance to provide profound insights for properties evaluation. The scanning electron microscope (SEM) and focused ion beam (FIB), combined known as FIB-SEM or DualBeam, are conventionally recognized as a highly effective method to acquire 3D volume information. FIB-SEM together with integrated serial sectioning software has made the automated 3D data acquisition and analysis possible. However, slicing using Ga ion beam at room temperature has been found inducing severe damage to the beam sensitive soft materials, resulting in significant deterioration of the 3D data quality. Cutting edge cryogenic FIB-SEM technique provide a fully automated workflow which allows large volume, damage-free ion beam slicing and high spatial resolution SEM acquisition during serial sectioning under cryogenic conditions. With automated 3D reconstruction of the micrograph stacks, we can subsequently recover the comprehensive volume information of such beam sensitive materials. In addition, cryogenic multiple ion source PFIB has been confirmed to be capable of fabricating high quality large area TEM lamellae without damaging the beam sensitive bulk samples. Coupled with cryogenic in-situ nanomanipulator, the TEM samples can be easily lifted out under cryogenic conditions and subsequently transferred to TEM for further investigation.
In this paper we present a series of large volume 3D imaging results and TEM sample preparation examples of extremely beam sensitive soft samples. The samples were processed on Thermo Scientific Helios 5 Hydra Plasma FIB platform with multiple ion species (Xenon, Argon, Oxygen and Nitrogen) combined with integrated state-of-the-art rotatable cryo stage. The slicing and imaging acquisition was achieved using the latest generation Automated Slice and View software and the subsequent data processing was conducted using Avizo 3D analysis and visualization software. The unique technical experiment set up and comprehensive application experience will be discussed in this presentation. In addition, inert gas transfer workflow of the beam sensitive materials from the plasma FIB to TEM will be discussed.

PS-02 (2), Lecture Theater 5, august 28, 2024, 14:00 - 16:00

Background incl. aims
Aluminum (Al) shows promise as an excellent conductor, but its usefulness in electrical and electronic industries is often limited by its relatively low strength. Alloying pure Al with other metals like Mg, Cu, or Ag can increase its strength, but this also results in a decrease in its electrical conductivity [1]. Another method to strengthen Al is by reducing the grain size through severe plastic deformation such as high pressure torsion extrusion. However, grain growth can occur at elevated temperatures [2]. Adding small amounts of Mg and Si can stabilize grain growth by forming MgSi precipitates, which hinder grain boundary migration. This phenomenon is known as the solute-drag effect [3]. The impact of these precipitates on electrical conductivity is primarily influenced by their size, shape, atomic structure, and composition. All these parameters depend on the thermomechanical treatment and this work aims to bridge between structural and physical properties including the influence of individual mechanism during the thermomechanical preparation of the material.
Methods
In this study, Al - 0.94 at.%Mg-1 at.%Si solid solution were plastically deformed at 100°C using high pressure torsion extrusion (HPTE) and subsequently aged at temperature between 130°C and 160°C for up to 48 hours to generate MgSi precipitates. Tensile tests and Vickers hardness measurments were carried out to get information about the mechanical strength at different areas of the sample. Electrical conductivitz was measured on the sample surface by the Eddy current method using a Sigmascope device.
To investigate the overall microstructure, scanning electron microscopy (SEM) in combination with electron backscatter diffraction (EBSD) was performed using a Yeiss Auriga 60 equipped with EDAX Digiview EBSD camera. Information about dislocation density and crystal size was recorded bz X-ray diffraction experiments.
The nanometer sized precipitates were studied using high resolution transmission electron microscopy (HRTEM) including geometric phase analysis (GPA) as well as advanced scanning transmission electron microscopy (STEM) techniques such as energy dispersive X-ray spectroscopy (EDS), electron energy loss spectroscopy (EELS) and 4D-STEM were conducted on a double corrected Titan Themis Z operated at 300 kV. Atom probe tomography was conducted correlatively for accurate quantification of the composition of the precipitates.

Results
The initial polycrystalline Al - 0.94 at.%Mg - 1 at.%Si was about 100 um. Following high-pressure torsion extrusion (HPTE), the grain size reduced by a factor of 20. Subsequent aging processes did not result in significant grain growth but rather induced texturing, as illustrated in the SEM-EBSD inverse pole figure (Figure 1a). STEM-EDS measurements detected the formation of magnesium silicide

(MgSi) precipitates at both grain boundaries (GBs) and within the grain interiors. It is noteworthy that the morphology of GB precipitates differs from those within the grains. Within the grains, precipitates primarily exhibit an elongated rod-like morphology, while at the GBs, precipitates appear as symmetrical spherical caps (see Figure 1b). This difference in morphology can be attributed to the higher energy of the GB, which attracts solute magnesium and silicon atoms more strongly. As an illustration, Figure 1c depicts a low-angle boundary with a misorientation angle of approximately 4^{o} between adjacent grains. Such a low-angle GB would be composed of a series of dislocations with spacings typically falling within the range of 11nm. Notably, GB precipitates were observed to preferentially form at the initial positions of these edge dislocations. Atomic-resolution imaging of a single precipitate revealed a core-shell structure with a partially disordered shell. 4D-STEM was utilized to determine the phase of the precipitate core, elucidating the presence of a complex U2-$MgSi_2$ phase.

Conclusion

The formation of MgSi-precipitates by HPTE is responsible for a higher strength and better electrical conductivity. Our electron microscopy studies reveal that the morphology, crystal structure and composition of GB precipitates differs from precipitates formed within the grains. The GB precipitate shows a core-shell structure with higher concentration of Si in the outer shell. This can be attributed to the higher segregation energy of Mg in Al than Si. Finally, the GB precipitate could mainly attribute to the better performance during conductivity measurements. HPTE can be used to increase the fraction of GB precipitates and this may open the path to engineer fcc-Al for better performance as electrical conductor.

PS-03 (1), Lecture Theater 2, august 29, 2024, 14:00 - 16:00

Precision in heterostructure control within III-V nanowires is essential for the advancement of future technologies, especially quantum computing and quantum internet. The ability to embed one crystal phase, e.g., zincblende, within another, e.g., wurtzite, can be used to determine the optical and electrical properties of so-called crystal phase quantum dots. This crystal phase engineering offers a sharp transition between phases, superior to compositional quantum dots, but its control remains challenging within traditional ex-situ growth environments. Integrated electron microscopy with gas handling capabilities offers a unique in-situ perspective, revealing the dynamics of crystal phase formation and the parameters influencing it. Our research study is focused on how changing the growth conditions can be used to enable atomically precise crystal phase control. We also look into the growth dynamics and the commonly assumed control parameter: the contact angle, to unravel its actual impact on crystal phase determination in GaAs nanowires.
We use a cantilever based microheater system for GaAs Metalorganic Vapor Phase Epitaxy (MOVPE) growth within a Transmission Electron Microscope (TEM) as depicted in the figure to the left. This setup enables us to map the crystal phase formation at different growth conditions, specifically varying temperature and group V precursor flow. Instantaneous adjustments in temperature and precursor flow allow for the real-time analysis of the dependencies between these growth parameters and the phase transitions as illustrated in the figure to the right. Additionally, we introduce a field perturbation technique to the catalytic droplet to decouple its shape from the underlying growth conditions, further investigating the mechanisms driving the phase formation.
Our findings reveal that crystal phase transitions can be controlled with atomic precision using temperature shift in-situ. The cantilever-based microheaters offer rapid temperature changes, achieving 100^{o}C variations within milliseconds, significantly outperforming the slower response of precursor flow adjustments, taking tens of seconds. This rapid temperature control is instrumental in creating atomically precise crystal phase quantum dots. We conduct an in-depth study of droplet geometry during these phase transitions, revealing critical insights into the growth dynamics. Furthermore, by applying an external electric field, we successfully deform the catalytic droplet, effectively decoupling the contact angle from the crystal phase formation process. This experimental approach underscores the complex interplay between physical conditions and nanowire growth mechanisms.
In conclusion, using microheaters within a TEM with an integrated gas handling system has enabled a detailed study of the growth dynamics and heterostructure formation in III-V nanowires. By having the advantage of instantaneous temperature changes, we have demonstrated the ability to form crystal phase quantum dots with atomic precision. Furthermore, our findings challenge the traditional coupling of the contact angle as a driving force for the crystal phase formation. This research paves the way for new methodologies in nanowire synthesis, potentially revolutionizing the approach to designing materials for quantum and nanotechnological applications.

acquiCHORD : track the rotating ROI !

Dr. Gabriel Dehnez L'Hôte[1], Dr. Joël Lachambre[1], M. Thierry Douillard[1], Dr. Hdr Cyril Langlois[1]
[1]INSA de Lyon, MATEIS Laboratory, Lyon, France

IM-02, Lecture Theater 3, august 27, 2024, 14:00 - 16:00

Background and aims:
Acquiring images automatically in a SEM opens up a multitude of possibilities: temporal tracking of surface evolution (mechanical tests, environmental SEM...), image mosaics to cover a large field of view, drift correction, 3D acquisition with FIB... This is not new, but often this aspect of microscopy has been the preserve of microscope suppliers or equipment manufacturers (EDX, EBSD...). With the progressive opening of control APIs, and more particularly the advent of the Python language as an interface with the microscope, it is becoming increasingly easy to take full control of the machine. We present here the software acquiCHORD dedicated to the acquisition of images of a sample rotating in the microscope around an axis perpendicular to the stage. Such series of images are used in the laboratory for two main subjects: 1/ the 3D reconstruction of the surface of objects in the micrometric range [1], and 2/ the use of channeling contrast in crystalline materials for the study of crystalline defects by ECCI [2], for the obtaining of crystallographic orientation maps by the eCHORD approach [3], and for the automatic determination of grain size distributions by Machine Learning [4].

Methods:
Despite the relative simplicity of the idea (rotation - image acquisition - rotation, etc.), several locks must be released to allow this type of acquisition. We present in this work how the different solutions have been implemented in the acquiCHORD software to manage i/ the significant geometric offset between the area of interest and the rotation axis used, ii) the tilt between the optical axis and the rotation axis, which is necessary to obtain usable contrast variations, and iii) the mechanical imprecision of the rotation itself. Moreover, in order to be able to implement the acquiCHORD software on different brands of scanning electron microscopes, the program was designed to place on one side the computational calculations and drift correction, and on the other side the application of movement commands to the microscope. Indeed, the geometric references and the senses of displacement are not always the same from one brand of microscope to another. The program, coded in Python language, has been successfully implemented on ZEISS and ThermoFisher brand SEMs, with automatic machine recognition and notably of the APIs available (old OCX for ZEISS on a SUPRA model; full Python API for ThermoFisher QUATTRO SEM).

Results:
Two examples are presented. The first concerns the surface reconstruction of an OstraCode from the collection of the Laboratory of Geology of Lyon (Ecole Normale Supérieure). The particularity is the micrometric size of the object which makes impossible a 3D reconstruction of the surface by classical methods of optical photogrammetry. The second example concerns the characterization of the microstructure of a copper film for microelectronics with twins of a few tens of nanometers. Obtaining series of images in rotation on objects as small as these adds experimental challenges that have been overcome thanks to the use of a piezo-electric control stage fixed in the microscope, also controlled by the acquiCHORD software. Two examples of the use of the corresponding image series (orientation mapping and grain size determination by clustering) are explained

Conclusion:
The acquiCHORD software now makes it possible to obtain series of images in rotation in a SEM that can be used for several objectives, ranging from 3D surface reconstruction to fine characterization of the microstructure of polycrystalline materials. The software is under CeCILL license (from CEA CNRS INRIA Free Software) which is a free software license adapted to both international and French legal matters, in the spirit of and retaining compatibility with the GNU General Public License (GPL). AcquiCHORD is available on request.

Novel tools for the Spatio-Temporal Photocontrol of protein-protein interactions

Dr Virginia Puente[1,2,3], Dr. Jan Tonnesen[3], Dr. Matthieu Sainlos[1]
[1]Interdiscipinary Institute for Neuroscience-IINS-CNRS, Bordeaux, France, [2]Faculty of Medicine-UPV/EHU, Leioa, Spain, [3]Biofika Center - CSIC, Leioa, Spain

LS-02 (1), Lecture Theater 4, august 26, 2024, 10:30 - 12:30

Background incl. aims
The dynamic regulation of AMPA glutamate receptors (AMPARs) trafficking into and out of the synapse is a major mechanism underlying synaptic plasticity, a fundamental basis of learning and memory. However, the detailed molecular mechanisms governing the dynamics of these postsynaptic receptors are still not fully understood, stressing the need for new methods to modulate and monitor these processes. With the purpose of controlling locally, acutely and in a reversible manner the interaction between proteins involved in AMPAR trafficking we have developed original biomolecular tools based on optogenetics. These approaches will be effectively applied with spatial and temporal precision on selectively targeted individual cells and they will work based on two strategies: by reversibly immobilizing proteins by light, or light-controlling the binding state (association / dissociation) of proteins. The design and production of these tools have involved molecular/cell biology, biochemistry and protein engineering for later on, validating them in heterologous cells and neurons by Advanced Fluorescence Techniques. Our tools effectively address current technical limitations in neuroscience and could allow investigating questions from further biological disciplines.

Methods
The design and production of these optotools have involved molecular/cell biology, protein engineering and biophysical characterization, for later on, validated them in heterologous cells by Advanced Fluorescence Techniques. In order to characterize these approaches in transfected eukaryotic cells as a model of complex cellular context, a new red shifted FRET pair has been developed to monitor protein interactions. Besides heterologous cells, the approaches have been also validated by u-PAINT in neurons.

Results
On one hand, we have designed Photoactivatable competing ligands to destabilize AMPARs by disruption of the natural interaction between Stargazin and PSD-95. On the other hand, we have engineered photoswitchable crosslinkers to specifically recognize AMPAR subunits and control with spatio-temporal resolution the mobility and local number of AMPARs.

Conclusions
The approaches we have engineered should most importantly allow tackling fundamental questions related to AMPARs mobility but also be of high impact on a large scientific community as they could be transferable to many systems.

IM-04 (1), Lecture Theater 1, august 27, 2024, 10:30 - 12:30

Background
Scanning transmission electron microscopy (STEM) has recently advanced in two major directions: atomic resolution imaging of surfaces using the Secondary Electron (SE) signal [1, 2], and ultra-high energy resolution electron energy loss spectroscopy (UHR-EELS) [3]. In this contribution, we review the progress at Bruker AXS (formerly Nion R&D) in these two fields.

Methods
A new SE detector for the Nion STEM has been developed, in the form of a compact Everhart-Thornley detector located within the objective lens polepiece, less than 20 mm from the sample. It uses an electrostatic deflector to direct slow electrons that came from the sample in an off-axis direction. The deflected electrons go through a wire mesh window and are accelerated towards a scintillator. Light produced by the scintillator is guided by a glass rod towards a fast and efficient photomultiplier tube (PMT). The design is UHV-compatible and bakeable. It avoids injecting any first or second-order aberrations, or significant instabilities into the primary beam traveling towards the sample, and the attainable spatial resolution of the STEM remains the same when the detector is turned on.

The generation of the SE signal is strongly affected by surface contamination on the sample, and we use a laser illumination system we have developed to clean samples in-situ. Samples cleaned in this way typically stay clean in the UHV sample chamber of our microscope. The microscope is normally equipped with an ultra-high energy resolution electron energy-loss spectroscopy (EELS) system, which can be used both for phonon studies and for general-purpose low loss and core-loss EELS, and elemental mapping. Combining SE imaging with EELS typically allows a more complete characterization of the sample than either technique on its own. Another advantage of our solution is that the Nion STEM is able to produce atom-sized electron probes at primary energies of 20-60 keV, for which the SE cross sections are larger, and the delocalization of the SE signal slightly smaller than for 100-300 keV operation.

Results
We have used SE imaging to examine several types of samples with many interesting results, which will be shown at the meeting. Monolayer and few-layer samples such as graphene, BN and MoS2 are especially interesting, as their thinness simplifies the modeling of how the incident fast electron beam interacts with the sample to produce SE signal.

As an example, in Figure 1 we show a medium-angle annular dark field image (MAADF), secondary electron image (SE) and an EELS map of the same area of monolayer graphene that contains single-atom substitutional impurities. All the images detect the single-atom substitutions, and provide further information. The MAADF image essentially "weighs" the atomic nuclei, the SE image allows atomic resolution to be reached on the surfaces of thick and even bulk samples, and the EELS map demonstrates that the chemical species of individual atoms can be readily identified by their energy loss signal.

On a parallel track, we continue to improve the energy resolution of our Ultra-High-Energy Resolution Monochromated EELS-STEM (U-HERMES) system. The best resolution we have attained so far is 2.6 meV (full width at half-maximum (FWHM) of the zero-loss peak (ZLP)), at 20 keV primary energy. These results and the challenges encountered when trying to push the resolution further will be presented at the meeting.

IM-11 (2), Lecture Theater 5, august 30, 2024, 10:30 - 12:30

Single particle analysis (SPA) of frozen-hydrated proteins using cryogenic electron microscopy (cryo-EM) enables the three-dimensional structure determination of biomolecules with ångström resolution. Despite the remarkable advances enabled by cryo-EM SPA, the technique requires extensive data acquisition and processing and suffers from size limitations. Cryo-EM techniques are limited for very large biomolecules and very small proteins, due to the presence of multiple-scattering and poor contrast arising from the low electron fluence necessary to prevent sample damage respectively.
Scanning transmission electron microscopy (STEM) techniques have traditionally not been applied to the study of biological samples, due to the high fluence requirements of the most easily interpretable imaging modality using high angle annular detectors (HAADF). However, considerable efforts have recently been employed to apply phase-contrast STEM methods to study biological structures [1,2,3]. Among these techniques electron ptychography, where one iteratively reconstructs the scattering potential using a set of converged beam diffraction patterns (4D-STEM), stands out due to its high dose-efficiency and relaxed sampling requirements [4].
Cryogenic electron ptychography has recently been used to obtain sub-nanometer resolution of apoferritin samples using a relatively small number (~11,000) of high signal-to-noise reconstructions [5]. This “serial” approach, where one uses the 4D diffraction datasets to reconstruct 2D projection images which are then subsequently used to reconstruct a 3D volume using standard cryo-EM methods, is not maximally dose efficient. In this talk, I will propose an alternative technique we term “joint” ptychographic tomography SPA, where the 3D volume is reconstructed directly from the 4D data. This has multiple advantages over 2D projection-based techniques: first, nonlinearities arising from multiple scattering in the sample can be accurately modeled; second, it enables 3D regularization directly which can more effectively fill-in information from missing projection directions; and finally, it can more accurately capture amplitude and phase variations of the scattering potential.
Figure 1 illustrates the technique on small (1728 particles) simulated datasets of virus-like particles (PDB ID:1dwn) and apoferritin (PDB ID: 8rqb). Representative reconstructed micrographs are shown in Fig. 1b for the two proteins using electron fluences of 45e/Å2 and 35 e/Å2 respectively. These are used to reconstruct 3D volumes “serially” using the commonly used SPA software cryosparc with and without imposing symmetry. Alternatively, the volumes can be directly reconstructed using our joint ptychographic-tomography implementation in the open-source software py4DSTEM [4]. The resulting 3D maps, together with the respective docked models are shown in Fig. 1c.
We estimate that, for properly oriented poses, joint ptychographic-tomography offers a 10-20% improvement in resolution, as assessed by gold-standard Fourier shell correlation. Finally, we

illustrate how joint ptychographic tomography can be used to estimate the unknown tilt orientations directly from the 4D data and show progress towards experimental results.

IM-03 (3), Plenary, august 29, 2024, 10:30 - 12:30

When a converged electron probe is scanned across a thin sample, it acquires phase-shifts due to sample interactions which scatter the incident electron wavefunction. Reconstructing these various scattering sources from phase-less measurements of the intensity at far-field detectors is a high-dimensional, non-convex, inverse scattering problem. Iterative electron ptychography is a phase-retrieval technique which attempts to solve this inverse problem using the redundant information in a set of converged-beam diffraction intensities with sufficient real-space illumination overlap [1], e.g., using defocused-probe 4DSTEM measurements [2].
We have recently introduced a general computational framework, implemented in the open-source analysis toolkit py4DSTEM [3], to reconstruct common coherent scattering sources using physically inspired forward and adjoint operators as-well as a suite of regularization constraints robust against common experimental artifacts. Here, we present recent experimental results using the ptychographic framework on a number of materials-science samples, including atomic defects in few-layer hBN, post-acquisition aberration correction on Au nanoparticles, few-layer twisted SrTiO3 moirés, and strain measurements in upconverting core-shell nanoparticles [4], as-well as biological samples, including single-particle analysis of frozen hydrated proteins at sub-nanometer resolution [5].
Moreover, we present simulated results on how the depth-resolution of these phase-retrieval methods can be extended by solving a joint inverse problem for orthogonal tilt-series directly to obtain the three-dimensional nature of scalar and vector scattering sources such as electrostatic (Figure 1a) and magnetic vector potentials (Figure 1b), respectively [3]. In contrast to "serial" ptychographic-tomography, where one performs 2D ptychographic reconstructions for each tilt projection before reconstructing the 3D object using standard tomographic methods, "joint" ptychographic tomography leverages the ability of multislice-ptychography to capture non-linear propagation, together with three-dimensional regularizations, to recover some information inside the "missing-wedge" due to sample-geometry limitations.
Finally, we discuss the transfer of information of iterative electron ptychography and derive various analytical expressions and numerical results for a white-noise model. We compare the results against other common iterative phase retrieval methods, notably differential phase contrast and tilt-corrected BF-STEM [3], to arrive at experiment design recommendations as a function of electron fluence and defocus (Figure 1c).
Phase-retrieval methods in STEM offer particular promise due to their remarkable dose-efficiency, enabling the observation of otherwise imperceptible signals, such as fields inside materials, and of radiation-sensitive materials, such as hybrid organic materials and biological samples.

Electron microscopy study of energy materials growth

Prof. Yue Lin[1]
[1]University of Science and Technology of China, Hefei, China

Poster Group 2

Background incl. aims
Different energy systems have diverse requirements for energy materials, ranging from single-atom materials to crystalline materials. The synthesis of various energy materials tailored to specific applications is a pressing research area. Our aim is to investigate the real-time growth mechanisms of both crystalline and single-atom materials using in situ aberration-corrected electron microscopy. This exploration aims to uncover the nucleation and growth processes of metal nanomaterial systems and elucidate strategies for manipulating their phases.
Methods
In this study, we employed in situ aberration-corrected electron microscopy to observe the real-time growth of energy materials. We synthesized desired crystal catalyst materials and transformed precursors into targeted single-atom materials. Additionally, we investigated the sintering mechanism of Pt-based catalysts and proposed a sulfur anchoring strategy to guide the fabrication of high-loading single-atom and ultra-small metal intermetallic compounds. We also utilized the Oswald mechanism to synthesize various single atoms and developed a thermal printing method for single atoms. The mechanism behind thermal printing was scrutinized using in situ electron microscopy.
Results
Our study revealed insights into the nucleation and growth mechanism of metal nanomaterial systems, facilitating the manipulation of multiple metastable phases. We also proposed a sulfur anchoring strategy for the fabrication of high-loading single-atom and ultra-small metal intermetallic compounds. Furthermore, we successfully synthesized various single atoms using the Oswald mechanism and developed a thermal printing method for single atoms.
Conclusions
Through our research, we have advanced the understanding of the growth mechanisms of single atoms and crystalline materials, as well as the control of their synthesis. These findings contribute significantly to the field of energy materials and hold promise for future applications.

Nanoendoscopy-AFM: A new technique to explore Focal Adhesions in living cells

Mohammad Shahidul Alam[1], Mr Takehiko Ichikawa[1], Mr Takahiro Fujiwara[2], Mr Clemens Martin Franz[1], Mr Takeshi Fukuma[1]
[1]Kanazawa University, Kanazawa, Japan, [2]Kyoto University, Kyoto, Japan

IM-09, Lecture Theater 5, august 29, 2024, 14:00 - 16:00

Introduction: Focal Adhesions (FAs) are complex structures containing several adapter proteins such as paxillin, vinculin, FAK, talin, and zyxin, which together create a dynamic nanostructure that mechanically links intracellular actin bundles to the extracellular matrix (ECM). They play important roles in various cellular processes including cell adhesion, cell migration, force transmission between the intracellular structures and ECM, or vice versa. Although several microscopic techniques have been employed to explore FA architecture, many of these methods face limitations when applied to living cells or involve complex sample preparation that can impact the natural function of FAs. Consequently, there is a strong demand to investigate various aspects including the dynamics of these multiprotein complexes in living cells using new techniques. A recent advancement in this regard is Nanoendoscopy-Atomic Force Microscopy (AFM), a technique that measures intracellular structures of living cells without disassembling the cell, maintaining intracellular structures in their physiological environment [1]. Here we use this advanced nanoendoscopy-AFM technique to visualize and study the dynamics behavior of FAs in living cells.
Methods: Fig. 1a shows the schematic of the 3D nanoendoscopy-AFM technique. A long and sharp AFM nanoprobe fabricated by electron beam deposition (EBD) or focused ion beam (FIB) milling is inserted into living cells to visualize FAs by collecting force versus distance (F-z) curve maps. The continuous penetration of the cell by this ultrathin nanoprobe does not damage the cell or negatively impact cell viability.
Results: We succeeded in imaging FA structure directly within living fibroblast cells by nanoendoscopy-AFM, as confirmed by complementary confocal microscopy (Fig. 1b,c). FA indentation or penetration by the AFM nanoprobe does not trigger FA disassembly. Using this approach we can monitor FA growth over time, as well as the dynamic rearrangement of stress fibers connecting to individual FAs (Fig. 1d,e). Moreover, FA thickness is reduced when it matures or grows from the cell periphery to the center. In addition, this technique enables us to obtain insights into the mechanical characteristics of FAs. Our findings reveal that FAs exhibit increased stiffness during maturation and undergo softening upon disassembly.
Conclusion: Our results provide a new nanoscale look at FA ultrastructure inside living cells and at the dynamic processes regulating stress fiber attachment to these structures. In the future, we aim to gain more detailed information on the structural and biomechanical intricacies of FAs in living cells.

IM-02, Lecture Theater 3, august 27, 2024, 14:00 - 16:00

Background incl. aims
In 2005, Ahmed H. Zewail merged ultrafast femtosecond laser with femtosecond precision with TEM's sub-nanometer spatial resolution developing Ultrafast Transmission Electron Microscopy (UTEM). This technique combines the sub-nm spatial resolution of TEMs with the fs temporal resolution of ultrafast lasers and is paving the way to the study of ultrafast fundamental processes at the nanoscale. In the last years, a new paradigm for the arbitrary modulation of the probing-electron wave function phase through quantized photon-electron interaction was put forward and has the potential for enhanced microscopic sensitivities to material properties [1]. The quality and the extent of the electron beam shaping strongly depend on matching the transverse coherence of the electron beam (~ 1 µm) with the spot size of the laser beam, which generally exceeds the former by more than one order of magnitude. This mismatch prevents the modulation of the electron wave function phase, which is crucial for the ability to probe specific materials degree of freedom (such as chirality of materials when adopting a vortex electron beam). In order to address this issue, we propose the integration of a crystallin silicon metalens in the platform that enables electron-light interaction.

Methods
The electron beam shaping inside the UTEM is facilitated by a Photonic free-ELectron Modulator (PELM). An external Spatial Light Modulator (SLM) imprints an arbitrary amplitude and phase pattern on an ultrafast optical field. The light is then projected on a flat electron-transparent metallic thin film on the PELM platform, where it interacts with the electron beam. The integration of a dielectric metalens into the PELM enables the focusing of incident light down to a few micrometers before its interaction with the electron beam. We fabricated a metalens on a free-standing silicon membrane kept in place by a silicon window. Then, we integrated the silicon windows to the PELM platelet positioned at 45° with respect to the metallic film. The focal distance of the metalens is on the order of several hundreds of µm's. This geometry allows the focusing of the light arriving horizontally from the side of the microscope on the metallic film, where the electron-photon interaction will occur. A metalens is composed of properly arranged nano antennas (also called meta-atoms) [2]. We designed the meta-atoms geometric parameters by performing extensive finite element method (FEM) simulations through the wave optics module of the COMSOL Multiphysics® software. The position and orientation of the meta-atoms on the metalens surface are then arranged to obtain the geometric phase spatial variation needed to focalize the incident light beam.
Results

From the Comsol simulations we obtained the meta-atoms dimension that optimizes the transmission and the phase difference condition, as well as mechanical constraints. The obtained theoretical transmission is equal to 44%. The metalens-integrated PELM geometry requires a focal length of 0.7 mm to let the electron beam interact with the focused laser spot and then proceed along the microscope. For that focal length and a 500 µm metalens diameter, the wave propagation simulations provide the focusing of the incident laser down to 2.5 µm.
We have also computationally characterized the performance of the designed dielectric metalens by simulating the propagation of a gaussian plane. Moreover, we explored the metalens robustness to non-idealities by applying a random noise on the phase and we verified that a transversely-patterned light beam, such as a Hermite-Gaussian profile, is correctly focused without distortions.
Conclusions
This setup is a compact solution that can be inserted in the UTEM to allow matching the laser spot size with the transverse coherence length of the electron beam, providing access to a wide range of excitation schemes and pump-probe geometries. Currently, we are working on the optical characterization of the metalens, in order to experimentally confirm its performances. The next step will be to mount the metalens windows in the PELM and characterize its performance inside the UTEM.

Funding
This work is part of the SMART-electron Project that has received funding from the European Union's Horizon 2020 Research and Innovation Programme under Grant Agreement No. 964591.

PS-04 (4), Plenary, august 27, 2024, 14:00 - 16:00

Solid-state batteries are of particular interest when it comes to safe high-energy storage as they potentially enable the usage of lithium anodes. Theoretically, a lithium metal anode has a more than 10 times higher specific charge capacity than graphite [1], which is typically used as anode material in commercially available lithium-ion batteries. But, industrial production of highly reactive lithium metal anodes is challenging. One approach is to electrochemically deposit lithium in a so-called anode-free cell. The lithium is plated between a current collector and the solid electrolyte during charging. In the half-cell assembly investigated throughout this study, the current collector consists of stainless steel and the solid electrolyte of argyrodite-type Li6PS5Cl. The latter is a promising solid electrolyte candidate due to its high ionic conductivity, but comes along with a solid electrolyte interphase (SEI) formation when in contact with lithium metal [2]. Therefore, the characterization of interfacial side reactions at the micro- and nanoscale is crucial.

Scanning transmission electron microscopy (STEM) offers structural insights at atomic resolution. Still, it comes with a challenging sample preparation that is further complicated by moisture and ion beam sensitivity of the battery materials. Furthermore, lithium metal and sulfide electrolytes like Li6PS5Cl require cryogenic conditions during ion- and electron-beam exposure to withstand the beam doses. The plasma focused ion beam (PFIB) system Helios 5 Hydra CX is capable of an inert-gas transfer from and to the glove box as well as sample preparation at temperatures around -190 °C. In the PFIB, the sample is thinned to electron-transparency (< 100 nm), from where it is transferred to the glove box and mounted in a sealed transfer holder (Mel-Build) for further investigation in a STEM (JEOL JEM-2200FS). Low-dose electron imaging and STEM-EDX (energy dispersive X-ray spectroscopy) at cryogenic temperatures are performed.

The lamella preparation of the highly sensitive lithium metal and Li6PS5Cl requires adapted preparation steps: low ion currents to preserve the Li | Li6PS5Cl interface as well as eliminating tungsten deposition. Usually, tungsten deposition is used to protect the sample during thinning and to attach the sample to the manipulator needle for lift-out and attachment of the lamella to the copper TEM grid. The high mobility of ions in Li6PS5Cl makes it impossible to distribute the tungsten atoms of the precursor gas locally. Hence, a complete gas-free workflow is needed. The manipulator needle is attached to the lamella gas-free using redeposition of the needle material. Also, the lamella is attached to the copper grid using redeposition of the grid. The steel current collector serves as a protection layer during thinning.
The thinned lamella is investigated in the STEM. A cryo-STEM EDX map and spectrum are depicted in Figure 1. The dark blue area (Figure 1b) encircles Li6PS5Cl with its characteristic peak relation of phosphorus, sulfur, and chlorine, as seen in the corresponding EDX spectrum (dark blue graph Figure 1c). Between lithium and Li6PS5Cl is a roughly 200 nm thick SEI, colored in light blue in Figure 1b, showing chlorine enrichment in the EDX map (Figure 1a) as well as in the corresponding EDX

spectrum (light blue graph Figure 1c). Lithium is not detectable using EDX, as it's characteristic X-rays have too low energy and are absorbed by the detector's window.

The preparation of electrochemically plated lithium and Li6PS5Cl using the PFIB is highly complex and requires the absence of air as well as cryogenic conditions. Nonetheless, the effort is necessary to gain structural and chemical information on the SEI. An approximately 200 nm thick chlorine-rich layer between plated lithium and argyrodite-type Li6PS5Cl is already observed. Further measurements like STEM-EELS (electron energy loss spectroscopy) to detect lithium and TEM-PED (precession electron diffraction) for structural information need to be carried out.

Image fusion for 3D reconstruction of SEM images

Dr Turkka Salminen[1], Dr Lucio Azzari[1]
[1]Tampere Microscopy Center, Tampere University, Tampere, Finland

Poster Group 1

Background
Image fusion is commonly used in photography and optical microscopy to merge a stack of images taken with different focal lengths to produce a single in-focus image. It is necessary in applications where details of a single image are required to be as sharp as possible (e.g., medical imaging and surveillance), and where acquisition conditions are limited (e.g., when the scene depth is much larger than the system's focal length). There are several approaches and algorithms to determine the in-focus regions in each image of the stack. The algorithms can be grouped into three main categories: spatial domain, transform domain, and neural network [Bhat2021]. Furthermore, when the focus depth of each image is known, a depth map of the scene can also be estimated as a byproduct of the fusion algorithm. This depth map will contain information about the apparent distance of each object in the image.
Scanning electron microscopes are known for their improved depth of field over light microscopes and perhaps that is the reason why image fusion has seen little use with scanning electron microscopy images [Ersoy2008, Marturi2013]. However, the focal depth in SEM is known with high precision and the depth of field can be adjusted with the operating parameters of the microscope.
Methods
The focus of our work is twofold: 1) create an in-focus image using multiple SEM images acquired with different focal lengths and 2) use that information to estimate a depth value for each pixel of the resulting in-focus image. To do that, spatial domain image fusion algorithms are the most suitable for the task, because each output pixel is selected from one of the corresponding input pixels, and thus its focus depth is unequivocally determined by the focus depth of the image from which the pixel is chosen. Transform domain algorithms do not offer this possibility because the output image is usually a weighted sum of the input images in a particular transform domain. Furthermore, because the algorithm must be accessible, fast, and independent from the input data, we have decided not to use a neural network-based algorithm.
Our approach is based on the algorithm proposed by Haghighat et al., where the in-focus image is built by finding, pixel by pixel, which input image has the maximum local variance. This algorithm assumes that local variance and sharpness are directly correlated.
Our method can be divided into three mains steps:
1. Compute the magnitude of each input image gradient, that will then be used to estimate each input image local sharpness.
2. Run a sliding window of size 8x8 across all the gradient images; for each block we compute its variance, and we find and store in a 2D array the index of the input image with the largest local sharpness (i.e. largest local variance).
3. Smooth the array of indices with a low pass filter to make the output more consistent.

Results
The output from the above algorithm is a map that contains, for each output pixel, the index of the sharpest input image. From this index map we can construct the output in-focus image and its associated depth map (from focus).

Because we process the image block-wise, some blocky artifacts might occur at the borders of objects. To mitigate this problem, we propose an additional post-processing filtering of the depth map using the guided filter proposed by Sun et al. This filter aims at refining the depth map using the in-focus image as a pilot (like a bi-lateral filter).
The in-focus image and its depth map can finally be used to create a 3D point cloud of the imaged sample for the user to inspect it in three dimensions.
Conclusion
Our results indicate that this is a promising technique for visualization of SEM data and offers the possibility to determine the surface profile of samples. We will present our protocol for obtaining the image stacks, the procedure to create an in-focus image, depth map and a 3D point cloud from the data using the in-house built application.

Dynamics at phase boundaries of active catalyst studied by multi-scale operando EM

Prof. Dr. Marc Willinger[1]
[1]Department of Chemistry, School of Natural Sciences, TU Munich, Garching bei München, Germany

PS-05 (1), Lecture Theater 1, august 28, 2024, 10:30 - 12:30

Catalysis is a highly complex phenomenon and intricately linked to the interplay between processes that dominate at different time and length scales. It is therefore impossible to understand the emergence of catalytic function solely based on the study of static atomic arrangements. Up to now, the full-scale complexity of catalysis is only poorly understood because the way in which atomic-scale processes influence the behavior and dynamics at larger scale is not well documented experimentally. The result is that we still, to a large extent, develop new catalysts on the basis of iterative trial-and-error approaches. Elucidating the link between atomic-scale structural dynamics, feedback mechanisms, and collective behaviour is the key to a deeper understanding and further optimisation of catalysts and processes. From imaging of quasi-static low- energy configurations through gas-phase-induced state switching to observation of complex non-equilibrium dynamics and oscillatory behaviour (Figure 1), electron microscopy has provided novel insights across several length and time scales and has meanwhile matured from a service tool for catalyst researchers to a driving force in catalysis research [1,2]. In my presentation, I will show that consideration of dynamics and processes taking place at different time and lateral scales as well as the consideration of non-linear and complex behaviour is essential for our understanding of working catalyst.

PS-05 (3), Lecture Theater 3, august 30, 2024, 10:30 - 12:30

Background incl. aims
The dealumination is one of the most efficient strategies for designing optimized catalysts of zeolite-type [1]. In aluminosilicates such as the zeolite Y, which is a widely employed material in the field of the heterogeneous catalysis, the dealumination involves the removal of Al atoms in the 4-fold coordination (with oxygen) from the crystalline zeolitic framework thus leading to an acquired hydrothermal stability and an interconnected hierarchical porosity [2], which are both beneficial properties in catalytic reactions. Although, the mechanism of structural rearrangement after the extraction of the framework Al atoms (FAL) from their tetrahedral sites turning into extra-framework Al atoms (EFAL), the evolution of the mesopores (pores from 2 to 50 nm of diameter), the elemental distribution of Si and Al as well as the chemical speciation between the FAL and EFAL are still considered as hot topics in the subject [3]. Our study aims indeed to provide an understanding of the phenomenology of the dealumination at the nanometric space resolution by combining different TEM-based approaches.
Methods
For this research work, a series of 4 zeolites Y at subsequent stages of a multi-step dealumination process, mainly obtained by alternating thermal treatments under steam and chemical treatments, was considered. A first hydrothermal treatment (steaming 1, 620°C and 80% humidity) is performed on the commercial CBV300 (Zeolyst) zeolite Y in a reactor and followed by a NH4 ionic bath, a second hydrothermal treatment (steaming 2, 700°C and 80% humidity) and a HNO3 (1M) leaching. These zeolites undergoing such protocol were characterized by Electron Tomography, STEM EDX, STEM EELS together with synchrotron STXM XAS in order to locate the chemical signatures of Si and Al within the grain and correlate with morphological modifications.
Results
The results of the electron tomography highlight the presence of a well developed system of mesopores that is structured in cavities and channels converging towards the core of the grains of zeolites. The facets of the zeolites Y are mainly belonging to the {111} smmetry and the results show the preferential elongation of the mesopores parallelly to the basal facets. Moreover, most of the channeling mesopores propagate at the intersection between two plans of the {111} simmetry. At more advanced steps of the dealumination, the mesoporous network is observed in conjunction with some extra material on the edges of the zeolite, inside its microporous matrix and into the mesopores. This extra-framework material, that is suspected to be amorphous, is associated to a phase enriched in Al as it is observed with the STEM EDX analysis. The characterization by STEM EELS on the K-edge of Al and Si reveals the gradient of these two elements on the edge of the grain and at the mesopore mouth. The Si/Al ratio is provided for this extra-framework material, that we consider as EFSiAl (Extra-Framework Silica Alumina) and, for the first time, related to morphological aspects at the nanometric scale. Moreover, the analysis by STXM XAS on the Al K-edge shows that the signal arising from such areas is mainly tetrahedral, in contrast with the current idea that the EFAl sites are

octahedral α-alumina type. These findings could be interpreted by assuming the flexibility of the the framework and its reversibility to 4-fold Al under experimental vacuum conditions. Although, small traces of 6-fold Al persist in the XAS spectrum and might provide a proof of the difference in terms of structure and stochiometry of the EFSiAl phase.

Conclusion

This study has evidenced the role of the {111} family of plans as preferential symmetry for the development of the mesoporous network within Faujasite Y zeolites during dealumination treatments. At the single crystal scale, the removal of material inside the grain is coupled in parallel with the presence of areas enriched in Al. This is termed as the EFSiAl phase, and it is considered as a collateral product of the dealumination. The EFSiAl is mainly observed at the edges of the grain and inside the mesopore. Contrarily to the expectations arising from the literature which tend to assign to the Al sites of the extra-framework material the 6-coordination, our results show a principal tetrahedral signal even for the Al on the EFSiAl phase.

Poster Group 1

Electron microscopical analysis frequently suffers from the criticism that we're only investigating a small region, a small percentage, of the whole material. When we only investigate minute regions of the sample, how can we make sure we're not biased by what we find or haven't found? How can we make sure that we're achieving a realistic overview of the sample? One strategy to increase the sampling is to acquire a large area mapping, where secondary electron (SE), backscattered electron (BSE) and X-ray signals are collected over 100 to 10,000's of fields by moving the stage to cover the entire sample. The rate limiting factor is usually the throughput and sensitivity of the energy dispersive spectrometry (EDS) detector(s) to collect enough X-rays to achieve an acceptable signal-to-noise ratio (SNR) for all elements in the sample.

One solution is to increase the solid angle of the EDS detector, by moving it under the pole piece of the scanning electron microscope (SEM), while keeping the ability to acquire SE and BSE signals simultaneously. In 2023, we introduced a detector which combines both X-ray and BSE sensors into one device (Unity, Oxford Instruments, UK). The head features two circular silicon drift detector X-ray sensors, two custom shaped BSE sensors and two cutouts to give unobstructed line-of-sight to conventional EDS detectors. Here, we will lift the lid on some of the important developments required to bring together the backscattered electron and X-ray (BEX) detector system. Figure 1 shows the type of data which achievable with this detector.

Firstly, the integrated BSE. Having two distinct sensors means both Z-contrast and topography can be produced. The unusual shape of the detectors maximises the collection area of the detector and therefore SNR, whilst still maintaining compatibility with additional standard EDS detectors. The Z-contrast is possible because the sensors are symmetrically positioned around the pole piece and cover a large solid angle. Combined experiments with a BSE signal is important because this has a much higher signal to noise and better resolution than x-ray elemental maps. In the overlaid results, Figure 1, the BSE is providing a sharpness to the image that wouldn't be present in the x-ray maps alone.

Secondly, the Unity detector is designed to work in parallel with a standard EDS. The Unity detector has a protective membrane over each of the X-ray sensors to help extend their life and cope with the high count rates an under pole piece detector is exposed to. Due to this membrane, there is limited detection of light elements, combining with a traditional EDS detector resolves this. Counterintuitively, having a second detector with a lower count rate is much better for mapping light elements, as it allows for the use of a longer process time, leading to improved energy resolution and therefore by association improved deconvolution of the lower energy X-ray lines. The BEX detector does not need to process low energy signals which means it can run faster and be optimised for the higher energies. This set up is technologically slightly tricky as it means the combination of two X-ray sensors which differ in size, shape, and sensitivity, in addition to the simultaneously acquired BSE signal. Unity is designed to maximise the throughput and achieve the optimal mapping resolution,

whilst the ideal process time for the conventional EDS detector can be selected based on the relative solid angle, detector sensitivity and geometry. A similar ratio and comparison of the variance optimizes the selection of the optimum X-ray map for each element. Map selection has also been optimized for a multidetector system, making sure the best results are being displayed, for each element.

BSE experiments are typically run with a constant dwell time where are EDS experiments are run with a variable dwell time but maintaining and constant live time. This must be taken into account when designing a synchronized experiment. We will present on the technology behind an improved workflow for synchronized multi-sensor and multi-signal experiments, including the importance of acquisition synchronization, combined processing and displaying of the final data.

Figure 1: Showing example results taken with a BEX detector, with a combined overlay of the BSE and several elemental maps (a). A larger view of (a) is shown in (b) emphasizing the sharpness of contrast which is achievable by this technique.

Background incl. aims
Uranium (U) is a ubiquitous element in the Earth's crust, and its biogeochemical behavior is primarily constrained by its redox transformation from soluble uranium (U) hexavalent species (U(VI)) to sparingly soluble tetravalent species (U(IV)) under anoxic conditions. U(VI) reduction by mineral phases, most commonly ferrous iron-bearing minerals, has been shown to produce crystalline U in the form of UO_2 as the end-product at circumneutral pH values. However, there is increasing evidence for the presence of pentavalent U (U(V)) in these minerals. Our work [1] has evidenced the presence of U(V) during U(VI) reduction by preformed magnetite and its persistence for days to weeks prior to the formation of fully reduced U(IV)O_2 nanoparticles. Despite this evidence, uncertainty about the mechanistic role of U(V) in uranium reduction pathways remains.
We reported the formation of single U oxide nanocrystals (1-5 nm) followed by the formation of nanowires that extended from the magnetite surface outward. Over time, the nanowires collapsed into ordered UO_2 nanoclusters, resembling those previously reported for the final product after U(VI) reduction by magnetite [2]. U(IV) was suggested as the dominant valence state in the nanowires based on both Fast Fourier Transform (FFT) on specific regions of HAADF-STEM images of the nanowires and the branching ratios (BR) obtained from M4/M5 peaks from U TEM-EELS spectra. However, due to the sensitivity of U(V) under the beam, the presence of mixed valence states may be overlooked by using the BR acquired from U TEM EELS spectra under high beam current. Differences between UO_2 and uranium oxides with mixed valence states, such as U_3O_8, are too small to be robustly differentiated with FFT analysis of HRSTEM images. Current work aims to measure O K-edge EELS STEM spectra of the nanoparticles within the nanowires and compare the edge feature to that of U oxides reference standards to characterize the valence state of nanocrystals.
Methods
We gathered low-loss and high-loss spectrum images of O-K edge and U N edges for UO_2+x standards and time-resolved U(VI) reduction samples. Solutions with magnetite (0.25 or 5 mM Fe) and U(VI) (30 or 200 uM) were prepared anoxically at neutral pH, and samples at various reduction stages were collected. Both U oxide standards and U nanowires formed during the reduction process are susceptible to electron beam-induced damage and reduction, changing the electronic structure of the samples. Thus, it is necessary to use ultra-low beam currents of 10-50 pAs, and we adapted the Gatan Continuum-K3 spectrometer-detector alignments to optimize sensitivity, dose rate per pixel, and the signal-to-noise ratio (SNR) at such low beam doses. We processed the EELS Data cubes with zero loss alignment, denoising, deconvolution, background subtraction, and spectral smoothing. Then, spectra from nanocrystals within the nanowires and in nanoclusters were extracted and

compared with those from UO_2+x standards. We also fit the O K-edge of these spectra with data from UO_2+x standards to determine the valency and state of sample reduction.

Results

STEM-EELS measurements were performed for the following U oxide standards that contain the three main U oxidation states or mixtures thereof: UO_2 U(IV), U_4O_9 2xU(IV)+2xU(V), U_3O_7 U(IV)+2xU(V), KUO_3 U(V), and $BaUO_4$ U(VI). The O K-edges of standards were compared with the corresponding simulations based on DFT calculations, see Fig.1(a). The U(IV) containing standards O K-edge (UO_2, U_4O_9, and U_3O_7) have a lower intensity at peak 1 (533 eV), whereas peak 2 (539 eV) has a higher intensity. In contrast, U(V)- and U(VI)-containing standards O K-edges (KUO_3 and $BaUO_4$) have a different electronic structure, with a higher intensity of peak (labeled 1) at 534 eV and a lower intensity peak (2) at 541 eV. The measured U oxides standards correspond well with their simulations, and averaged spectra of each standard (at least 8 measurements) are used for the multiple linear least fitting within the region of O K-edge (520-620 eV) in nanowire samples. Figure 1(b-f) shows that the experimental setup allows us to obtain high-quality spectra from a single pixel even though the thickness of the nanowires does not exceed 10 nm. Fitting shows the presence of mixed valence state oxides U_4O_9 and U_3O_7 within the nanowires, thus confirming the presence of U(V).

Conclusion

We measured O K-edges of U oxide standards with various valence states and samples comprising nanowires composed of 1-5 nm size particles with as low as a 50 pA dose. The fits of reduced nanowire samples and comparison UO2+x standards O K-edge spectra confirm the presence of mixed valence state particles in nanowires, thus evidencing the presence of U(V).

Fig.1: (a) Comparison of O K-edge spectra for measured (M) U oxides standards and its respective simulations (S) that show varying peak 1 and 2 heights and their eV shift that reflects distinct U oxidation states. (b) Sample containing nanowires. (c) Detail of approximately 30 nm long nanowire sitting between 2 magnetite grains. (d) High loss spectrum imaging (SI) of the selected region with background subtraction, the red square represents 8 angstrom-sized pixels. (e) EELS spectrum from selected pixel (red square) of SI shows the quality of data. (f) Multiple linear least square fitting (MLLS) map shows the presence of mixed valence state U oxides U_4O_9 and U_3O_7.

Background
Terahertz (THz) radiations with low energetic photons (meV) are used today in a wide range of applications such as imaging, sensing or spectroscopy. The low photon energy of THz radiation has the advantage of inducing low damages on fragile materials by reducing heating encountered when a visible wavelength is used.
Our research is based on the combination of a single-cycle THz source with atom probe tomography (APT) to study THz-assisted field evaporation on a wide range of materials, including metals, ceramics, semiconductors (crystalline silicon), and insulators (amorphous silica). Using our homemade THz-assisted APT setup - “TERA-SAT” - we aim to explore the new impacts of THz pulses on materials characterization at the atomic level.
Methods
Atom Probe Tomography (APT) is an imaging technique based on controlled field evaporation of atoms from a nanometric needle-shaped sample under a strong electric field. Evaporation of atoms is triggered by a laser pulse in the UV or THz domain. The ions are then directed onto a time- and position-sensitive detector. The 3D atomic positions are reconstructed through a back-projection algorithm and the chemical nature is determined by calculating the mass-to-charge ratio.
The experimental setup used (fig. 1(a)) in this study is composed of a pulsed THz source based on the two-color plasma generation process coupled with an APT chamber.
Results
THz radiation has been proven to be beneficial for the reduction of thermal effects in field evaporation of metals and low band-gap materials such as LaB6.
Further tests have also been performed on pure silicon nanotips, where the presence of thermal effect is strongly dependent on the spectrum of the THz radiation.
Finally, we analysed nanotips made of sol-gel amorphous silica, which is chosen as matrix for bio-molecules embedding for future studies. First, we demonstrated the possibility of field-evaporating such material in a well-controlled way using THz pulses. A more detailed comparison of the mass-to-charge ratio spectra obtained with THz-APT and UV-assisted APT (fig.1 (b)) reveals an increase of the signal to noise as well as an improvement in the mass resolving power which is inversely proportional to the full width of the peak at 1 and 10% of the maximum.
Conclusion
We have analyzed different materials using our TERA-SAT setup, demonstrating its ability to trigger field evaporation. The use of THz radiation is proven to reduce local heating phenomena, especially in the case of metals, allowing a-thermal field evaporation.

We have obtained encouraging results also for non-metallic samples, but further investigation will be necessary to find out the optimal parameters (THz amplitude, DC field) to improve the accuracy of compositional analyses, thus to increase the signal to noise ratio and the mass resolution power of the mass spectra.

Layered chalcogenides ternary alloys and heterostructures are known as great thermoelectric, topological insulators as well as non-metallic plasmonic building blocks. We present on a multimodal approach based on in situ transmission electron microscopy (in situ TEM), monochromated electron energy loss spectroscopy (mono-EELS) in conjunction with density functional theory (DFT) calculations and electron-driven discrete dipole approximation (e-DDA) simulations to establish a holistic understanding spanning across nanoscale dynamics, interfacial properties and ultimately correlating structural evolution and heterogeneities to plasmonic modulations in Bi-Sb-Te ternary alloys and heterostructrues.

Using in situ heating TEM and DFT calculations, we identify the sublimation pathways, the role of native point defects and edge configurations in anisotropic sublimations of Bi2Te3-Sb2Te3 in-plane heterostructure and Sb2-xBixTe3 alloy. Structural evolution consisted of formation, growth, and coalescence of thermally induced nanopores and ultimately preferential sublimation initiating at reactive regions with structural heterogeneities. The preferential sublimation sites are center, heterointerface and outer edges for the heterostructure and only outer edges for the alloy counterpart. Excessive Te in the center of the structure and high density of defects on the heterointerface are anticipated to be the main driving force for preferential depletion of chalcogenide (Te) from these reactive sites. Additionally, The DFT calculations provide a mechanistic understanding on the role of native defects and edge formation energies, revealing the antisite defects including TeBi and TeSb to be the dominant native defect, promoting preferential Te sublimation and playing a key role on the defects assisted sublimation.

To understand defect-plasmon interactions, we perform mono-EELS, e-DDA simulation and SVD analysis to understand the electron-driven plasmon excitations in the ternary heterostructures. We successfully resolved the nanoscale spatial variation of surface plasmon resonances in the pristine heterostructure as well as in the presence of intrinsic or extrinsic defects (i.e. thermally induced defects). Furthermore, we have used singular value decomposition (SVD) analysis to disentangle the spectral data and identify the individual spectral contributions of various corner, edge, and face modes. Finally, the experimental mono-EELS findings are validated with e-DDA numerical simulations. Layered chalcogenide ternary systems as a less explored plasmonic system holds great promises as emerging platform for integrated plasmonic. Understanding the sublimation pathways, nanoscale interfacial dynamics and ultimately introducing controlled structural defects can open avenues for defect engineering and ultralocal modifications of plasmonic properties in these non-metallic plasmonic systems.

Background incl. aims
Electrochemistry plays a crucial role in various hydrogen production technologies [1], yet understanding the intricate nanoscale processes that govern these reactions remains a significant challenge. To address this gap, we employ advanced electron microscopy techniques to visualize and unravel the nanoscale mechanisms behind electrochemical phenomena.
Methods
While the Plasma Focused Ion Beam (PFIB) tomography at room temperature allows us to visualize the evolution of solid oxide fuel cell (SOFC) [2] electrodes due to operation, and the cryo PFIB tomography allows characterizing proton exchange membrane (PEM) [3] of low-temperature water electrolysis. This coupled with the in-situ TEM allows us probing the mechanisms of low and high-temperature electrolysis.
Results
PFIB tomography enables us to generate high-resolution 3D reconstructions of SOFC materials, revealing the evolution of triple-phase boundaries and potential degradation sites that influence ion transport and catalytic activity. In situ TEM experiments, utilizing MEMS chips, allow us to monitor electrochemical processes in real time. By studying $Sr_{0.95}Fe_{0.9}Mo_{0.1}O_{3-\delta}$ (SFM) [4] and related materials, we demonstrate exsolution mechanisms that can impact the performance of SOFCs. Further, we showcase the application of MEMS-based chips in visualizing power-to-x processes, exemplified by methane generation on Ni catalysts.
For PEM MEAs, maintaining the original hydration level is crucial to understand degradation mechanisms. Our cryo workflow which includes largescale surface investigation using a laser scanning microscopy (LSM), preserves hydration throughout sample preparation, FIB tomography, TEM lamella preparation, and TEM characterization, ensuring optimal sample preservation for TEM imaging.
Conclusions
Our research highlights the transformative power of electron microscopy in unraveling the nanoscale secrets of hydrogen production. By visualizing these intricate processes, we gain a deeper understanding of the factors influencing material performance and optimize material design to enhance the efficiency and durability of hydrogen production technologies. This approach holds immense promise for advancing the H_2 value chain and driving the transition towards a clean energy future.

Background
In recent years, nanomaterials have seen widespread usage in fields as diverse as biomedicines, energy storage and catalysis due to their unique chemical and physical properties. Hence, in-depth 3D characterization of these properties is critical to improving our understanding of nanomaterials and allows researchers to design nanomaterials better suited towards application. Electron tomography allows researchers to characterize the 3D volume of nanomaterials by acquiring a series of 2D projections at various angles (tilt series).1 Unfortunately, the acquisition of multiple projections to acquire a single 3D volume necessitates long acquisition times and electron beam exposure which can damage sensitive samples. To minimize such damage, researchers often try acquire fewer projections through tilt undersampling schemes, which can induce additional imaging artefacts. Therefore, it is important to determine the optimal number of projections that minimizes both beam exposure and undersampling artifacts for accurate reconstructions of beam-sensitive samples. Current methods for determining this optimal number of projections involve acquiring and post-processing multiple reconstructions with different numbers of projections, which can be time-consuming and requires multiple samples due to sample damage.2 Herein, we propose a novel workflow3 that combines a continuous acquisition scheme known as golden ratio scanning (GRS)4 with a quasi-3D real-time electron tomography software (RECAST3D)5 to simplify the process of tilt undersampling optimization.

Methods
To determine the optimum number of projections, a tilt series is collected continuously using GRS and a quasi-3D reconstruction is performed in real-time with RECAST3D. The reconstruction quality is determined using two metrics: i.) the signal to noise ratio and ii.) the change in the reconstruction as new projections are added. When the optimum reconstruction quality is achieved the acquisition is terminated. To validate this approach, the resulting optimum reconstruction is compared to a standard tomographic procedure for both a simulated structure undergoing beam damage and a Au nanoparticle. Finally, the application of this technique is highlighted by applying the technique to two beam sensitive metal-organic framework complexes: Au@NU-1000 and Au/Pd@ZIF-8.

Results
In both the simulated and experimental cases, the use of this methodology resulted in a significant improvement in reconstruction quality when compared to standard tomographic acquisition and comparable results to conventionally optimized tomography. However, whilst typical tilt-undersampling optimizing takes several acquisitions and post processing to perform, this workflow can achieve similar results during a single acquisition saving significant time for the microscopist.

Conclusions

Herein, we present a novel workflow for optimizing tilt undersampling during a single acquisition using GRS and real-time quasi-3D reconstruction. Simulated and experimental studies demonstrate that reconstructions of beam-sensitive samples optimized using this workflow have higher fidelity with the pre-damaged sample than reconstructions using standard incremental acquisition. Through application to MOFs, we demonstrate that this approach can be used to effectively optimize imaging conditions of beam sensitive samples during a single acquisition.

Figure 1. Golden ratio scanning is used to acquire new projections which can be continuously added to the tilt series increasing sampling density. The reconstruction quality is monitored using a quasi-3D reconstruction software (RECAST3D) which quickly reconstructs 3 orthoslices during the acquisition. The acquisition can be arbitrarily terminated when the optimum reconstruction is obtained.

Background incl. aims
Lipid Nanoparticles (LNPs) are the most clinically advanced delivery vector for both small molecules (liposomes) and genetic material payloads, such as siRNA or mRNA (ionizable cationic LNPs).[1] Their recent development has unlocked a wide range of therapeutic approaches, overcoming the limitations of naked genetic payloads and of previous delivery strategies.[2] This is testified by the fact that the majority of clinically approved nano-systems are of lipidic nature.[3] However, much is still unclear about the release of genetic material in the cytoplasm upon LNPs cell internalization and trafficking in the endo-lysosomal compartment. This process, known as endosomal escape, is a crucial step of the delivery process but to date is inefficient and often considered the bottleneck for the clinical efficacy of LNPs.[4] Most of the methods for detection and quantification of endosomal escape are either indirect assays, usually based on detection of endosome damage indicators, or rely on fluorescent labelling of LNPs. The latter, however, has proven to significantly alter the surface properties of nanoparticles and thus their biodistribution and cell interaction properties.[5] While the direct imaging of LNPs in biological samples is impossible given the nature and elemental composition of LNPs, which are practically identical to the composition of cells. To overcome these limitations, a new hybrid Liposomal-Gold nano-system (namely Lipo-Gold) has been here developed for the direct analysis of cellular interaction and intracellular trafficking of LNPs.
Methods
The Lipo-Gold have been synthetized by a modified thin lipid film hydration method: specifically, the lipid film composed by saturated phospholipid DPPC, cholesterol and PEGylated lipid DSPE-PEG (2000 Da), has been hydrated with an aqueous solution of biocompatible reducing agent, namely ascorbic acid (vitamin C). The vesicles encapsulating the reducing agent have been extruded to the desired dimension and a size-exclusion chromatography column has been employed for the quick removal of free ascorbic acid. Upon addition of metal precursor, HAuCl4, AuNPs spontaneously and quickly formed in the LNPs aqueous compartment. The formation of hybrid Lipid-Gold nanoparticles has been optimized and characterized by quantification of encapsulated ascorbic acid, UV/Vis spectroscopy, dynamic light scattering (DLS), nanoparticles tracking analysis (NTA) and electron microscopy techniques. Then, MTS cytotoxicity assay, flow cytometry, confocal and hyperspectral darkfield microscopy, as well as TEM, have been used to evaluate the cellular biocompatibility and cell interaction properties of the nanoparticles and to verify whether the hybrid Lipo-Gold system could be used as a model for the study of LNPs.
Results
The optimization of the methods resulted in formation of very monodispersed ~130nm LNPs encapsulating 15-35nm AuNPs. The resulting nano-system has proven to be highly biocompatible through MTS cytotoxicity assay after 24 or 48 hours even at very high concentrations. Unlabeled hybrid Lipid-Gold nanoparticles have been employed for the analysis of cellular internalization by

TEM and hyperspectral darkfield microscopy, while fluorescent labeling with DiD dye (Ex/Em: 647/663nm) have been used to compare the properties of the hybrid system in comparison with empty LNPs. Both flow cytometry and confocal microscopy clearly showed that the cellular internalization and intracellular localization is not altered upon AuNPs synthesis as compared to empty LNPs, both quantitatively and qualitatively. This proves that the hybrid Lipid-Gold nano-system is a potential good model for the direct analysis of LNPs interaction with cells, taking advantage of AuNPs optical properties.

Conclusion

This work resulted in the development of a hybrid Lipo-Gold nano-system that showed promising results towards its employment as a reporter system for the visualization of LNPs cellular internalization and intracellular trafficking. This could enable further and easier optimization of Lipid Nanoparticle platform, enhancing the efficacy of the endosomal escape and thus the overall clinical relevance. Furthermore, Dynamic TEM measurements are ongoing on this system, with the aim of getting real-time visualization of the intracellular path of nanoparticles in response to an external optical/thermal trigger. The method will be developed in standard biological samples prepared for electron microscopy analysis (i.e. dehydrated cells included with epoxy resin), thus with a low biological relevance. However, the method would be a proof of concept that could then be employed in state-of-the-art, and more biologically relevant, techniques such as Cryo-TEM for the time-resolved, high-resolution analysis of intracellular trafficking of LNPs in biological samples.

IM-10 (2), Lecture Theater 3, august 29, 2024, 14:00 - 16:00

Background
In recent years, nanomaterials have seen widespread usage in fields as diverse as biomedicines, energy storage and catalysis due to their unique properties. The efficacy of nanomaterials for an application are significantly dependent on their physical and chemical properties. Electron tomography is an invaluable technique, which allows researchers to determine these properties in 3D by reconstructing a series of 2D projections collected at various angles (tilt series).1 However, the 3D spatial properties alone are insufficient to fully characterize nanomaterials and their application. In real world conditions, material properties are rarely static and they change as a result of environmental conditions such as pressure, heat and chemical reactions.2,3 To fully characterize the dynamic behaviour of materials, researchers must move towards 3D volume + time characterizations. Unfortunately, collecting a single tilt series for electron tomography can take about an hour, resulting in loss of temporal information and motion blurring artefacts in the resulting reconstructed volume. Herein, we propose a novel reconstruction method that uses a deep image prior self-supervised neural network (DIP-NN)4 to determine the 3D volume as a function of time. This allows researchers to collect a series of 3D volumes with a temporal resolution of less than a minute.

Methods
To reconstruct a volume time series, 1D slices of the tilt series were used as an input to the DIP-NN. Each slice was mapped to a depth and time coordinate. A 2D orthoslice of the reconstructed volume-time series was predicted for the specified coordinates. To train the network, the orthoslice was forward projected and compared back to the original tilt series. During the reconstruction, the volume-time series is reconstructed slice-by-slice, until the full volume-time series is acquired (Figure 1). Hence, for every 2D image collected in the tilt series a full 3D volume was acquired at the same time of acquisition. This methodology was used to reconstruct simulated nanoparticles with morphological and compositional changes and experimental Au/Ag nanoparticles that were subject to changes in both shape and alloying as a result of in situ heating during electron tomography.

Results
In both the simulated and experimental cases, a significant improvement was observed in temporal resolution compared to conventional tomography. In the simulated case, a set of 100 images in the tilt series was used to reconstruct a set of 100 volumes, where only one would be acquired using conventional electron tomography. In the experimental case, we were able to obtain a frame rate of approximately 1 volume per minute, far outpacing even fast tomography. In both experimental and simulated cases, the reconstruction quality, determined based on the signal-to-noise ratio and the structural similarity index, were comparable to conventional tomography.

Conclusions

Herein, a machine learning method is presented which allows the reconstruction of a series of 3D volumes with a temporal resolution of less than a minute. Unlike supervised machine learning approaches, this method can be trained solely from the acquired tilt series. This method was validated with both simulated and experiment studies on Au and Ag nanoparticles during heating.

Figure 1. DIP-NN algorithm takes in 1D slices of the tilt series using the coordinates for the depth (z) and time (t) to predict a 2D orthoslice of the reconstruction at the same coordinates. For training, this 2D orthoslice is forward projected and compared back to the tilt series. To reconstruct a full volume time series, the 2D orthoslices are stacked slice by slice for every z and t value.

PS-06, Lecture Theater 1, august 29, 2024, 10:30 - 12:30

Background incl. aims
For hundreds of millions of years, nature has evolved a large assortment of organic-inorganic hybrid materials that are optimally adapted for a wide range of functions, including navigation, protection and mechanical support1. These materials not only exhibit exceptional material properties but also display multifunctionality, including features such as adapting, sensing and self-healing2. Among the most remarkable biominerals found in nature is the shell of the brachiopods Discinisca tenuis and Lingula anatina. These shells are constituted of an inorganic phase, composed of carbonate-substituted fluorapatite in the form of francolite that comprises ~68 % of the shell weight and an organic fraction that is composed of proteins, glycosaminoglycans and chitin and comprises the remaining 32% of the shell weight3. We previously reported in D. tenuis that absorption of water by the shells causes, within minutes, structural changes at the molecular, nano- and micron-scales, resulting in the material switching from harder than bone when dry, to flexible when hydrated, to the point that the shell can be folded in 2 without fracturing4. Although the L. anatina shells (Fig. 1a) exhibits similar behaviour upon hydration, they have different structures to D. tenuis and as such, the mechanisms that underpin such changes in mechanical properties are still unknown.
The aim of this research is to determine how the structure of the L. anatina shell changes as a result of hydration, resulting in the shell going from stiff when dry to flexible when hydrated. Our starting point was to characterise at the nanoscale the structure of the shell, in particular the interface between the francolite crystals and the organic matrix components. This was done using transmission electron microscopy (TEM) techniques, including high-resolution TEM (HR-TEM), electron diffraction, scanning-transmission electron microscopy (STEM), and electron energy loss spectroscopy (EELS) on thin sections of the shell, prepared using the focused-ion beam-scanning electron microscope (FIB-SEM).
Methods
We used FIB-SEM to prepare a ~70 nm-thick lamella from the L. anatina shell. The lamella was then transferred to a transmission electron microscope equipped with an energy filter, STEM and EDX detectors. HR-TEM and electron diffraction combined with dark-field imaging were used to determine the crystallographic orientation of the francolite nanocrystals, together with the size of the single crystalline domains. High-angle annular dark field STEM (HAADF-STEM), together with EELS, were used to identify and image the organic matrix components (mainly chitin) within the bundles of francolite crystals. Micro-computed X-ray tomography (microCT) and cryo-FIB-SEM were used to determine structural changes to the shell, caused by the absorption of water.
Results
TEM imaging of the FIB-SEM section showed that the shell consists of fancolite rods that are ca. 200 nm in length and 60 nm in width (Fig. 1b). Using electron diffraction and dark-field imaging, it can be

seen that these rods are polycrystalline containing domains with different crystallographic orientations (Figs. 1c-d). Within these domains, individual crystals measure ca. 2-4 nm in thickness and 15-20 nm in length. Lattice images obtained with HR-TEM show that the angular spread in the crystallographic orientation of each domain is in the order of 10-15 °, showing slight misalignment in the orientation of the individual crystals that compose such regions (Figs. 1e-f). Using HAADF-STEM and EELS, we could identify the presence of organic matrix, mainly chitin, intermixed with the crystalline domains within the francolite rods and between individual rods (Figs. 1g-h). Taken together, this is the first nanoscale characterisation of the structure of the shell of the brachiopod L. anatina. This characterisation will pave the way to understanding how hydration changes the shell structure, resulting in different mechanical properties. In this regard, considering that the interaction between chitin and the mineral weakens with hydration, it is conceivable that the intercalation of the two components – chitin and francolite single crystals - at the nanoscale plays a critical role in the responsiveness of the mechanical properties of the material to hydration and dehydration. MicroCT demonstrated that regions of the shell that are predominantly organic swell upon hydration. Additonally, cryo-FIB-SEM showed the presence of water in voids at the organic-inorganic interface.
Conclusion
We show that the shell of the brachiopod L. anatina, at the nanoscale, is composed of polycrystalline rods of francolite nanocrystals. Within the rods, the crystals are organized into domains with similar crystallographic orientations that are closely associated with chitin fibers. We speculate that this close association between these two components is an important factor that underpins the changes in mechanical properties that the shell undergoes as a response to hydration. We also speculate that chitin has an important role to template the orientation of the francolite crystals during their formation. Finally, the organic components of the shell play a key role in the absorption of water.

Poster Group 2

Background and aims
Photon Induced Near-Field Electron Microscopy (PINEM) is a novel imaging technique that relies on the inelastic interaction between a free-electron beam and laser light, mediated by a thin film or a nanostructure [1]. This technique is generally employed to study the ultrafast dynamics of local fields generated by light-induced polaritonic excitations in nanoscale systems. Recently, we further exploited the quantized nature of electron-light interaction, that is intrinsic to PINEM, to achieve coherent control of the electron wavefunction [2-4]. So far, light-induced shaping has relied on Gaussian laser beams illuminating plasmonic nanostructures. In contrast, on-demand electron modulation for dynamic and versatile control has not yet been fully explored. Here, we show that shaped light can be used to introduce an arbitrary modulation on the transverse electron beam profile [5]. In fact, it is already possible to arbitrarily control light fields through spatial light modulators (SLMs) and our goal is to exploit PINEM to transfer this tunability to electron beams, thereby broadening the capabilities of ultrafast TEMs (UTEMs).

Methods
Our experiments are conducted in a UTEM, specifically a JEOL 2100 TEM modified as shown in Fig. 1. A 200 keV electron beam interacts with a femtosecond IR laser beam within a Photonic-based ELectron Modulator (PELM), an additional module of our TEM with an extra sample holder. The laser profile is shaped using a HOLOEYE Phase-Only SLM. We probe the electron-light interaction either by energy filtering imaging (UTEM @ EPFL) or by imaging the momentum distribution of the electron beam in High Dispersion Diffraction (HDD) mode with a 100-m camera length on a direct electron detector (UTEM @ UNIMIB).

Results
We used the SLM to induce a Hermite-Gaussian (HG) shaping of the laser profile and, through energy filtering, we imaged at different focal planes only the electrons that interacted with light. By comparing the obtained data with simulations of an analytically modeled system (Fig. 2), we determined the coherence length δ of the electron beam to be larger than 50 nm. This is a crucial parameter that sets an upper limit to the laser phase profile that can be completely transferred to the electron beam for coherent electron modulation. Additionally, we have directly imaged the momentum distribution of the electron beam and probed the transverse-momentum exchanges at the PELM plane following the electron interactions with quanta of the IR photon beam. In these measurements, we have reached values of transverse coherence on the order of $\delta \sim 1\ \mu m$. By acquiring momentum images in HDD mode with a micrometric aperture at the image plane, we have obtained simultaneous momentum-and-space-resolved information at the PELM plane. Fig. 3 shows

the light-modulated electron-beam profile. The inset illustrates the reconstruction of the SLM-modulated laser-beam profile at the PELM plane.

Conclusions

In conclusion, our findings demonstrate the potential of using shaped light fields in PINEM for enhanced tunability of electron modulation. The ability to control the electron wavefunction with such precision opens up new possibilities for the study of electron-light interactions. This could have far-reaching implications for various scientific domains, including life sciences, materials science, and nanotechnology. The rich dimensionality of light-electron interaction, spanning the transverse, longitudinal, temporal, and energy domains, harbors untapped potential and paves the way for future investigations in this dynamic field.

Funding

This work is part of the SMART-electron Project that has received funding from the European Union's Horizon 2020 Research and Innovation Programme under Grant Agreement No. 964591.

PS-02 (3), Lecture Theater 4, august 30, 2024, 14:00 - 16:00

Background incl. aims
γ/γ'-strengthened Ni- and Co-base superalloys for applications at high temperatures rely on the precipitation-strengthening effect of the $L1_2$-ordered γ' phase embedded into the face-centered cubic γ matrix phase. Therefore, the microscopic mechanisms by which the γ' phase can be sheared crucially influence the mechanical properties of the alloy, and their understanding is of key importance. In this context, an established method to discriminate between intrinsic and extrinsic stacking faults (SFs) is their edge-on imaging in high-resolution scanning transmission electron microscopy (HRSTEM) in ⟨110⟩ projection. The superlattice ordering within the $L1_2$ phase gives rise to a larger variety of fault structures – namely, complex and superlattice variants of both intrinsic and extrinsic stacking faults. Notably, whether a given SF is complex or not may not be reliably revealed by studying one ⟨110⟩ projection alone [1, 2]. We present an experimentally feasible approach that enables this differentiation in a reliable and unambiguous way. This approach entails examining the fault structure not only in ⟨110⟩ projection, but also in a neighboring ⟨211⟩ projection, which is achieved by tilting the specimen by 30° in the TEM. Two applications of this analysis technique are discussed in this contribution: the first is the experimental validation of microscopic details of a well-known formation mechanism for superlattice extrinsic stacking faults, and the second concerns the shear-based γ'-to-χ phase transformation often observed in superalloys based on the Co-Al-W system, in which χ is an equilibrium phase [3].

Methods
Fault structures in the single crystalline Co-base superalloys ERBOCo-4 (composition in at.%: Co43.2-Ni32.0-Al8.0-Cr6.0-Ti2.8-Si0.4-Hf0.1-Ta1.8-W5.7) and ERBOCo-VF60 (composition in at.%: Co79.8-Al8.9-Ta2.3-W9.0) are analyzed. HRSTEM imaging was performed at a double Cs-corrected FEI Titan³ Themis at 300 kV as well as a probe-corrected Thermo Fisher Scientific Spectra 200 C-FEG at 200 kV. On the latter, spatially resolved energy-dispersive X-ray spectroscopy (EDXS) was conducted using the Super-X G2 detector.

Results
The first example concerns a high-temperature deformation mechanism of the γ' phase which involves the formation of SFs. Details of this study can be found in Ref. [2] and are briefly summarized in the following. Under [001] compression, a common deformation mode resulting in the formation of superlattice extrinsic SFs (SESFs) is the well-known Kolbe mechanism [4]. Here, two identical a/6⟨112⟩ Shockley partial dislocations shear into γ' on neighboring planes, leaving behind two neighboring complex intrinsic SFs (CISFs) which together constitute a complex extrinsic SF (CESF).

Complex variants of SFs typically possess high SF energies due to nearest-neighbor violations in the superlattice ordering; therefore, the central fault plane of the CESF undergoes a diffusion-mediated reordering step which effectively translates that plane by a/2⟨110⟩ and transforms the fault into a lower-energy SESF. While numerous observations of this mechanism have been made in Ni- and Co-base superalloys since its model description in 2001, two key aspects have previously eluded experimental verification: firstly, a direct observation of the complex nature of the intrinsic segment between the two leading partials, and secondly, the occurrence of reordering. By imaging the fault structure and leading partials in a compressively deformed sample of Co-base superalloy ERBOCo-4 not only in ⟨110⟩ projection (which may be ambiguous regarding the complex or superlattice character of a fault), but also in ⟨211⟩ projection, we were able to reveal the intrinsic and extrinsic segments as CISF and SESF, respectively, directly confirming both aforementioned aspects [2].

In the second example, microscopic details of the γ'($L1_2$)-to-χ($D0_{19}$) phase transformation were elucidated in the Co-base superalloy ERBOCo-VF60 (see figure). The accelerated formation of the χ phase during annealing (850 °C, 20 h) was prompted by the diffusion of Cr into the superalloy, destabilizing the γ/γ' microstructure. Coherent, plate-shaped χ precipitates have formed on {111} planes. Based on the fcc-to-hcp transformation, the transformation of the $L1_2$ structure (ABC stacking) to the $D0_{19}$ structure (AB stacking) is shear-based and can be achieved by the introduction of an SISF after every other plane of the $L1_2$ structure. By studying the leading partials driving the transformation at the tip of a precipitate in HRSTEM, details of the transformation process were uncovered [5]. In [110] projection (bordered in red), the formation of SFs is evident, causing a change in stacking. Furthermore, a change in the alternating bright/dark contrast of atomic columns on the planes marked by dashed red circles implies the involvement of a diffusion-mediated reordering process. By additionally imaging the fault structure in [211] projection (bordered in black), the Burgers vectors of the leading partials were determined unambiguously (from superlattice shifts made visible by Fourier filtering in this projection) as noted in the schematic drawing. Notably, the transformation does not progress directly through shearing by a/3⟨112⟩ partials necessary to form SISFs, but rather by a/6⟨112⟩ partials which leave behind CISFs. The smaller Burgers vectors facilitate shearing and reduce elastic strains at the transformation front. At the same time, the high-energy CISFs are transformed into lower-energy SISFs by reordering processes. As illustrated in the schematic drawing, this fault configuration can serve to transform the ABC stacking of γ into the AB stacking of χ. The sum of all translation vectors in this configuration, and therefore the net strain introduced into the microstructure, is zero. Fault configurations following this pattern of three a/6⟨112⟩ partials creating CISFs followed by reordering to SISFs were observed repeatedly at the transformation fronts, indicating that this may be the preferred transformation mechanism. Besides the change in crystal structure, the formation of the χ phase also involves a significant enrichment of W and Ta supplied by diffusion from the surrounding microstructure. An in-depth characterization and discussion of elemental distributions associated with this phase transformation was conducted based on EDXS measurements down to the atomic scale.

Conclusion

We have presented two experimental applications of a novel HRSTEM-based method to reliably and unambiguously identify the complex or superlattice nature of both intrinsic and extrinsic SFs in the $L1_2$ structure. In both cases, microscopic details of shearing mechanisms in the γ' phase of high-temperature superalloys were elucidated. In the future, this method may help uncover the details behind other $L1_2$ shearing processes.

Background
Chemical Looping Combustion (CLC) presents a midterm solution for fossil fuel utilization with inherent carbon dioxide capture, utilizing oxygen carrier materials. These carriers replace air to provide oxygen for combustion across a wide range of fuels, operating through reduction/oxidation cycles in a circulating fluidized bed reactor at high temperatures [1]. Copper oxide supported on alumina grain (CuO/Al2O3) is widely considered a promising oxygen carrier (OC) for industrial CLC use due to its benign nature and flexible redox behavior, ensuring high reactivity and oxygen transfer capacity. However, successive high-temperature (800-900°C) reduction (combustion) and oxidation (regeneration of oxide phase) cycles induce chemical and morphological changes in the material, leading to degradation in its oxygen-carrying properties. The evolution in the cycled material is attributed to the diffusion of Cu-phases at the grain scale [2]. Herein, we bridge the gap in understanding between the observed µm-scale migration of Cu-based phases and nanoscale transformations of Cu nanoparticles (NPs) by employing a multi-scale characterization approach, both temporally and spatially, using Scanning Transmission X-ray (STXM) and Scanning Transmission Electron (STEM) Microscopies, and operando Quick X-ray Absorption Spectroscopy.

Methods
We conducted a study on CuO supported on 50-100 µm sized γ-Al2O3 grains, synthesized via incipient wetness impregnation and calcined at 900°C. To replicate the cyclic nature of (CLC), we subjected the fresh samples to oxidation and reduction under air and H2 at 900°C using a thermogravimetric analyzer (TGA). Ultramicrotomy sections with a thickness of 100 nm were prepared for SEM, STXM, and TEM characterizations. Energy stacks and mappings were generated at the Cu L-edge and Al K-edge to identify specific spectral features of each compound. In situ TEM analysis was conducted using a probe Cs-corrected microscope equipped with closed-cell in situ gas setup featuring a sealed environmental cell (e-Cell), operating at atmospheric pressure. Finally, operando XAS measurements were performed in a capillary tube under identical reaction conditions as in the TGA. By acquiring relevant reference material spectra and utilizing chemometric data processing, we extracted chemical-structural phase distribution over the course of 50 redox cycles at 900°C.

Results
The microscopic study reveals significant transformations in the CuO/γ-Al2O3 system during redox cycling (Figure 1 a and b) [3]. Initially, fresh grains consist of γ-Al2O3 with uniformly dispersed CuO nanoparticles (10-20 nm). After 50 redox cycles, observation at the grain scale (µm) demonstrates the progression of the gamma to alpha reaction front within the solids. This front exhibits a distinct structural-chemical gradient, characterized by three zones: zone 1 displaying non-stoichiometric Cu (II) aluminate, zone 2 with an intermediate thin layer (< 200 nm) of Cu (II) aluminate enriched in Cu,

and zone 3 composed of α-Al2O3 phase containing large CuO particles. The proportion of copper varies significantly across these zones, ranging from 10 wt% Cu in zone 1 to ~25 wt% at the edge of the reaction front in zone 2. In situ STEM observation at 900°C under H2-reduction reveals the migration of copper, forming copper nanoparticles from a starting oxidized sample predominantly composed of homogeneous Cu (II) aluminate. This suggests that copper mobility during redox cycling is associated with the phase transition of γ to α-Al2O3.

Furthermore, the spectral evolution during oxidation and reduction reactions, depicted in Figure 1c, highlights changes in the concentration of different Cu-Al species [4]. The oxidized state initially consists of CuxAlyO4, gradually transforming into the metallic copper phase with increasing redox cycles. Notably, a threshold circa 25 cycles indicate a drastic conversion from the aluminate phase to copper oxide. At the end of the redox cycles, the oxygen carrier predominantly comprises α- Al2O3 and CuO. The transition point is linked to the growth and propagation of α- Al2O3, suggesting a mechanism involving particle size influencing the alpha alumina phase transition, proceeding through an initial slow seeding phase followed by rapid propagation.

Conclusion
The integration of spectroscopic and microscopic techniques, both in situ and post-mortem modes, provided a comprehensive understanding of the material evolution in terms of morphology and the diverse phase interactions across spatial dimensions and over extended reaction durations.

Background incl. aims
Solid oxide fuel cells (SOFC) are a class of solid-state electrochemical conversion devices that produce electricity directly by oxidizing a fuel gas. They consist in an anode-cathode duet separated by a solid electrolyte, i.e., a material conducting oxygen ions. The anode is fed with hydrogen or other fuels whereas the cathode is in contact with air, meaning oxygen. Overall, a SOFC operates thanks to the combined action of two external stimuli: a gaseous environment and temperature. Owing to the recent advances in in situ and operando transmission electron microscopy (TEM), we have set up an experiment to operate a SOFC inside an environmental TEM to identify how the device microstructure determines its electrical properties. To do so, an elementary anode-electrolyte-cathode sandwich was prepared by focused ion beam (FIB) and mounted on a heating and biasing microelectromechanical (MEMS)-based specimen holder (DENSsolutions) and inserted in an Environmental TEM (FEI Titan ETEM), as shown in Figure 1 a,b.
Methods
Standard SOFC materials were investigated: the cathode was strontium-doped lanthanum manganite (LSM) co-sintered with yttria-stabilized zirconia (YSZ), the electrolyte was YSZ, and the anode a cermet of NiO co-sintered with YSZ. NiO was first reduced to Ni, leaving pores in the structure due to the volume loss and hence enabling the penetration of the fuel to the triple phase boundaries Ni/YSZ/porosity at the anode side. For practical reasons, we used a single chamber configuration to trigger the operation the cell: the anode and cathode were exposed simultaneously to the oxidant and reducing gases. Due to a difference in the catalytic activity between the electrodes, O2 should reduce at the cathode, while H2 should oxidize at the anode, thus leading to a voltage difference between the two terminals.
Results
The reduction of NiO was first performed under a forming gas N2:H2 in the ratio 20:1 under 15 mbar up to 750°C (N2 was constantly used as a mixing gas for safety reasons due to the need of mixing O2 and H2 in the single-chamber configuration). The O2 to H2 ratio was then increased to trigger the operation of the cell. A small quantity of O2 was introduced into the microscope, leading to a total pressure of about 16 mbar at 600°C. At this point, the variation of voltage between the anode and cathode was correlated to the gas composition and the anode microstructure (see Figure 1 c-g). The latter was analyzed by means of conventional and high-resolution imaging, diffraction, and EELS (electron energy-loss spectroscopy). The system was cycled several times by decreasing and re-

increasing the O2 concentration in the gas flow, and correlations between microstructure, gas composition, and cell voltage were established, as it will be discussed at the conference. Results were further confirmed by macroscopic ex situ tests in an oven using the same materials [1].

Conclusion

The operation of a SOFC in a single chamber configuration was demonstrated using operando ETEM. Such operando experiments open numerous perspectives to investigate the root cause of failure pathways affecting SOFCs, like poisoning of active sites or coarsening of the Ni catalyst [2].

Prospects of nanofluidic cavities for cryo-EM sample preparation

Dr. Arjen J. Jakobi[1,2], Stefan Huber[2], Edin Sarajilic[3], Roeland Huijink[3], Dr. Wiel H. Evers[2]

Cryogenic electron microscopy (cryo-EM) has become an essential tool for 3D structure determination of biological macromolecules. Despite many technical advances, the difficulty to reliably prepare samples with uniform ice thickness and the excessive sample loss during grid preparation still present a barrier for routine high-resolution imaging and limit the current throughput of the technique [1,2]. Nanofabrication techniques employed for Micro-/Nanoelectromechanical Systems (M/NEMS) provide new opportunities to miniaturise and automate cryo-EM sample preparation. We have recently shown that MEMS-based nanofluidic sample supports with well-defined geometry can be used to prepare cryo-EM specimens with uniform ice thickness from picolitre sample volumes and allow for high-resolution structure determination [3]. Despite these promising prospects, several key challenges remain to be addressed to transform this approach into a viable alternative for widely used holey support films, most prominently mitigation of beam-induced specimen movement and putative interaction with the water-support film interface. I report on the present status of our developments, describe recent efforts in addressing some of the outstanding challenges and elaborate on others that require additional work to resolve. I will also showcase recent results demonstrating the potential of new chip generations to provide new capabilities for further automation of the cryo-EM workflow, and to explore new frontiers for cryo-EM applications such as time-resolved imaging and high-throughput screening.

Poster Group 2

Over the past decades, significant interest was directed towards the optical properties of nanoscale structures. As they are highly sensitive to slight changes in material, geometry, size and arrangement, controlling these aspects in every detail allows to tailor their plasmonic response according to the targeted operation and opens up access to a multitude of applications in research and development. With miniaturization reaching its limits, expanding the nanostructures into the third dimension could give access to horizontal and vertical mode coupling, reduce substrate damping, increase device performances and allow for the investigation of novel optical effects. Herein, we present how Focused Electron Beam Induced Deposition (FEBID), a 3D manufacturing technique capable of printing nanostructures with feature sizes down to around 10 nm, can be applied to fabricate and tune the plasmonic properties of planar and free-standing gold nanostructures.[1] Therefore, planar gold nanowires as well as free-standing nanotips of varying geometries are printed and purified with a focused electron beam and their plasmonic response investigated through STEM-EELS mapping measurements. Corresponding plasmon simulations provide additional backing to our experimental discoveries, displaying excellent agreement (see Figure 1). This study lays the foundation for on-demand spectral tuning of the plasmonic response in 3D systems through upfront modeling and design of tailored nanostructures, thereby unlocking opportunities for innovative plasmonic applications in 3D space.

Poster Group 1

Background incl. aims
Subtle changes in stoichiometry and crystal symmetry govern the fundamental physics of perovskite oxides. Particularly in thin films, the interplay between chemistry and structure can be altered by fine-tuning the conditions for epitaxial growth. A good example is the family of multiferroics $AMnO_3$ (A = Ca, Sr, Ba) perovskite antiferromagnets in which ferroelectricity driven by the off centering of the magnetic cation Mn4+ can emerge through selective crystal distortions [1]. In this talk we will explore how the polar states of the family of epitaxial Sr1-xBaxMnO3-δ (SBMO), thin films [2] can be controlled by careful selection of the substrate, growth conditions and post-deposition annealing parameters.

Methods
Epitaxial Sr1-xBaxMnO3-δ ($0 \le x \le 0.5$) thin films with thickness in the range 7–18 nm were grown by pulsed laser deposition (PLD) using a KrF excimer laser, a fluence of 1 J/cm², and a pulse repetition rate of 10 Hz on single-crystalline (001)-oriented (LaAlO3)0.3(Sr2TaAlO6)0.7 (LSAT) substrates. The crystal structure and thickness of the films were studied by X-ray diffraction (XRD) and X-ray reflectivity (XRR), while atomic-level analysis of the SBMO films was performed by scanning transmission electron microscopy (STEM). The atomic displacements were measured from the annular bright field (ABF) and high-angle annular dark field (HAADF) images by determining the displacement of the Mn and O sublattices with respect to the centrosymmetric positions defined by the Sr/Ba sublattice, from which the film polarization was evaluated. Electron energy loss spectroscopy (EELS) was performed to assess the oxygen content of the films. The fine structure of the background-subtracted O–K edge was fitted to a double Gaussian to quantify the Mn valence following the procedure described by Varela et al. [3]

Results
A combination of macroscopic XRD characterization and atomic scale STEM of the SBMO films has evidenced that the polar displacements are extremely dependent on the oxygen stoichiometry, Ba content and epitaxial strain. The parent compound $SrMnO_3$ grown on LSAT upon tensile strain is known to present in-plane polar displacements along the pseudocubic <110> directions [4]. On the other hand, this scenario can be altered by tuning both the Ba doping and oxygen stoichiometry. As an example, in the case of x = 0.4, the epitaxial strain shifts from tensile to compressive when the annealing conditions change from 550 ºC at 400 Torr O_2 to 650 ºC at 350 Torr O_2 (see Fig. 1a). The EELS fine structure of the O-K edge shows that this phenomenon is accompanied by a remarkable variation of the oxygen content (from δ=0.15 to 0.25), and therefore of the nominal valence of the Mn cation (Fig.1b). Atomic resolution ABF enables to resolve the Mn and O sublattices, revealing that structural and chemical variations induce a drastic change in the axis of polar displacements of Mn

and O. While highly oxygenated SBMO (x = 0.4) presents in-plane atomic displacements with an estimated value of in-plane polarization of approximately 30 µC/cm² (Fig. 1c), the more oxygen deficient and compressively strained film with the same Ba content, shows a predominantly out-of-plane polarization with a deduced polarization as high as 95 µC/cm² (Fig. 1d) [5].

Conclusion

Polarization is intimately linked to the sign and magnitude of epitaxial strain, film thickness and oxygen stoichiometry. It can be tuned either in-plane or out-of-plane with respect to the substrate plane by the adequate choice of the substrate-induced strain, Ba doping and O content –induced by controlled annealing. This chemistry-mediated engineering of the polarization orientation and magnitude of oxide thin films opens new venues for the design of functional multiferroic architectures and the exploration of novel physics and applications of ferroelectric textures with exotic topological properties.

Poster Group 2

Background incl. aims

Electron backscatter diffraction (EBSD) is a popular technique for the identification of sample morphology, providing information about the crystal orientation and grain boundaries present [1]. Although detector technology has significantly improved, analysis times can be long, on the order of hours, depending on sample type and size. Additionally, long dwell times are often needed to enable sufficient signal to be collected, making the technique unviable for beam sensitive samples.

Recently, compressive sensing techniques have been applied to electron microscopy, wherein low-dose and fast acquisition methods are enabled through the use of subsampling. To date, subsampling has been successfully applied in STEM and FIB-SEM [2-4].

EBSD datasets are 4-dimensional (4-D), meaning multiple applications of subsampling and reconstruction are possible. Demonstrated here is the application of probe subsampling in EBSD datasets. For reconstruction 2-D, 3-D and 4-D data volumes were investigated.

Methods

A low noise Ni-superalloy dataset consisting of 416 x 512 probe locations was used, with a mask applied to simulate 25% subsampling. The reconstruction methods investigated used 2-D, 3-D and 4-D data volumes to reconstruct the full dataset.

Probe location maps are formed by taking each pixel from the full set of EBSD patterns at a single probe location, forming an image similar to a pattern quality map. 2-D reconstruction consists of inpainting the probe positions on an image by image basis. In 3-D reconstruction the dataset is vectorised. In 4-D reconstruction the data is inpainted in the position it was acquired in.

Results

The results of inpainting the 2-D and 3-D data volumes are shown in Figure 1 (Reconstruction quality of 25% sampled EBSD datasets using 2-D or 3-D data volumes for inpainting).

For 2-D inpainting a minor decrease in hit rate is observed, dropping from 99.80% to 99.53%. The band contrast map is less defined at grain boundaries than in the fully sampled dataset and an overall smoother map being output with the surface texture being lost.

For 3-D inpainting the hit rate drops to 97.87%. This is evident in the IPF Z map, where significant zero solution pixels can be seen around the grain boundaries. By using a 3-D data volume for inpainting there is a greater overlap of EBSD patterns between grains which results in a less distinct EBSD pattern being inpainted. Despite this, the band contrast map is slightly sharper than the 2-D reconstruction, although some grain boundaries are no longer evident.

Although 4-D reconstruction shows promising results on a heavily cropped dataset (8x10 pixels), the memory currently required for this method limits its applicability. Due to this cropping, the datasets cannot be indexed in AZtec and hit rate is not recorded. Further work looking into optimising the datasets and inpainting parameters may help to improve this.

Conclusion

Pre-indexing reconstruction has been demonstrated. 2-D reconstruction is thus far the most effective method, with 3-D reconstruction through probe positions providing valid but slightly lower quality reconstructed patterns. Although the output quality of 4-D reconstruction is good it is currently unfeasible given the memory requirements.

Different decay paths govern plasmon damping. Among them, direct charge transfer has incredible potential in several applications from quantum optics to biosensing, but its exact mechanisms are still an open question [1][2][3]. We investigate the optical properties of plasmonic gold nanosphere-dimers separated by nanometer sized gaps towards the optimization of direct charge transfer. The dimers are synthetized with a molecular junction of conductive dithiol molecules in the gap. The optical response of metal nanoparticles is ruled by their exact three-dimensional morphology [1]. This is particularly critical for investigating charge transfer, which depends on the exact gap size. Different techniques are available to investigate the shape of nanomaterials. Among them, transmission electron microscopy (TEM) allows for atomic resolution. However, TEM images are 2D projections of 3D objects, resulting in the loss of valuable three-dimensional information. This loss can be especially detrimental for extracting quantitative information for non-symmetric structures or in case of objects that do not lie perfectly flat on the substrate. Three-dimensional information can be obtained by electron tomography (ET).

In this work, we begin by addressing the limitations of 2D high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM) and 3D ET, with particular focus on the gap reconstruction. We discuss the difficulties that emerge, both in 2D and 3D, when defining thresholds for extracting the quantitative morphology. We then combine experiments and simulations to address ET's challenges in reconstructing (sub)- nanometer gaps in gold dimers. We introduce a model for fitting sub-nanometer interparticle gaps. The proposed model is based on the convolution of a Gaussian function and a step function. Finally, the results are correlated with optical measurements. Optical properties are investigated using a homemade confocal dark-field spectroscopy setup and electron energy loss spectroscopy (EELS).

We start by highlighting the limitations of 2D STEM for gap reconstructions. Different experimental STEM images of the exact same dimer taken at different tilt angles resulted in different gap sizes and strongly varied with the chosen image threshold. By changing these two parameters, the gap size can vary between 0.1 nm and 2 nm. Such large differences in gap sizes have tremendous effects on the optical properties. As shown in Fig.1, even rather minor changes in morphology significantly impacted the optical properties of the system. The inaccuracy in determining the gap sizes from the 2D STEM images (Fig. 1b) made it also impossible to simulate the optical properties of the dimers. In Fig. 1c the scattering cross sections were simulated based on the 2D morphology information. For that, the STEM images were thresholded with the Otsu method to extrapolate the morphological parameters, which were then used as input for the optical simulations. The simulations were performed using the MATLAB toolbox MNPBEM[4]. In Fig.1c, the experimental and simulated

scattering spectra of four different dimers are displayed. The discrepancies between simulated and experimental scattering spectra suggest that 2D STEM images alone are insufficient for retrieving the morphology of the dimers.
Even when moving to electron tomography, we observed that the choice of threshold remained critical for the final gap reconstruction. Therefore, we developed a model to fit the data and retrieve the gap size without running into the thresholding problem. The proposed model is based on the convolution of a Gaussian function and a step function. The validity of the model was first investigated on simulations and them applied to fit experimental data.
We are currently working towards extending the convolutional model to analyse 2D STEM data by including the thickness-dependent HAADF-STEM intensity[5] in the fitting procedure. This will enable gap size extrapolation without relying on thresholding methods.

In conclusion, in this work we highlight the limitations of 2D imaging for retrieving the morphology of plasmonic particles. We then advocate the use of electron tomography to achieve a better reconstruction of the system morphology. We introduce a model tailored to fit experimental data from electron tomography and extrapolate nanogap sizes with one pixel accuracy. Finally, by correlating optical properties and morphology, we demonstrate the importance of this accurate three-dimensional reconstruction. Being able to accurately simulate the optical properties and experimentally correlate it to the exact morphology will finally allow us to design plasmonic systems with fine-tuned properties. This can be crucial for applications in catalysis, sensing and quantum optics.

IM-13 (1), Lecture Theater 5, august 27, 2024, 10:30 - 12:30

Fluorescent nanodiamonds (FNDs) are diamond nanoparticles containing color centers that emit visible light at room temperature. Among the color centers in FNDs, the nitrogen-vacancy centers (NV) have drawn the most attention due to its exceptionally stable optical properties and great prospect in sensing and biomedical diagnostic applications [1]. The current understanding of the optical properties of the FNDs relies largely on the optical measurement methods from either ensemble of materials or from few single particles. As most of the FND fabrication is a top-down process where larger diamond crystals are milled to desired nanometer size, FNDs generally have broad size distribution and irregular shapes [2]. Therefore understanding of FNDs structure-property relationship using ensemble measurements only is insufficient.

We have developed a new method based on correlative transmission electron microscopy and photoluminescence (TEMPL) [3]. TEMPL allows a direct correlation of the fluorescence brightness and three-dimensional size and shape of individual nanoparticles. PL provides optical information with exquisite energy resolution, and TEM provides structural information with exquisite spatial resolution. Unsupervised machine learning (ML) with the generalized 3D shape descriptors, is used to analyse correlations between the PL brightness and 3D shape of FND particles. The automation provided by machine learning allows TEMPL to be applied to large sample areas (2-3 orders of magnitude larger than a typical TEM field of view) containing a statistically significant number of particles.

Using this new method, we directly reveal that the volume-averaged PL brightness of thin, flake-like nanodiamond particles is up to several times greater than that of three-dimensional-shaped, thicker particles provided the particle diameter is less than the sub- wavelength limit. With the assumption that the number of NVs within a particle is proportional to its volume, this implies that individual NVs within thinner particles are brighter. This experimental observation is supported by the theoretical simulations on simplified particle geometries on a range of supporting substrate and surrounding medium. The simulations indicates that the comparative brightness of thinner particles, either on a thin supporting substrate or in a low- index medium, is attributable, at least in part, to the constructive interference of partial light waves in these particles. With increasing particle thickness, such an effect becomes damped. The sub-wavelength dimension of the substrate plays an important role, as it results in higher effective reflectivity comparable to diamond particles in a low-index medium (e.g., a low- index solution).

We have introduced a machine-learning-assisted correlative TEMPL method, which enables direct elucidation of the 3D morphological−fluorescence relationship of fluorescent nanoparticles. We emphasize that the method provides three-dimensional morphological information, which is potentially crucial for a variety of fluorescent nanoparticle systems but rarely achieved. Another significant advantage is that, in contrast to ensemble-based methods, TEMPL is performed ultimately at the level of individual particles. Notwithstanding this, machine learning assistance permits the analysis of a statistically meaningful number of particles. By using the TEMPL method to analyse the 3D morphology-fluorescence relationship of NV-containing nanodiamonds, we directly reveal that the volume-averaged brightness of thin, flake-like nanodiamond particles is up to several times greater than that of three-dimensional-shaped, thicker particles.

Background incl. aims
Three-dimensional nanomagnets and curved magnetism are nowadays exciting topics in Nanomagnetism. The appearance of novel spin textures and topologically protected magnetization states may be the key to develop 3D spintronic devices for magnetic data storage, magnetic logics and sensing [1]. One of these exciting architectures are ferromagnetic nanotubes (NTs), in which the predicted core-less spin states are ideal for stable and fast domain wall (DW) motion beyond the Walker limit [2]. Even though they have modelled and predicted theoretically, a detailed experimental observation of these DWs is missing. In this work we aim at revealing the nature of magnetic DWs in cobalt NTs.

Methods
Focused electron beam induced deposition (FEBID) [3] has been used to synthesize 3D cobalt NTs. FEBID is an exceptional nanolithography technique to produce high-quality magnetic architectures. It is a direct one-step nanolithography technique that allows 2D and 3D growth of architectures of almost arbitrary shape on virtually any substrate or surface geometry. It is based on the decomposition of an organometallic gas precursor by the electron beam to produce a deposit. In the case of 3D nanostructures of magnetic materials, such as cobalt or iron, the deposits are mixed with carbon and oxygen residues of the precursor. This contamination reduces its purity and therefore its magnetization. Thermal annealing procedures in high vacuum of an environmental SEM have been performed to increase the metallic content of as-grown cobalt layer [4]. Structural and chemical characterization of the as-grown and annealed NTs have been carried out by STEM-EELS in a probe-corrected Titan. Quantitative magnetic imaging of the remanent state and DW structure of a 3D ferromagnetic cylindrical NT has been achieved by off-axis Electron Holography (EH) in aberration-corrected Lorentz (field-free) transmission electron microscope (TEM) Hitachi I2TEM. Magnetic and electrostatic phase images have been obtained through holograms obtained before and after flipping the specimen. Micromagnetic simulations of the cobalt NTs have been carried out using the OOMMF software.

Results
12-nm-thick cobalt layers have been deposited on non-magnetic vertical Pt-C nanowire templates with a diameter of ≃70 nm, and then annealed at 450 ºC in high vacuum to produce high-purity, chemically and structurally homogeneous cobalt NTs (see Fig. 1a,b). They present a good cylindrical symmetry and homogeneous cobalt coverage over the Pt-C template, with a very thin (1-3 nm)

oxidation layer at the surface caused by exposure to ambient atmosphere. While as-grown NTs present a low cobalt content (< 70% at.), the thermally annealed ones present very high purity (approx. 95% at.). The magnetization state of the FEBID cobalt NTs determined by EH evidences a magnetic induction value near bulk values (>1.55 T), comparable to the magnetic induction measured in homogeneous cobalt nanowires annealed in similar conditions [3]. The thermally annealed cylindrical NTs give evidence for the nucleation and pinning of a DW during the magnetization reversal process induced by a excitation of the objective lens of the microscope. A quantitative analysis of the magnetic phase image and its comparison with detailed OOMMF micromagnetic simulations have confirmed that the magnetic contrast corresponds to a core-less head-to-head vortex DW, , as shown in Fig. 1c-e. In this coreless magnetic structure, the magnetization is confined in the nanotube plane with the spins rotating perpendicular to radial direction of the cylindrical structure.

Conclusion

Thermally annealed NTs with high-purity cobalt have been successfully grown by FEBID. EH performed in an aberration-corrected Lorentz TEM gives evidence for a high magnetization of the NTs in agreement with the increased metallic content achieved by high vacuum thermal annealing. A DW has been nucleated, imaged and quantitatively characterized for the first time. A comparison of phase images with micromagnetic simulations demonstrates the formation of a head-to-head vortex DW, as predicted in the literature according to the nanotube geometrical dimensions.

IM-04 (2), Lecture Theater 1, august 27, 2024, 14:00 - 16:00

Background incl. aims
As an era-defining technological advancement in the field of nanoscience and beyond, the effective implementation of aberration correction has allowed electron microscopy to routinely reach deep sub-angstrom-level spatial resolution. Recently, ultra-high-resolution monochromators relying on related electron-optical designs have further enabled electron energy loss spectroscopy (EELS) in the meV regime. Among many impactful consequences, these developments have seen the widespread adoption of low-voltage instruments, which can maintain very high spatial resolutions thanks to their aberration correctors, even down to 20kV, with 2-dimensional materials often providing the ideal sandbox and test objects, leading to the advent of practical 'single-atom microscopy' [1].
Beyond single-atom sensitivity, low-voltage operation is highly sought-after for reasons such as reduced knock-on damage to samples or increased inelastic cross-sections resulting in a high signal for spectroscopy. However, for a large number (perhaps even a majority) of practical materials science applications, the complexity and price of such instrumentation, especially when analytical capabilities are added, can be a drawback. In contrast, high-throughput capabilities with lower entry barriers in terms of cost and complexity, but which maintain a relatively high-resolution (but not always single-atom sensitivity), can often be preferable in order to address numerous scientific questions. These may in turn reveal further avenues for investigation that more complex instrumentation may then be used to explore.
Methods
One possible approach in recent years has led to the emergence of (low-voltage) scanning electron microscopes (SEMs) operated in a transmission geometry – or (T)SEMs [2]. When equipped with cold field emission sources, these instruments have been shown to reach 0.2nm information transfer in bright-field STEM imaging [3], and to provide remarkable flexibility for surface and spectroscopic investigations of functional materials [4].
Here, we show how the capabilities of such a high-resolution (T)SEM can be pushed even further towards near-atomic resolution. We use a Hitachi SU9000EA microscope, a low-kV (≤30kV) uncorrected (T)SEM equipped with a diffraction camera and a Hitachi electron energy-loss spectrometer developed for this instrument, which thanks to its cold-field emitter has a native energy resolution of ~0.3eV. In the optical configuration chosen for the experiments, the estimated probe size at 30kV acceleration voltage was below 0.4nm, sufficient to demonstrate atomic-resolution imaging and spectroscopy in carefully selected materials systems.
Results
Figure 1a shows a high-angle annular dark field (HAADF) image of a La1/3NbO3 ceramic (LNO) observed in [001] zone axis. The sample was prepared by crushing pellets of the sintered material into fine crystallites, and dispersing a chloroform suspension onto a lacey carbon support film, as described elsewhere [5]. The overall structure of this highly promising candidate thermoelectric

material is that of a perovskite, but it exhibits two distinct alternating A-site planes: one fully occupied by La ions, while the alternate position is fully La-deficient: a model is overlaid on figure 1a. The Fourier transform of the image, inset, demonstrates information transfer down to 0.26nm in HAADF (similar performance was also observed in bright field images, while atomic plane resolution was also observed in secondary images).
In this projection, the distance between non-deficient La cation planes is 0.8nm, making it an ideal test sample to use EELS to map with atomic-plane resolution the location of La in the structure. The observed oscillations, peaks and troughs, of the integrated intensity of the La M4,5 edge in an EELS linescan acquired along the indicated orange segment, figure 1b, follow exactly those of the simultaneously acquired HAADF signal – with the darker layers corresponding to La-deficient positions. The use of the La M4,5 edge, whose onset sits at the relatively high energy loss of 832eV, also serves to highlight the applicability of EELS in this uncorrected 30kV system, even at high energy losses.
Conclusion
These results demonstrate unambiguously atomic-plane resolution in EELS mapping in an uncorrected SEM, used in a transmission geometry. Together with high spatial resolution imaging capabilities across multiple signal channels (HAADF, BF, SE), this further demonstrates the versatility of these microscopes, whose advanced capabilities as (T)SEM-EELS instruments belie their relative operational simplicity and low cost.

Background incl. aims
The use of a segmented detector has become standard for various STEM observations, particularly for Differential Phase Contrast (DPC) STEM[1] and Optimum Bright Field (OBF) STEM[2]. DPC STEM can visualize weak electromagnetic fields such as p-n junction interfaces[3] and magnetic skyrmions[4]. In low-dose experiments with beam-sensitive materials, like zeolites and metal-organic frameworks (MOFs)[5], OBF STEM method achieves noticeably better contrast during live imaging. The applications of a segmented detector are further extending across a variety of material and life science fields. As an example, this research shows a combined analysis of these advanced imaging techniques with elemental analysis methods, EDS and EELS, simultaneously acquired in our new FEMTUS platform.
Methods
The sample was a semiconductor memory. The experiment was performed using JEM-F200, equipped with SAAF-Quad detector (an annular four-segmented detector), Dual SDD detector for EDS, CEOS Energy Filtering and Imaging Device (CEFID) with Dectris ELA hybrid-pixel electron detector, and integrated analysis platform FEMTUS developed by JEOL. In the FEMTUS platform, all detectors and cameras can be synchronized and simultaneous acquisition becomes possible with easy operation. For all experiments we chose an accelerating voltage of 200 kV, STEM mapping was performed with a dwell time of 10ms, convergence semi-angle of 6.6 mrad, and EELS collection semi-angle of 2.2 mrad limited by the central hole of SAAF-Quad detector.
Results
Figure 1 shows the result of DPC STEM and EDS/EELS elemental mapping, acquired simultaneously in a single scan. Fig. 1a shows the x-components of the center of mass (COM) DPC STEM derived from the signals of four SAAF-Quad detector channels. It can be seen that the COMx image reveals thin line contrasts around the regions indicated by the arrows. The DPC STEM method has better sensitivity for differences in projected potential, originating from both electromagnetic field and/or local chemical composition. Fig. 1b and 1c represent a magnified view of the EDS and EELS count maps, respectively. EDS mapping has an advantage in detecting heavy elements such as tungsten and titanium, which are difficult to access using the phase imaging method (DPC or OBF STEM) and EELS. As complementary information, the EELS mapping shows clear contrast for light elements (oxygen, nitrogen, and silicon) with higher S/N ratio compared to EDS. All of this information can be used to analyze the origin of DPC STEM contrast. Fig. 1d shows intensity profiles of COMx and EELS data extracted from the area indicated by the white square. The peaks of COMx intensity correspond to the increase of oxygen component, whereas the amount of nitrogen decreases in the interface region. Such combined information is very helpful to investigate the origin of phase contrast images, such as the composition difference between SiOx film and SiNx bulk region shown here.
Conclusion
In summary, we acquired DPC STEM, EDS, and EELS data of semiconductor samples simultaneously and revealed that the origin of DPC STEM signals was due to changes in the local chemical composition. Without the additional information from EDS and EELS, it was difficult to clarify

whether the obtained phase contrast represents chemical composition, electromagnetic field, or just a difference in local thickness. Such simultaneous acquisition of DPC, EDS, and EELS enables us to directly understand the origin of the observed phase image contrast. Furthermore, since compared to EDS and EELS mappings, DPC STEM is very sensitive to changes in the projected potential, it will be possible to clarify compositional differences by integrating the EDS and EELS signals of regions where phase contrast differences could be observed, even under low-dose conditions. This should also be useful for the composition analysis of electron beam-sensitive materials whose structures are destroyed with just a few scans. On the day of the presentation, we will show the details of the experimental results and additional instances of simultaneous data acquisition including OBF STEM.

Poster Group 1

Background incl. aims:
The current quest for sustainable energy and environmental technologies calls for a new view on catalysis. Today, catalysis of chemical reactions is commonly perceived as a complex surface phenomenon that inescapably links structural dynamics and functionality of the catalytic nanomaterials [1]. However, insight into this intricate relation between catalytic active surface sites and their mechanistic actions has remained limited due to the lack of suitable atomic-resolution imaging competences. The Center of Visualizing Catalytic Processes (VISION) addresses this core scientific challenge by introducing new electron microscopy technology and applications. In this contribution, we demonstrate a new-generation environmental transmission electron microscopy (ETEM) enabling three-dimensional atomic-resolution imaging of catalytic nanomaterials under exposure to reactive gas atmosphere in a chemical meaningful way.

Methods:
The VISION PRIME microscope is based on an ultra-stable Thermo Fisher Scientific SPECTRA ULTRA platform and designed for in-line holography to retrieve time-resolved exit-wave functions of catalyst nanomaterials during exposure to reactive gas environments at pressures of up to 10-20 mbar. The microscope is equipped with (i) a new 5th order aberration-corrector for the objective lens in broad-beam mode (CETCOR Prime), (ii) a four-stage differential pumping system for confining a reactive gas environment in the mbar range to the vicinity of the sample (ETEM), (iii) a monochromator setup to extend the information limit below 50 pm and (iv) direct electron detection acquisition (Falcon 4i) for low-dose-rate imaging to suppress electron-beam-induced sample alterations.

Results:
Here we present the design of this new-generation ETEM as well as selected performances and applications. Specifically, the ultra-stable electron optics allow the high-resolution transmission electron microscopy (HRTEM) mode to reach 60 pm resolutions routinely, and to further extend the resolution toward 50 pm, in both high vacuum and environmental modes. This is achieved by exploiting the high stability base and optics of the Spectra platform and integrating the ETEM module into it.

Using the flexible microscope illumination system enables to generate Nelsonian illumination with a rapid and flexible electron dose-rate control. This is key to suppress electron-beam-induced sample alterations [2,3]. Furthermore, direct electron detection capability in HRTEM mode helps to achieve the largest image signal for the fewest number electrons. In conjunction with the ultra-stable electron optics direct detection enables the recovery of the electron exit-wave functions at the highest sensitivity from focal image series acquisitions. This uncovers the three-dimensional atomic structure of the catalyst nanomaterial [3,4].

Conclusions:
The VISION PRIME electron microscope offers a sample-limited rather than optical-limited resolution under high vacuum and environmental conditions. This atomic scale visualization capability offers new means to address the three-dimensional atomic structure and dynamic behavior of catalytic nanomaterials during exposure to relevant reaction conditions. The VISION PRIME is therefore key for uncovering the role of gas-surface interactions in complex catalytic nanomaterials at the atomic-scale and for advancing new catalyst design strategies.

Investigation of Ferroelectricity using Advanced Microscopy

Xinxin Hu[1], Felip Sandiumenge[2], Umair Saeed[1], Rohini Kumara Cordero Eduards[1], Gustau Catalan[1,3], Jordi Arbiol[1,3]
[1]Catalan Institute of Nanoscience and Nanotechnology(ICN2), CSIC and The Barcelona Institute of Science and Technology(BIST)), Barcelona, Spain, [2]Institute of Materials Science of Barcelona (ICMAB-CSIC), Barcelona, Spain, [3]ICREA, Barcelona, Spain

Poster Group 1

Backgrounds:
Ferroelectric materials, characterized by their ability to exhibit spontaneous electric polarization switchable under applied electric fields, manifest intricate interactions among electrical, thermal, and mechanical properties. These materials, pivotal in various applications such as spintronics, computing, communications, memories, actuators, motors, and sensors, undergo changes in behavior and properties in response to factors like temperature, electric field, pressure, and strain. To explore ferroelectricity, some basic techniques, such as single-crystal X-ray diffraction, second harmonic generation measurement and dielectric measurement, were used to investigate the crystal structure, symmetry and dielectric anomaly. However, it is difficult to accurately determine whether the crystal structure is centrosymmetric or non-centrosymmetric down to nanoscale level by virtue of these basic measurement. This has hindered the progress of investigating the ferroelectricity related properties in the past.
Methods:
Advanced microscopies including Piezoresponse Force Microscopy (PFM) and Scanning Transmission Electron Microscopy (STEM), have been regarded as powerful approaches for evaluating the physical properties of materials down to nano, or even atomic scale. PFM has already been an essential method to investigate materials with piezoelectric properties. Especially, PFM shows its superiority in the studies of local non-destructive visualization of ferroelectric domain structures. In addition, Scanning Transmission Electron Microscopy (STEM), a fundamental tool in nanoscience, facilitates the acquisition of atomic-scale images and spectra. These images and spectra provide information on the structural and chemical properties of the studied nanostructures. As a result, STEM aids in a comprehensive understanding of the physical properties of functional materials at the atomic level. Consequently, combining advanced microscopies such as PFM and STEM has been shown as a powerful approach for evaluating the ferroelectric properties down to nanoscale even atomic level.
Results:
This study delves into a comprehensive examination of several ferroelectrics including organic-inorganic hybrid perovskites and traditional inorganic ferroelectrics utilizing advanced microscopies including PFM and STEM. These approaches enable a profound understanding of the intricate relationship between domain structure, electric polarization, lattice structure, and electronic states, thereby offering control over the nuanced mechanisms of ferroelectrics. Leveraging advanced microscopy including PFM and high-resolution STEM, we precisely investigated ferroelectric domain structures, the atomic and electronic structures of ferroelectric materials, shedding light on the impacts of domain properties, atomic displacements, and electronic configurations on ferroelectrics.
Conclusions:
The findings of this research hold significant implications for deepening the understanding on the ferroelectric properties, including changes in the ferroelectric domain structure and atomic level displacements, potentially paving the way for the creation of more efficient and reliable memory

storage, sensors, and energy converters. We anticipate that our research will establish a robust foundation for the examination of ferroelectricity and other complex functional materials down to atomic level.

PS-04 (2), Plenary, august 26, 2024, 14:00 - 16:00

Background incl. aims
Lithium-ion batteries have become integral for energy storage in various applications, including electric vehicles, and portable electronics [1]. Cathode materials such as LiNi1−x−yMnxCoyO2 (NMC), LiNixCoyAl1−x−yO2 (NCA), LiCoO2 (LCO), and LiMn2O4 (LMO) are widely used [2]. However, challenges like fast capacity fade, high cost, and poor cycling performance persist. Layered LiNiO2 (LNO) shows promise but suffers from structural changes and oxygen evolution during cycling [3]. During cycling we can identify three distinct stages where, the layered O3 stacking sequence is reduced from trigonal structure with rhombohedral symmetry $R\bar{3}m$ to monoclinic C2/m, then into a layered mixture of O3 and O1 (H2-H3) stacking and further to a rocksalt phase ($Fm\bar{3}m$) [4]. Among all phases, the H2 to H3 transformation results in poor structural stability especially while operating at high voltages [5]. This study aims to investigate the degradation mechanism of LNO cathodes, focusing on its initial O3 stacking sequence.

Methods
The degradation dynamics of LNO cathodes were investigated using in situ electron microscopy, electron energy loss spectroscopy (EELS), and four-dimensional scanning transmission electron microscopy (4D-STEM). This degradation has been monitored in real-time, which traces for the structural changes taking place for Li+ diffusion and degradation taking place with the chemical composition. A constant potential of +4.3 V was applied and the first delithiation cycle was examined via in situ TEM. On the other hand, EELS contributed to valuable insights regarding the changes of chemical composition during cycling, while 4D-STEM aided in obtaining high-resolution images and analysis of diffraction in order to complete the characterization of structural transformations taking place within the material of the cathode.

Results
Observations revealed the layered structure of pristine LNO, with cation mixing layers rapidly forming new Ni-rich phases mixed with Li2O phase near the reaction front and pure NiO species further away. During the first delithiation cycle, expansion occurred as the particle was charged versus a Li metal source as the anode, resulting in increased c lattice parameters and phase transitions from H1 to monoclinic, then to H2 and H3 (representing collapse of the layered structure).

Conclusion
The study sheds light on the degradation mechanism of LNO cathodes with the O3 stacking sequence, elucidating structural and compositional changes during cycling. Future work will focus on comparing simulated and experimental phase reconstruction mechanisms from layered to spinel phases and investigating oxygen loss in LNO cathodes during cycling.

Background incl. aims
Lithium-ion batteries (LIBs) dominate the industry, but limited lithium supplies and safety concerns with their electrolytes push the search for alternatives. Rechargeable aluminium batteries (RABs) are promising among post-lithium battery chemistries, which exhibit considerable potential as candidates for future applications due to the low cost of component materials and excellent theoretical energy density. Most research on aluminium batteries (AlBs) has focused on enhancing cathode materials [1] and ionic liquid electrolytes [2], overlooking attention to Al anodes [3]. It is crucial to note that the inherent metallic nature of aluminium increases susceptibility to dendrite formation during reversible plating and stripping processes [4]. Dendrites pose safety risks by breaching separators, leading to anode disintegration and cell failure. Uneven Al deposition, resulting in dendrite formation, can cause cell short circuits, particularly under repeated cycling at high capacities [5]. Therefore, it is of great importance to obtain in-depth understanding of the Al dendrite growth mechanism to increase battery safety. Multiple approaches were adopted to restrain the Al dendrite growth and identify the dendrite growth mechanism. Whilst most studies are preferred to reveal the mechanisms from the perspective of electrochemistry, electron microscopy is able to provide more straightforward approaches from crystallographic perspectives to understand the dendrite growth mechanism.
Methods
Chronoamperometry (CA) was performed to electroplate Al on Al foil from the [EMImCl]/AlCl3 electrolyte. The electrodeposited Al dendrite morphology was observed by a ThermoFisher Helios 5CX FEG FIB-SEM. The grain growth and orientation of the dendrite were determined by Transmission Kikuchi Diffraction (TKD) techniques, using an Oxford Instrument Symmetry S3 Electron Backscatter Diffraction (EBSD) detector. The scanning transmission electron microscopy (STEM) and corresponding EDX elemental analysis were carried out using a ThermoFisher Scientific Spectra 300 aberration-corrected microscope, operated at 200kV. Samples for STEM were fabricated by the ThermoFisher Helios 5CX FIB.
Results
In this work, we employed Focused Ion Beam-Transmission Kikuchi Diffraction (FIB-TKD) and STEM techniques, to investigate the crystallographic structure of the Al dendrite and the chemical species formed during the Al-dendrite growth. Figure 1 shows a tree-shaped Al dendrite, with clear primary dendrite feature and secondary dendrite arms. The corresponding STEM EDX and FIB-TKD maps from the cross sections parallel and perpendicular to the growth direction enable us to identify the

chemical segregation inside the dendrite and the grain growth along the dendrite. In combination with the detailed aberration-corrected STEM images and the corresponding spectroscopy study, we are able to determine the detailed chemical species inside the dendrite arms and thereby investigate how they affect the Al dendrite growth, including growth orientation and preference.

Conclusion

This investigation provides new understanding of Al dendrite growth and offers insight into the reaction mechanism between the Al and electrolyte, which could guide the future development of new rechargeable Al batteries.

ACOM-TEM Investigation of the white etching layer formation in rail track

Pr Muriel Véron[1], Matteo Russo[2]
[1]Université Grenoble Alpes, CNRS, Grenoble INP, SIMaP, F-38000 Grenoble, France, [2]Univ. de Lyon, INSA Lyon, CNRS UMR 5510, MATEIS, F-69621 Villeurbanne, France, [3]Univ. de Lyon, INSA Lyon, CNRS UMR 5259 LaMCoS, F-69621 Villeurbanne, France

PS-02 (3), Lecture Theater 4, august 30, 2024, 14:00 - 16:00

The growing concern to reduce the environmental impact of freight and passenger transport has increased the importance of rail as an energy-efficient mode of transport. Rail track maintenance has often been carried out on a preventive basis. In order to control costs and primary-source and primary consumption, while taking into account the increase in traffic, a more optimized approach to maintenance is necessary. This involves better anticipating the appearance of rail defects and modeling their evolution. The aim of the OPTIMRAIL(*) Project is to make maintenance predictive, by determining behavioral laws for the evolution of rail microstructure leading to the formation of defects, such as "squat", which accounts for 70% of rail defects following the survey conducted by SNCF in 2021 [1]. The squat defect is characterized by a collapse of the rail tread and a more or less pronounced network of cracks. [Figure 1 (a)]. It is linked to a surface tribological transformation (STT) leading to crack initiation. The latter is called the white etching layer (WEL) because of its appearance under the optical microscope after chemical etching [Figure 1 (b)]. The mechanisms by which the initial perlitic microstructure of railway steels evolves into the white phase are still debated in the literature. Two mechanisms are generally proposed. The first involves a thermally activated mechanism leading to martensite formation following austenitization followed by rapid quenching. The second mechanism is driven by an accumulation of plastic deformation that ultimately leads to nanograins of ferritic structure supersaturated with carbon atoms.

In the aim to clarify the mechanisms, samples of rails that had been in service under real traffic conditions were collected, and metallurgical analysis of the rolling band and the near surface layer was performed [2]. In particular, thin foils have been prepared by FIB at the near surface, allowing to study detailed microstructures from the surface up to 30 microns bellow. Automated crystal orientation and phase maps were produced using ASTAR technique [3] to investigate microstructure evolution (phases, orientation and disorientation). Perlitic structure remains fine and well organized 30 micron below the surface [Figure 1 (c)]. 20 microns below the surface, optical microscopy revealed a transformation in white phase, and ACOM-TEM maps start to show disorganization of perlitic structure, and only Fe3C and ferrite phases. At the surface, the organized perlitic structure is totally lost [Figure 1 (d)]. In some area, richer in carbides, ferrite quality of indexation is poor. Austenite phase seems to have a better reliability in this area, still with some discrepancy between modeled and real diffraction pattern, probably due to strain field induced by the many carbides. To verify the presence of austenite, orientation and phases maps were conducted at two different tilt (0° and 15°) along X axis. Austenite was still better recognize in similar region for the two maps, and coherency of orientation between the two maps was verified. We can then conclude that retained austenite was formed during rail track service, meaning that the mechanism at the origin of the WEL involves austenitization followed by rapid quenching. This information also provide clues of the temperature reached during friction. Martensite and carbide formations are currently under investigation.

Background
One of the biggest challenges facing the development and profitability of new ways to obtain H_2 by water splitting method is to find new materials for Hydrogen Evolution Reaction (HER) electrocatalysis that are not based on Pt, with the aim to obtain electrodes which are both performant and sustainable. The synthesis of TMD(Transition metal dichalcogenide)-based materials is one of the most promising strategies. MoS_2-Au hybrid systems have shown high HER activity, and the plasmonic properties of gold makes it an interesting proposal in photoelectrocatalysis. In this work, we report the synthesis and complete physical and chemical characterization of both Au@MoS_2 and Au@Mo(W)S_2 core-shell nanostructures. In addition, we have studied the influence of thermal reduction treatment in hydrogen atmosphere to increase the activity of these systems via a precise control of the number of shell layers and associated defects.

Methods
Electrochemical HER behavior of the samples was determined by using linear sweep voltammetry (LSV), cyclic voltammetry (CV) and vhronoamperometry, the last one in combination with a light source to study the plasmonic properties. The measurements were carried out in a three-electrode standard set-up in acid conditions (H_2SO_4 0.5M) by using a Biologic potentiostat/galvanostat (SP-150e) with platinum, Ag/AgCl and glassy carbon electrodes as a counter, reference and work electrodes. Structural characterization was performed in a double-corrected Transmission electron microscope (FEI Titan Cubed) in combination with in-situ TEM studies of the evolution of the sample under thermal hydrogen conditions carried out in environmental gas-cell (Climate Holder, DENS Solutions). Other complementary techniques, such as XPS and Raman spectroscopies, were performed to give a complete insight on the structure and chemistry of the samples.

Results
Au@Mo(W)S_2 systems with different W/Mo ratios (including W/Mo=0) were synthesized. TEM analyses highlight the presence of W atoms in the shell layers of the nanostructures. Moreover, a reduction in the number of shell layers additional thermal treatment can be observed by applying a thermal treatment in reducing conditions, as evidenced by both ex situ and in situ TEM studies. The incorporation of such defects induce to a change in the electrochemical properties of the material: low W/Mo ratios enhance the HER activity with respect to the pure Mo sample. However, the thermal treatment affects differently each sample: the best activity being observed for the pure Mo sample heated at 800°C whereas the ternary Au@Mo(W)S_2 samples show an improvement at lower temperature, highlighting thus the interplay between heteroatoms and structural defects on the HER

properties. Moreover, plasmonic properties of the sample was evidenced, by both light-assisted electrochemical studies and low-loss STEM-EELS analyses.

Conclusion
This work provide a complete overview on both the integration of W hetetoatoms and the incorporation of structural defects by thermal treatment into 2D-based core-shell structures. The detailed structural and electrochemical characterization of these processes allow us to link the structural and electrochemical properties as well to fine-tune the chemistry of theses systems.

Background
Optical shaping of electron beams, e.g. in the form of longitudinal attosecond bunching that promises increased temporal resolution [1], significantly extends the range of experiments possible in transmission electron microscopes (TEM). Based on inelastic scattering with an optical field, the momentum and energy of the electron are modified by absorption or emission of photons [2]. This inelastic interaction can, in turn, be employed to investigate the nano-optical response of samples with high spatial resolution in photon-induced near-field microscopy (PINEM) [3]. However, due to the weak coupling of free electrons and photons, inelastic field probing and beam shaping techniques so far required intense optical pulses and short electron pulses available in ultrafast TEMs.
Methods & Results
Here, we present the efficient modulation of a continuous electron beam by integrated photonics microresonators made from silicon nitride (Si3N4) that are optically pumped with a continuous-wave (CW) laser [4]. The fiber-coupled, chip-based resonator is placed inside a TEM, as illustrated in Figure 1a, such that the continuous electron beam can pass over the chip parallel to its surface before being analysed with an imaging spectrometer. Swift electrons interacting with the resonator's guided optical mode can absorb or emit photons from the laser field coupled to the resonator. This leads to the formation of electron energy sidebands spaced by the photon energy (~0.8eV, corresponding to ~1550nm) in the spectrum as shown in Figure 1b. The inelastic electron-light scattering is facilitated by the velocity matching of the electrons to the optical phase velocity as well as the high-Q resonant field enhancement. We characterise the latter by employing electron energy-gain spectroscopy (EEGS). To this end, the frequency of the CW pump laser is scanned across the cavity resonance at a low input power while electron spectra are recorded in parallel. We retrieve the laser detuning-dependent electron-light coupling strength (Fig. 1c) that exhibits a linewidth of 390 MHz corresponding to a spectral feature of only 3.1µeV width. From this EEGS trace, we infer a cavity quality factor of 7.7*105.
Increasing the optical pump power coupled to the microring resonator, the inherent nonlinearity and anomalous dispersion cause the parametric generation of new optical frequencies via four-wave mixing. We observe the formation of various nonlinear optical intracavity states whose spectral and temporal properties strongly depend on the laser detuning from the cavity resonance frequency. When scanning the laser across the resonance at a power > 100mW, we can thus perform an EEGS measurement on the nonlinear optical states by recording electron energy spectra in parallel [5]. The resulting electron spectral trace, shown in Figure 1d, exhibits prominent changes when entering different nonlinear optical states (marked by dashed white lines). For stable and chaotic intensity modulations (regions 1 and 2), resulting from the superposition of different optical wavelengths,

averaging over different instantaneous interaction strengths leads to a smoothening of the electron spectra. However, the interaction of electrons with dissipative Kerr solitons (region 3), self-stable short optical pulses with a broad spectrum, yields a broad, low-intensity plateau and a strong central peak since only a fraction of electrons interacts with the high-intensity pulse and scatters to high energy changes.

Conclusions

In conclusion, we characterise the inelastic interaction between electrons and the optical mode of an integrated photonics microresonator. By performing EEGS on one of the cavity resonances, we achieve an unprecedented energy resolution that might be transferred to both the study of material excitations as well as the probing of quantum optical excitations with free electrons. The observed strong interaction of a continuous electron beam with a low-power CW laser, moreover, enables efficient longitudinal electron beam modulation with optical fields in a conventional TEM setup. Harnessing the toolbox of optical waveform shaping in integrated photonics, we employ the multicolour fields of optical frequency combs and their impact on the electron energy spectra upon interaction to further extend these beam-shaping capabilities.

Poster Group 2

Owing to the rapid development in growth of synthetic MX_2 (where M is the metal and X is the chalcogenide) materials in recent years, their average grain sizes are fast approaching several tens to hundreds of micrometers [1]. Epitaxial growth on a single crystalline template is the favored approach to achieve wafer-scale and industrially compatible growth of high-quality single crystalline MX_2 monolayers. Despite the control over orientation provided by templated approaches, selective growth of domains with a single orientation while avoiding the anti-parallel orientation (or 60^o rotated domains) has proven to be challenging [2]. Inclusion of such anti-parallel domains inevitably leads to the formation of 60^o grain boundaries which are detrimental to electron mobility due to the presence of mid-gap states [3]. It is therefore necessary to develop methods to enable rapid and large field of view (FOV) mapping of the anti-parallel domains in epitaxial MX_2. We present a novel approach using segmented detector geometry to rapidly map the 60^o grain boundaries over a large FOV in epitaxially grown MX_2. This relies on the asymmetry of diffraction peak intensities which split into two families Ka and Kb due to reduced symmetry from 6-fold to 3-fold in a monolayer of MX_2 [4]. The specimens are prepared by transferring the MoS_2 from sapphire to a carbon coated TEM grid using a tape assisted method described elsewhere in detail [3]. The conventional dark-field TEM (DF-TEM) is carried out on a Thermofisher Metrios 80-200 TEM operating at 200 kV by placing the smallest objective aperture on any first order diffraction spot. A large number of images with a certain overlap are automatically acquired in a grid pattern, preprocessed, and stitched together to form a montage with significantly larger FOV. This process is repeated for the opposite diffraction spot to obtain the complementary image. The novel segmented detector approach is carried out in a Helios5 FX dual beam operated in a “STEM in SEM” setup at 2kV and equipped with a segmented annular detector. The six segments of the detector are operated such that only 3 of the 6 segments are active for the acquisition and transmitted beam is centered as shown in schematic Fig.1 a. In this mode, as the three segments are separated from each other by 120^o, the detector segments selectively collect the intensities from either the Ka or the Kb spots depending on the orientation of the grains resulting in a contrast which helps differentiate between 60^o grains in monolayer MX_2. The segmented detector approach is first tested on a small grain sample with high density of 60° twins. Fig.1(b) shows a color overlay of the two complementary images wherein the contrast in a monolayer is reversed between the two images making the layer appear either more green (0°) or more red (60^o). The boundary separating these two regions can be either a β or γ grain boundary [3]. The images are segmented using a gaussian mixture model and assigned classes to obtain statistics on 60° twin inclusion in monolayer as well as various stacking orders in bilayer MoS_2 (Fig.1(c)). The method is then applied on large grain samples and compared with the more conventional montage DF-TEM approach used so far. Fig.1(d) shows a similar color overlay obtained by montaging several DF-TEM images acquired at 200kV. The contrast between the main orientation and 60^o rotated domains is rather weak and images are noisier compared to those obtained with a segmented detector at 2kV shown in Fig. 1(e). Moreover, the stacking in bilayer cannot be uniquely identified with the conventional DF-TEM due to influence of unintended specimen tilt [4] which in case of the

segmented detectors is overcome by design through radial integration. A drawback, however, is that 2kV electrons don't have enough energy to see through the carbon support.
The segmented detector in SEM provides superior results from a large FOV in a fraction of the time it takes for montage acquisition and processing, i.e., few minutes compared to several hours or days. In addition. in bilayer, the stacking order can be easily assigned and not influenced by sample mistilt.

PS-04 (3), Plenary, august 27, 2024, 10:30 - 12:30

Background incl. aims
Electrocatalysts require high activity as well as long-term stability to ensure their practical and economic viability. Nevertheless, although critical, the stability consideration is oftentimes overlooked in research[1]. For instance, manganese dioxides are considered promising electrocatalysts to substitute expensive noble metals due to their high abundance, low price and oxygen evolution reaction (OER) activity. However, their electrochemical and structural stability during operation is still controversial[2]. Herein, we will address the stability of MnO_2 using identical location (IL-EM) and electrochemical liquid phase electron microscopy (ec-LPTEM), which offer an excellent platform to investigate the electrocatalysts performance in-situ[3].

Methods
The structure and morphology evolution of the MnO_2 electrocatalysts are characterized using SEM and (S)TEM imaging and associated spectroscopy techniques such as EDS and EELS in ex-situ, in identical locations and in-situ in ec-LPTEM. This combination approach allows the dynamic study of structural changes within the liquid as well as the effects of longer electrochemical operation.

Results
Our results address the debated existence of a stability window for the operation of MnO_2 catalysts for the acidic OER. Measurements based on IL-EM and ec-LPTEM are presented on the specific potential range and conditions of operation within the stability of the catalyst. Beyond the stability window, the structural evolution of the catalyst from its synthesis will be directly correlated through time-resolved imaging to the electrochemical stability during OER operation to resolve mechanisms governing the catalyst instability.

Conclusion
We present a thorough study addressing the growth and electrochemical and structural stability of MnO_2 electrocatalysts for the acidic OER using IL-EM and ec-LPTEM. Such results are key for the design of durable non-noble electrocatalysts.

Poster Group 2

In situ (scanning) transmission electron microscopy ((S)TEM) experiments in gases became widely possible with the development of sandwiched MEMS-based samples carriers (e.g. Nano-Chips) – gas Nano-Reactors. Various stimuli like heating or biasing in gaseous environments have been employed to study materials synthesis [1], catalyst [2], ferroelectrics [3], resistive switching [4] and more. The majority of the commercial in situ (S)TEM sample holders, however utilize only four electrical contacts that limit the combination of stimuli that the user can simultaneously apply. Real life applications, like proton exchange membranes, fuel cells, and non-volatile memory, etc, on the other hand, require combined application of thermal and electrical stimuli at ambient environmental conditions and thus, higher number of electrical signals.

In this work we present our new platform for in situ and operando environmental (S)TEM experiments. The heart of this platform is a newly designed holder that has eight electrical connections and allows the application of thermal and electrical stimuli in ambient environmental conditions. This is achieved through a newly designed dual chip environmental cell with an increased number of contacts. Additional electrodes are used to characterize the electrical performance of a FIB lamella sample either in 2- or 4-contact mode. The holder has a removable tip that has generic design and fits different brands of TEM, which substantially improves the correlation of the same sample between different TEM platforms. Furthermore, the design of the holder allows to rotate the tip making it suitable to both, TEM and STEM operation.

Using the new holder, it is possible to achieve high resolution at ambient gas pressure as obvious from the TEM image below. When rotating the tip by 180 degrees, the sample will become on top, which is beneficial for the high resolution STEM imaging. Since the tip flipping is done without the Nano-Reactor disassembly, it is possible to observe the same sample in different modes and easily trace the same region of interest. We will also demonstrate the capability of the holder in terms of elemental analysis using EDS and EELS analysis. We will show a few experimental examples of the new environmental operando system and explain how our new platform can be used in correlative studies involving different experimental methods like in situ TEM, SEM and beamlines.

Graphic
During the in-situ experiments, the user has full flexibility to define if the sample should be on top (better for STEM imaging mode) or on the bottom (better for TEM imaging mode). Therefore, the user can simply flip the tip 180 degrees (as seen in Figure a-c). Despite the rotation of the tip, the user can always preserve the same environmental and stimuli conditions constant. Figures d-f) show that the same tip is mounted on Thermo Fisher and JEOL holder bodies. The high resolution image of a nano-particle at ambient pressure in TEM (left) and STEM(right) imaging modes. The inset in the TEM image correspond to the sample place of the sample imaged in the STEM mode.

Cryo Lift-out Technique to Study Host-Pathogen Interaction on Cell Monolayer
Gautham SANKARA1, Sylvie GOUSSARD1, Guillaume DUMENIL1, Daria BONAZZI1*.
1Pathogenesis of Vascular Infections Unit, Inserm U1225, Institut Pasteur, Paris, France.

Background:

Cryo lift-out technique is an advanced sample preparation technique for cryo-TEM microscopy. Here, a bulk from the sample surface is lifted out in a vertical orientation using a cryo-needle and thinned using FIB milling, allowing the study of tissue or thicker samples in TEM. In addition to that, the recent development of serial lift-out technique would allow us to understand the information along the volume of the sample. However, in cell biology researc, traditional cryo-FIB that yields horizontal lamella is used, which poses a bottleneck to study the vertical structures in the cells (missing wedge issue). Lift-out is not possible on cell monolayers because of the smaller thickness of the samples. Therefore, we developed a sample preparation technique using hydrogels to grow cell monolayers, followed by high-pressure freezing (HPF) and then lift-out to study the vertical (apico-basal oriented) structures in cells.

Methods:

Optimized hydrogel preparation is vital for performing lift-out on cell monolayer. Here, we used acrylamide gels that have better water content which suits cryo-microscopy. HUVEC cells are used as a model because of our interest in studying a novel (unpublished) actin cytoskeleton structure that is formed from the apical side of the cell to the basal (through the cell volume), due to an extracellular bacterial infection. The hydrogel-Cell-Bacteria sample is frozen using HPF technique, and the lift-out and FIB thinning were performed on Aquilos-2 FIB SEM. Tomograms were acquired using Glacious or Titan TEM.

Results:

Hydrogel preparation, including parameters of polymer concentration, height, and width of the gels, is optimized. The lift-out, which is a completely manual process, has been semi-automated with the help of the IFLM module to perform correlation microscopy using the Maps software. At present, we are replacing the half-moon grids with a rectangular track to perform serial lift-out with the cell samples. The ongoing efforts are to obtain the region of interest with the help of Cryo-CLEM and IFLM techniques to build tomograms.

Conclusion:

Cryo-EM's contribution to cell biology research provides a huge potential to understand the proteins' structures, arrangements, and their microenvironment in their native state. On the contrary, apico-basal polarity and corresponding structures are common in cell biology. For instance, structures such as cell-cell junctions, intestine villus, pedestals, podosomes have specific functions and unique orientation. To study these structures at their native orientation at TEM is physically not possible, due to its alignment along the beam path and missing wedge issue. Therefore, we have developed a sample preparation technique that would allow the researchers to use cell monolayers to perform lift-out techniques to study the vertically aligned structure in a horizontal lamella.

Revealing atomic structure and composition in ultrahigh energy storage density ferroelectric thin-films

Prof Shery Chang[1,2], Dr Daniel Stroppa[3], Dr Richard Webster[1], Prof Danyang Wang[2]
[1]Electron Microscope Unit, Mark Wainwright Analytical Centre, University of New South Wales, Sydney, Australia, [2]School of Materials Science and Engineering, University of New South Wales, Sydney, Australia, [3]Dectris Ltd, Baden-Daetteil, Switzerland

Poster Group 1

Ferroelectric thin film material is positioned to be a strong candidate for nano/microelectronics component with ultra-high energy storage density with low electric field [1]. One of the key strategies to achieve such high energy storage density is by creating a secondary phase nanostructure around the morphotropic phase boundary.

Here we show detailed characterisation of (Bi, Na)TiO3 (BNBT) thin films grown on SrTiO3 single crystal substrate. The nanostructures in the thin films as well as their electronic structures and composition variations were characterised using 4D STEM. Due to the presence of Na, it has been found that the BNBT structure can change under the electron beam, causing by the migration of Na. The ultra-fast ARINA detector allows acquisition of 4D STEM data with only few pA current, and short dwell time to avoid the electron beam damage to the BNBT film. Moreover, electron energy loss spectroscopy (EELS) was acquired using the K3 detector, to probe the composition and the electronic structure across the nanostructured domains.

We found that there is Bi segregation forming strips of half unit cell wide Bi2O3 layers. Such composition is confirmed by the atomic resolution EELS maps, showing no presence of Ti within the Bi2O3 bright strips. The effect of the Bi2O3 layers is to laterally displace the lattice above the defect by half a unit cell, resulting a morphotropic anti-phase domain boundary. In addition, the Bi2O3 segregation layer gives about 22% longer c-axis for the 3 unit cell around the defect. Such large expansion of c-axis is attributed to the presence of the super-tetragonal phase (super-T) [2-3]. The electronic structures of Ti and O sites adjacent to the Bi2O3, measured using EELS Ti L edge and O K edge, is consistent with the lattice distortions. Density functional theory calculations were carried out to probe that the origin of the super-T structure is likely due to the oxygen vacancies around the Bi2O3 strips.

Such complex nanostructures with multiple structure phases con-existent forming nanodomains is found to be the key for the ultra-high performance of such ferroelectric thin films.

Poster Group 2

Background including aims.
Misfit layered compounds (MLCs) have garnered considerable attention due to their fascinating chemistry and properties [1]. MLCs consist of two different layered oxides or chalcogenides that are stacked alternately along their c direction. The MLC stack is composed of metal chalcogenide (MX) which possesses a distorted rock salt structure and a transition metal dichalcogenide (TX2) which crystallizes in a hexagonal structure [1,2]. The properties of MLCs are determined by the chemical and structural interplay between MX and TX2. MLC-nanotubes (NTs) synthesized via the chemical vapor technique (CVT) offer potential applications in thermoelectrics due to the complementary properties of the two layered compounds [1]. Recently, a modified synthesis method of MLC-NTs has permitted the introduction of additional elements to form a quaternary compound starting from LaS-TaS2 [3,4]. Here, we present an in-depth electron microscopy analysis of the novel family of (SmxY1-x)S-TaS2 nanostructures [5]. In this novel family, the partial exchange of Sm(S) by Y(S) provides a pathway for the fine control of the MLC structure and its properties.

Methods
MLC-NTs made of (SmxY1-x)S-TaS2 were synthesized via the CVT technique [1-3] by varying the precursor proportions of Sm vs Y between x=0 to x=1. The samples will be designated by the Sm percentage, Sm20 corresponds to (Sm0.2Y0.8)S-TaS2 and similarly. To analyze these NTs, different TEM techniques (high-resolution (scanning)TEM (HR(S)TEM) imaging, selected area electron diffraction (SAED), electron energy loss spectroscopy (EELS) and energy-dispersive X-ray spectroscopy (EDS)) were performed. These TEM studies were developed using two aberration corrected Thermo Fisher Scientific Titan microscopes. Raman spectroscopy has also been employed to study these NTs.

Results
The detailed analysis of the NTs by electron microscopy and different spectroscopies verifies the partial substitution of Sm by Y in the (Sm,Y)S subsystem and also reveals the structural changes when compared to the pure SmS- or YS-TaS2 MLC-NTs. These structural changes can be linked to the slight difference in the lattice parameters of SmS and YS. Figure (a) corresponds to the SAED pattern of Sm40 (Sm0.4Y0.6)S-TaS2 sample where the reflections marked by the green dotted circles represent the reflections from (Sm,Y)S and reflections marked by red dotted circles represent the TaS2 subsystems, respectively. The c-axis periodicity (1.13 nm) is indicated by yellow arrows. The c-axis is perpendicular to the tube axis, which is given by the purple double arrow. A high-angle annular dark-field STEM image of a Sm80 NT is shown in Figure (b) and illustrates the repetitive layer stacking of (Sm,Y)S and TaS2. The inset of (b) shows a low-magnification TEM image of the Sm80 NT. Figure (c)

depicts a Raman spectrum acquired from an individual Sm80 NT, which was fitted using a set of Lorentz functions. In a vibrational spectroscopy such as Raman, a Lorentz line shape is used to model pure vibrational modes, which only undergo homogeneous line broadening. Raman spectroscopy measurements of the whole set of samples reveal the tunability of the vibrational properties of these NTs. The study of the elemental composition of these NTs by EDS is shown exemplary for a NT of the Sm80 sample in Fig 1(d), which reveals an average atomic weight percentage of around 17 at. % Ta, 24 at. % Sm+Y, and 59 at. % S. The EDS results obtained from all the samples show that the substitution of Sm by Y is homogeneous and in-phase with structural changes in the lattice parameter. Further low-loss EELS studies and electric properties of these samples are in progress. These investigations will also provide a more complete understanding of these systems including their electronic/optoelectronic properties.

Conclusion

In summary, through comprehensive electron microscopy and spectroscopy analysis, we have shown the successful synthesis of an unexplored group of quaternary MLC-nanotubes. The MLC structure is observed in all samples and the compositional analysis shows a homogeneous substitution of Sm by Y.

In situ (scanning) transmission electron microscopy ((S)TEM) experiments in liquid phase gain momentum due to the development of sandwiched MEMS-based samples carriers (e.g. Nano-Chips) – liquid Nano-Cells. Various stimuli like heating or biasing in liquid environments have been employed to study materials nucleation and growth [1], ion batteries [2], electrocatalysts [3] and more. The majority of the commercial in situ (S)TEM sample holders utilize only four electrical contacts that limit the combination of stimuli that the user can simultaneously apply. However, to mimic the real-world operation conditions in applications like proton exchange membranes, Zn-ion batteries, etc require combined application of thermal and electrical stimuli and thus, higher number of electrical signals.

In this work we present our new platform for in situ and operando environmental (S)TEM experiments. The heart of this platform is a newly designed holder with eight electrical contacts and multiple liquid inlets that allows the application of thermal and electrical stimuli next to liquid flow and mixing capability. The specially designed liquid Nano-Cells with eight electrical contacts contain a heater and four biasing (Working, Reference, Counter + 1) electrodes for combined electrochemical and thermal experiments. The holder has a removable tip that has a generic design and is compatible with different TEM vendors. Additionally, the design of the holder allows to rotate the tip making it suitable for both TEM and STEM operation.

We will demonstrate the capability of the holder in terms of TEM and STEM imaging, elemental analysis using EDS and 4DSTEM. We will show a few experimental examples of the new environmental operando system, including electroplating and stripping of metals as a function of temperature and the flow.

Self-supervised deep learning method for in-cell cryo-electron tomography

Frosina Stojanovska[1,2], Anna Kreshuk[3], Julia Mahamid[1,3], Judith Zaugg[1,4]
[1]Structural and Computational Biology Unit, European Molecular Biology Laboratory, Heidelberg, Germany, [2]Collaboration for Joint PhD Degree between EMBL and Heidelberg University, Heidelberg, Germany, [3]Cell Biology and Biophysics Unit, European Molecular Biology Laboratory, Heidelberg, Germany, [4]Genome Biology Unit, European Molecular Biology Laboratory, Heidelberg, Germany

IM-10 (2), Lecture Theater 3, august 29, 2024, 14:00 - 16:00

Cryo-electron tomography (cryo-ET) is a powerful technique for visualizing and analyzing macromolecular complexes within their native cellular context. However, cryo-ET analysis is hindered by the low signal-to-noise ratio (SNR) inherent to cryo-ET data and the lack of ground truth data, which pose significant challenges for supervised automated mining of molecular patterns within the cellular environment. As a result, the accurate localization and identification of macromolecular structures of interest, particularly those that are small and less abundant, continue to be a major challenge in the analysis of cryo-ET data.
To address these challenges, we developed a new self-supervised deep learning approach tailored for the dense (voxel-wise) representation of in-cell cryo-ET data. This method generates high-resolution representations of cellular information at the voxel level, facilitating precise segmentation of structural details within tomograms, including particles (globular macromolecular complexes) and filaments (for example, DNA). To evaluate the performance of the model, we created an extensive simulated dataset (Purnell, 2023) that closely mimics a crowded cellular environment, featuring membranes, actin and microtubule filaments, and over 100 PDB protein structure entries of varying sizes. Additionally, we enhanced the dataset by simulating the presence of DNA structures.
Experimental results from the simulated data from the 2021 SHREC competition (Gubins, 2020) and our new simulated crowded dataset demonstrate the efficiency of our method in extracting detailed information about membranes, actin, microtubules, particles, and filaments on a voxel level. To achieve further separation of different types of particles, we conducted an experiment in which we extracted subtomograms for each detected particle and generated embedding representations for every subtomogram. This approach resulted in a new representation space, where distinct clusters were formed using unsupervised clustering, effectively separating different types of particles. The ability to distinguish and separate different types of structural information highlights the potential of our method for advancing the analysis of complex cellular structures in cryo-ET data.
Furthermore, we applied our method to tomograms of Mycoplasma pneumoniae (O'Reilly, 2020), which capture the entire cell in a single tomogram. We successfully extracted structural information of the membrane, particles, and putative DNA filaments, creating a comprehensive 3D structural cell model.
In conclusion, our novel self-supervised deep learning approach demonstrates significant potential in overcoming challenges associated with ground truth generation and accelerating biological discoveries from cryo-ET data. By enabling accurate segmentation and extraction of macromolecular and filament information, even in cases with limited or missing annotations, our method advances the analysis of cryo-ET data. Furthermore, the proposed approach can be utilized to construct a comprehensive 3D Mycoplasma pneumoniae cell model from in situ tomograms, showcasing its potential for diverse applications in the field.

Poster Group 1

Background incl. aims
Electron Tomography (ET) is a widely used technique for the 3D characterization of nanomaterials. To obtain faithful reconstructions, high-quality projection data must be acquired over the full 180° tilt range and at tilt increments of 1-2°. However, for slab-like sample geometries, the tilt range is often limited due to geometric restrictions within the TEM, and a large tilt increment is used to minimize the total electron dose. These restrictions lead to blurring and distortions in reconstructions obtained with conventional algorithms such as simultaneous iterative reconstruction technique (SIRT). Compressed sensing (CS) approaches have been introduced to improve the quality of reconstructions. Although CS techniques outperform conventional methods in sparse-view acquisition scenarios, they fail to correct artifacts due to the limited angular range. Data-driven deep learning (DL) approaches have been proposed for denoising and distortion correction of X-ray tomography and ET reconstructions. Although promising, these approaches are highly dependent on the availability of high-quality data sets for neural network training. Such data sets are often not available in practice, making it difficult to apply DL methods to a wide range of samples. Recently, Deep Image Prior (DIP) has been proposed for several image restoration problems, and adapted to limited-angle X-ray tomography. The method uses a neural network as a prior for the reconstruction, but has the advantage of not requiring any training data set, making it suitable for ET applications.
Methods
In this work, we apply DIP with total variation regularization (DIP-TV) to a sample consisting of carbon-supported platinum nanoparticles (NPs) dispersed on a carbon grid. ADF-STEM and HAADF-STEM tilt series were acquired from -60° to +60° with an increment of 2°, using an FEI Titan Themis operating at 200kV. In HAADF-STEM projections, only Pt NPs were visible, while in ADF-STEM mode, both Pt NPs and C support were visible but the images were affected by diffraction contrast. DIP-TV was applied for 3D reconstruction in both imaging modes, using increments of 2°, 10° and 20°. Results were compared with those obtained with SIRT and CS with TV regularization (CS-TV).
Results
Figure 1 shows the reconstruction of a slice from ADF-STEM and HAADF-STEM tilt series, obtained with SIRT, CS-TV and DIP-TV. The tilt range is [-60°:+60°] for all reconstructions, with the missing wedge in the horizontal direction, while the tilt increment is set to 2°, 10° and 20°. In HAADF-STEM reconstructions (left), only Pt NPs are visible. SIRT suffers from elongation artifacts and ‘star artifacts’ as the tilt increment increases. CS-TV slightly improves the quality of the reconstructions but suffers from oil painting effects. DIP-TV reconstructions appear consistent under all acquisition conditions, with near-spherical, well-contrasted particles. The ADF projections are more complex, as the carbon support is visible and superposed on the Pt NPs. SIRT reconstructions suffer from significant artifacts in the support, which increase as the number of projections is reduced. CS-TV still manages to reconstruct the particles, but the carbon is not well retrieved. In particular, for both SIRT and CS-TV reconstructions, the carbon appears heterogeneous and porous below and above each NP. This is probably due to the non-linear intensity in ADF images (diffraction contrast). In contrast, DIP-TV retrieves near-spherical NPs and a homogeneous carbon support, under all acquisition conditions.

Using 20° increment (7 projections in total), the shape of the carbon is slightly distorted on the right-hand side, but the technique largely outperfoms SIRT and CS-TV.

Conclusion

This work shows the robustness of DIP-TV for ET using a limited number of projections and a restricted tilt range. The method benefits from the power of neural network architecture, but requires no training data set, making it suitable for ET and extremely versatile since it can be used under different acquisition conditions. Moreover, the method could be applied to different modalities of the same material and potentially directly for 3D reconstruction.

Characterisation of red fluorescent protein FLIM properties and comparison with novel StayGold live cell imaging

Dr. Philipp Tripal[1], MSc Hanan Said[2], Dr. Benjamin Schmid[1], Dr. Ralph Palmisano[1]
[1]Optical Imaging Competence Centre, Friedrich-Alexander Universität, Erlangen, Germany,
[2]University of Applied Science, Coburg, Germany

LS-03 (1), Lecture Theater 4, august 26, 2024, 15:00 - 16:00

Red fluorescent proteins (RFPs) have become indispensable tools in molecular and cell biology, facilitating a wide range of applications including live cell imaging, protein tracking, and gene expression analysis. However, the increasing availability of RFP variants poses a challenge in selecting the most suitable probe for specific experimental requirements. In this study, we conducted a comprehensive comparative analysis of eight commonly used RFPs: mCherry, mCherry2, mCarmine, mKate2, TagRFP, mScarlet, mScarlet-I, and mScarlet-H, with a focus on their fluorescence lifetime properties.
We employed time-correlated single photon counting (TCSPC) and fluorescence lifetime imaging microscopy (FLIM) techniques to characterize the fluorescence lifetimes of these RFPs. Our results revealed significant variations in fluorescence lifetimes among the tested RFPs. mCherry exhibited the shortest fluorescence lifetime, followed by mCherry2 and mCarmine. In contrast, mKate2, TagRFP, mScarlet, mScarlet-I, and mScarlet-H displayed longer fluorescence lifetimes, with mScarlet-H demonstrating the longest lifetime among the tested variants.
Furthermore, we investigated the potential of fluorescence lifetime imaging (FLIM) as a tool to distinguish between these RFPs in live cell imaging experiments. By analyzing the fluorescence decay curves and calculating the average fluorescence lifetimes for each RFP, we observed distinct lifetime signatures that enable discrimination between the RFP variants. Additionally, we evaluated the photostability and brightness of these RFPs under similar experimental conditions, providing comprehensive insights into their performance characteristics.
Our findings highlight the importance of considering fluorescence lifetime properties when selecting RFPs for specific imaging applications. The ability to distinguish between RFP variants based on their fluorescence lifetimes expands the toolkit for multicolor imaging and facilitates the development of advanced imaging techniques such as fluorescence lifetime imaging microscopy (FLIM) and Förster resonance energy transfer (FRET) assays. Moreover, the availability of RFPs with diverse fluorescence lifetime characteristics enhances the versatility and applicability of fluorescence-based imaging approaches in biological research.
In conclusion, this comparative analysis provides valuable insights into the fluorescence lifetime properties of commonly used RFPs, paving the way for informed selection of RFP probes tailored to the requirements of specific imaging experiments.
Subsequently, we extended our investigation to compare the performance of tagRFP against a novel StayGold fluorescent protein (FP), despite its established suitability for super resolution spinning disc laser scanning microscopy. Our comparative analysis revealed the superiority of StayGold over tagRFP in several key aspects.
Firstly, StayGold exhibited enhanced photostability compared to tagRFP, enabling prolonged imaging sessions with minimal photobleaching effects. This attribute is particularly advantageous for long-term live cell imaging studies where maintaining fluorescence signal intensity over extended periods is critical.

Secondly, StayGold demonstrated superior brightness and signal-to-noise ratio (SNR) when visualized under super resolution spinning disc laser scanning microscopy. The improved brightness of StayGold allowed for enhanced image clarity and resolution, enabling the detection of finer cellular structures and dynamics with greater precision.
Furthermore, StayGold exhibited favorable fluorescence lifetime properties, with a distinct fluorescence decay profile that distinguishes it from tagRFP. This unique characteristic not only facilitates multiplexing experiments but also provides additional flexibility in fluorescence imaging applications.
Moreover, we explored the functional capabilities of tagRFP and StayGold by tagging them to different actin markers. TagRFP was attached to Lifeact as an actin marker, while StayGold was either tagged to F-tractin or utrophin as an actin skeleton marker. Our results demonstrated the suitability of StayGold for visualizing actin structures with high specificity and resolution, surpassing the performance of tagRFP in this context.
In conclusion, while red fluorescent proteins (RFPs) are traditionally favored for imaging deeper tissue layers due to their longer wavelength, our study suggests that StayGold may emerge as the superior alternative, particularly for long-term live cell or organoid imaging using super resolution spinning disc laser scanning microscopy (LSM).
Despite the conventional advantage of RFPs in imaging deeper tissues, StayGold offers distinct advantages that make it a compelling choice for specific applications. Its enhanced photostability, superior brightness, and favorable fluorescence lifetime properties, as demonstrated in our comparative analysis, position StayGold as an ideal candidate for long-term imaging studies where sustained signal intensity and minimal photobleaching are critical factors.
Moreover, StayGold's ability to achieve high-resolution imaging of cellular structures, such as the actin cytoskeleton, coupled with its suitability for super resolution spinning disc LSM, further enhances its utility in dynamic imaging scenarios. The precise and specific labeling provided by StayGold, particularly when tagged to actin markers like F-tractin or utrophin, underscores its potential for visualizing intricate cellular processes with exceptional clarity and resolution.
While RFPs remain valuable tools for certain imaging applications, our findings suggest that StayGold may offer unique advantages in the context of long-term live cell or organoid imaging, especially when coupled with advanced microscopy techniques such as super resolution spinning disc LSM. Continued exploration and optimization of StayGold FP hold promise for further advancements in fluorescence microscopy and biomedical imaging, providing researchers with enhanced capabilities for studying complex biological systems with unprecedented detail and precision.

Preparation of biological samples for cryo-electron microscopy using the HPF "Waffle" method

Mrs. Jana Moravcová[1], Petra Reznickova[2], Martin Polak[1], Jiri Novacek[1]
[1]Masaryk University, Central European Institute of Technology, Brno, Czech Republic, [2]Thermo Fisher Scientific, Brno, Czech Republic

Poster Group 1

Background incl. aims
Cryo-electron microscopy (cryo-EM) has emerged as a pivotal technique in structural biology, offering unparalleled insights into the architecture of macromolecules at near-atomic resolution.
A crucial requirement for acquisition and collection of high quality data is properly vitrified and highly concentrated specimen. However, sample preparation still presents challenges in thicker specimens as bigger cells or cellular clusters, those are frozen by conventional plunge freezing method and may suffer with improper vitrification. Another problems could be low concentration or inadequate distribution of sample on electron microscopy grid or preferred orientation of the specific sample [1]. Here, we focus on the recently introduced "Waffle" method [1] and show it potential for preparation of various types of sample used in cryo-EM.
Methods
The waffle method is based on sample vitrification within the thickness of the TEM grid bars and it combines plunge freezing on the electron microscopy grid with a technique of high pressure freezing, that provides an advantage of proper vitrification of specimens thicker than 15um.
Thus, a 20-30um thick layer is prepared which needs to be further processed by cryo-focused ion beam micromaching (cryo-FIBM) to final thickness ~200nm before cryo-EM imaging.
Results and conclusions
We show benefits and limitations of the waffle method for vitrification of purified proteins, protein crystals, bacterial cell suspensions and eukaryotic cells.

Elemental segregation at substrate/metal interface to manipulate heterogeneous nucleation

Dr Shihao Wang[1,2,3], Dr Yun Wang[3], Dr Zhongyun Fan[3], Dr Quentin Ramasse[1,2]
[1]SuperSTEM Laboratory, STFC Daresbury Campus, Daresbury WA4 4AD, United Kingdom, [2]School of Chemical and Process Engineering, University of Leeds, Leeds LS2 9J, United Kingdom, [3]BCAST, Brunel University London, Uxbridge, Middlesex UB8 3PH, United Kingdom

PS-02 (3), Lecture Theater 4, august 30, 2024, 14:00 - 16:00

Background incl. aims
Heterogeneous nucleation on a substrate in a metallic melt is a fundamental step in tailoring the microstructure of engineering materials with desired properties, and therefore it is a research topic of critical scientific and technological importance to meet the goals of the 'circular economy' [1]. The structural and chemical compatibility at a substrate/metal-liquid interface dictates the heterogeneous nucleation process. This can be altered by elemental interfacial segregation, affecting the nucleation behaviour accordingly [2]. Atomic-scale interfacial segregation has been linked to the successful application of TiB2-based grain refiners for aluminium casting, also explaining some of their limitations depending on the nature of segregation structure [2,3]. Interfacial segregation has also been applied as a strategy to modify native oxides in aluminium and magnesium alloys, whereby naturally occurring oxides can then be harnessed for grain refinement [2,4]. Studies of the microstructure and composition across the substrate/metal interface, down to the atomic scale, are thus essential in determining nucleation potency.
Advances in aberration-corrected scanning transmission electron microscopy (STEM) and electron energy-loss spectroscopy (EELS) now routinely allow for both atomic-resolution imaging and compositional analysis of materials. In this work, we use advanced STEM-EELS to investigate different substrate/metal interfaces including TiB2/Al, MgO/Mg, and γ-Al2O3/Al in the corresponding casting alloy ingots of different grain refinement performances, aiming to provide an overview of our atomic-level understanding of the behaviour of interfacial segregation and its resultant effect on heterogeneous nucleation and grain refinement.
Methods
Casting experiments were used to evaluate the grain refinement. Pressurized melt filtration was applied to different alloy melts to collect the inoculant particles, by which the possibility of substrate/metal interface appearing in a TEM foil specimen is greatly increased for characterization. STEM imaging and EELS acquisition were performed on a Nion UltraSTEM100 scanning transmission electron microscope, equipped with a Gatan Enfina EELS spectrometer retrofitted with a MerlinEELS direct electron detector. The microscope was operated at an accelerating voltage of either 100 or 60kV, depending on the beam sensitivity of the observed structures, with the probe-forming optics configured for a 31mrad convergence semi-angle and a probe size of 1Å or smaller.
Results
High-precision high-angle annular dark field (HAADF) STEM imaging and EELS mapping offer an atomic-level view of how interfacial segregation affects the grain refining performance in model alloy systems, with an example of the TiB2/Al system shown in Figure 1. Rigid- or non-rigid registration were applied to series of (spectrum) images, taken with short dwell times and along different zone axes, to reveal the precise structure and chemistry of an atomically thin, so-called Al3Ti 2-dimensional compound (2DC) segregation layer at the interface between inoculant TiB2 particles and Al matrix: figure 1d. This structure was shown to account for the grain refinement achieved in an Al-

0.2Al5Ti1B alloy. Similarly, a Zr-segregation-induced Ti2Zr 2DC (figure 1e) is atomically resolved at the interface, which poisons the grain-refining effect of TiB2: a coarse and columnar grain structure forms in Al-0.1Zr-0.2Al5Ti1B. Interestingly, the grain refinement behaviour is rejuvenated after the addition of Mg (Al-0.1Zr-0.2Al5Ti1B-1Mg), which results in the dissolution of the poisoning Ti2Zr 2DC and the formation of hitherto never-observed Mg-rich layers adopting a local structure similar to bulk Al, and thus termed Al-like layers (figure 1f-h). Analysis of the electron energy loss near-edge fine structure (ELNES) provides additional information regarding the valence state and/or electronic structure of these interfacial structures, for instance confirming the nature of the 'Y-O' bonding within a Y-rich segregation layer at the MgO/Mg interface [4].

Conclusion

Atomic-resolution STEM-EELS has provided conclusive evidence to clarify the role of interfacial 2DCs in determining the nucleation potency of TiB2 and thus the grain refining performance. With the high spatial resolution and single-electron-sensitive EELS detector, advanced STEM-EELS is expected to be a powerful tool in understanding heterogeneous nucleation, designing grain refiners, and controlling solidification structures and mechanical properties across a wide range of metallic materials.

IM-03 (3), Plenary, august 29, 2024, 10:30 - 12:30

Background incl. aims
Control over and knowledge of the electron probe is important in all scanning transmission electron microscopy (STEM) techniques. This is emphasized even more in ptychography where the exact electron probe is required to deconvolve its effects from that of the specimen. Here the introduction of probe retrieval into iterative schemes has greatly increased their capability [1] and today iterative optimization of the electron probe is standard in most ptychographic schemes such as the extended ptychographic iterative engine (ePIE) [2]. However, in most cases the electron probe is reconstructed on a pixelated grid and thereby not limited to solutions physically realizable by the optical system. Here we present a method to characterize reconstructed probes by conventional lens aberrations. The fitted aberrations are then used to investigate the quality of the retrieved probes and their consistency is examined in a systematic study using 4D-STEM focal series recorded for a thin SnS2 2D-flake. Additionally, the influence of partial coherence and limited electron dose on the retrieved probes is analysed and the usefulness of the retrieved probes for different ptychographic methods, such as single sideband ptychography (SSB) and gradient descent-based schemes, is elucidated.

Methods
As a basis for the study 4D-STEM focal series were chosen as these datasets should only differ in defocus with the specimen and other aberrations being constant. 4D-STEM focal series were recorded of a thin SnS2 2D-flake using a Medipix3 detector and a probe corrected FEI Titan Themis STEM. ePIE reconstructions were performed using a GPU accelerated implementation in the pytorch framework. A probe fitting procedure was developed to fit axial lens aberrations up to third order by minimising the mean square error between the fitted probe and the ptychographic probe.

Results
The reconstructed phase gratings and the obtained probes are shown in Fig. 1. All phase gratings show the hexagonal atomic structure of the 2D-material with the heavy tin and lighter sulphur columns. Direct comparison is however hindered by specimen drift. The probes all show a strong contribution of coma. The excellent agreement between fitted and ptychographic probe is visible in both the real space amplitude and the reciprocal space phase plate (Fig. 1, bottom left). Here fitting against the complex wave function proved to be more successful than fitting the unwrapped reciprocal space phase plate. While fitting against only the real space intensity also worked it can result in the complex conjugate wave function i.e. a probe with opposite defocus.
Plotting the fitted defocus versus the defocus applied at the microscope shows the expected linear relationship (Fig. 1, middle). The other aberration coefficients are in very good agreement with each other (Fig. 1, right). The standard deviations for the mean aberration coefficients throughout the series are comparable to the ones obtained using a conventional Zemlin-tableau.

The obtained aberration coefficients are then applied to other ptychographic methods e.g. single-sideband ptychography, where only the correction of higher order aberration allowed the imaging of the atomic structure, or as a start for gradient-based maximum likelihood methods where multiple scattering and partial coherence are considered (Fig. 2).
Despite the good match between fitted and ptychographic probe some deviations appear, in comparison with the fitted probe the fine oscillations of the ptychographic probe vanish earlier into a noise background. Additionally, the reciprocal space amplitude deviates from theory, it is not flat inside and contains amplitude outside the apparent aperture. Simulations show that in our experiment these deviations are mainly produced by the limited electron dose while the effect of partial coherence is less important (Fig. 3). Experiments using CsPbBr3 nanocubes and gold nanoparticles additionally showed that the fitting procedure also performs well for thicker, strongly scattering specimen.

Conclusion
The successful fitting and good agreement of the aberration coefficients with each other indicate that the ptychographic deconvolution was effective and that the retrieved probes are physically meaningful. The good agreement of the aberration coefficients throughout the focal series suggests the use of the fitted aberrations to correct the alignment of the microscope during a session without requiring a dedicated alignment grid.

PS-04 (2), Plenary, august 26, 2024, 14:00 - 16:00

Background incl. aims
Phonons play a critical role in many physical properties of a materials including their thermal and electrical conductivities. Changes in normal phonon mode frequencies occur in the presence of defects. In thermoelectric materials (TE), such defect-induced localised modification of the vibrational response is widely used to tailor the thermal conductivity [1]. In previous work [2,3] it was shown that atomic-level defect engineering resulted in the enhancement of the TE performance of (Al,Nb)-doped TiO2. The introduction of crystallographic shear (CS) structures leads to the reduction of lattice thermal conductivity, which is believed to occur through enhanced phonon scattering. Therefore, it becomes important to measure the spatial distribution and dispersion of the localized vibrational response across the CS structure, in order to gain insight into the heat-conduction process. Recent advances in scanning transmission electron microscopy (STEM) and electron energy-loss spectroscopy (EELS) have provided powerful and flexible tools to study phonons at high spatial resolution, down to single atom sensitivity [4]. In this work, we use STEM-EELS to probe the localised phonon response in CS structures at atomic resolution in the polar (Al,Nb)-doped TiO2.

Methods
EELS measurements were performed on a Nion UltraSTEM100MC 'Hermes' scanning transmission electron microscope, equipped with a Nion IRIS high energy resolution EELS spectrometer with a Dectris ELA direct electron detector. The acceleration voltage was 60 kV and the probe convergence semi angle was 31.5 mrad, resulting in a 1 Å probe size. The experimental optical geometry follows the conditions in Ref [4], in which the off-axis , or dark-field EELS (DF-EELS) geometry significantly reduces the contribution to the EELS signal of electrons having undergone delocalized dipole scattering, while promoting that of localized impact phonon scattering. This approach enables in principle single-atom sensitivity of phonon scattering.

Results
Fig. 1(a-b) shows a HAADF STEM image of the {120}-type CS structure in (Al,Nb)-doped TiO2 acquired along the [001] (rutile-equivalent) zone axis. The CS structure, which results in complex atomic lattice re-arrangements, is accompanied by the segregation of Al along the shear planes, with Al-rich columns preferentially occupying the Ti sites indicated by white arrows on Fig. 1b. Atomically resolved VEELS measurements performed across (Fig. 1(c-d)) reveal atomic scale variations localised at the CS structure boundaries. Changes in both the intensity and the frequency of the main modes

are observed at the boundaries, with localised effects on the Al-rich columns. Results are discussed in context of the local structure and chemistry, determined at the same position through careful chemical mapping, while phonon map simulations using the frequency-resolved frozen phonon multislice method [5] are used to rationalize the experimental findings.

Background incl. aims:
MEMS-based phase plates play an important role in shaping electron beams within transmission electron microscopes, opening avenues for diverse applications such as generating vortex beams [1], orbital angular momentum (OAM) sorter [2], aberration corrector phase plates, and more [3]. Despite their significance, designing and modeling phase plates pose challenges due to the difficulties encountered in obtaining analytical solutions. In the design process of phase plates, simulation using numerical methods such as Finite-Difference Time-Domain (FDTD) or Finite Element Method (FEM) stands as a crucial step. This capability allows us to compare numerical results with the expected phase shift produced by a phase plate. While simulation proves fundamental in designing phase plates, finding an optimal topology and parameters can often be challenging due to the complexity of the design space. Consequently, a significant portion of the potential of a MEMS phase plate remains unexplored. In recent years, the emergence of Machine Learning and computational tools has revolutionized design optimization processes. In this study, we leveraged the potential of utilizing numerical simulation alongside optimization tools to enhance the functionality of different types of phase plates. A crucial aspect of our investigation involved simulating, analyzing, and enhancing the proposed MEMS-based phase plate devices, scrutinizing the interaction of the generated field by the phase plate with the electron beam prior to fabrication and experimental testing.
Methods :
In our study, we utilized COMSOL Multiphysics software, a powerful FEM tool renowned for its versatile capabilities in simulating MEMS devices, complemented by other numerical methods such as Deep Neural Networks (DNN). COMSOL provides various Finite Element simulation techniques alongside optimization approaches such as Parameters, Topology, and Shape optimization. Moreover, we investigated alternative methods, including Inverse design using DNN, to explore new avenues for advancing phase plate design. In certain studies, to navigate the complexity barrier and enhance the design process, we employed a hybrid optimization method that combines inverse design of phase plates with additional forward optimization. In these specific instances, we utilized a Hybrid Machine Learning (HML) approach, leveraging the TensorFlow library in Python, coupled with forward optimization tools available in COMSOL.
Results :
In this paper, we present an analysis of three distinct phase plates, detailing their simulation and optimization methodologies.
In the first design, we investigated the performance of an Electrostatic Spiral Phase Plate. The primary objective of this phase plate is to generate a linear distribution of phase to produce a vortex beam. Upon optimizing the parameters, it was observed that the applied potential should take on the form of a rounded curve, with minimal bias variation in the direction facing the 'chopstick electrodes' and a steep gradient in their proximity. Forward optimization of parameters was employed, utilizing the absolute difference between simulation results and the aimed phase shift as the objective function (Fig a).

In the second example, we investigated the electrical and thermal properties of OAM sorter phase plates. Unlike the Spiral PP, which requires a linear phase distribution on the boundary, the boundary conditions in this case are more complex. We initialized our optimization study with a circular symmetric design involving a needle and 42 boundary electrodes. However, due to the limitation of the number of bias connections in a real TEM holder, having 42 biases would not be feasible. Nevertheless, this optimization gives us a broad understanding of the possible design and can later serve as an initial guess for Topology Optimization. To reduce the number of electrodes, the design underwent topology optimization, which suggested a change in the geometry to a non-symmetric design. Additionally, we simulated the Joule Heating effect of the OAM sorter phase plate, as heating effect can help avoid contamination. Figure b illustrates the simulation results of the electrical and thermal response of the OAM sorter phase plate, along with the optimized boundary potential. Figure c showcases the simulation and optimization of an aberration corrector phase plate. This thin-film phase plate aimed to compensate for the aberration of the electron beam by imposing a continuous quartic function as a phase shift. In addition to precise simulation, we enhanced the optimization process with DNN machine learning. A HML approach using the TensorFlow library in Python was employed to determine the optimal set of electrode potentials that result in the desired quartic phase shift. A Convolutional Neural Network (CNN) was trained using over 100000 2D simulations with random bias voltages applied to six electrodes as inputs, and the resulting total phase shift as the output. The output of the HML model was subsequently used in a parameter optimization process within COMSOL Multiphysics® to address any inaccuracies in the machine's predictions.

Conclusion:

In this study, we demonstrated how numerical and computational methods can enhance the functionality of MEMS phase plates. Utilizing powerful simulation tools allowed us to predict results before fabrication and hands-on testing. By leveraging optimization tools, we were able to explore new design possibilities and optimize phase plate geometries to achieve enhanced performance and functionality. Our findings underscore the importance of employing advanced computational techniques in MEMS design and pave the way for further research in this field.

Enhanced nanoscale phase characterisation in modern steels using precession electron diffraction and energy filtering

Aleksander Brozyniak[1], Matthias Wallner[2], Philipp Kürnsteiner[1], Peter Oberhumer[1], Katharina Steineder[2], Heiko Groiss[1]
[1]Christian Doppler Laboratory for Nanoscale Phase Transformations, Center for Surface and Nanoanalytics, Johannes Kepler University Linz, Altenberger Str. 69, 4040 Linz, Austria, [2]voestalpine Stahl GmbH, voestalpine-Straße 3, 4020 Linz, Austria

PS-02 (3), Lecture Theater 4, august 30, 2024, 14:00 - 16:00

Background incl. aims
The development of lightweight and ductile Advanced High-Strength Steel hinges upon a comprehensive understanding of phase change kinetics during production. In addition to various techniques for chemical characterisation, transmission electron microscopy (TEM) is an essential tool for the structural analysis of examined phases. In this work, we showcase a significant enhancement in the acquisition of diffraction patterns (DPs) for nanostructured phases in modern steel systems, such as quenched and partitioned (Q&P) steels. We combined zero-loss energy filtering (EF) with precession electron diffraction (PED) to access crystallographic information of nano-inclusions inaccessible by standard diffraction techniques.

Methods
Selected area electron diffraction (SAED) is usually not suitable for the challenging task of nano-inclusions crystallography, which requires information about different zone axes for unambiguous phase identification. Due to the large aperture size, dynamic diffraction effects and, in particular, the intricate steel matrix containing arbitrarily oriented, strained and ferromagnetic grains, an in-depth analysis of SAED patterns is limited. To address these limitations and achieve a high lateral resolution, we employed site-specific nanobeam diffraction in PED mode with a beam diameter of approximately 1 nm and a precession angle of 1 - 3° around the central axis. Unlike standard DPs, where dynamical effects are unavoidable, PED provides quasi-kinematical results and a larger number of reflections through pattern integration, thus compensating for small variations in sample thickness or misorientation. The influence of inelastic and multiple scattering was mitigated through additional zero-loss filtering, noticeably enhancing the signal-to-noise ratio of our PED patterns. The experiments were performed with a JEOL JEM-2200FS equipped with an in-column Ω-filter and a TVIPS universal scan generator using a TemCam-XF416 CMOS camera.

Results
One application example is the investigation of iron carbides embedded in Q&P steels with varying Si or Al content, annealed at 320°C and 420°C. Our site-specific PED patterns provided enhanced clarity, revealing a multitude of carbide diffraction spots and enabling a more reliable analysis compared to results obtained via SAED. By conducting sample tilt series towards different crystallographic zone axes (Fig. 1), we achieved unambiguous identification of the carbide phase, its orientation relationship to the martensitic matrix, and the lattice parameters. The presence of orthorhombic θ-Fe_3C [2] was confirmed, in line with prior X-ray diffraction (XRD) measurements in the steel alloys annealed at 420°C. In alloys annealed at 320°C, where XRD results were inconclusive, the tilt series approach revealed the presence of transition carbides ε-Fe_3C (hexagonal) and η-Fe_2C (orthorhombic/quasi-hexagonal) [3][4]. Utilising the tilt series approach alongside the improved

accuracy of the PED patterns allowed for a definitive distinction between ε- and η-transition carbides, overcoming previous challenges [1]. Further examples of PED applications are shown.

Conclusions
Our findings underscore the benefits of employing PED together with EF for characterising the crystallography of nanostructured phases in modern steel systems. Through comparison of DP quality, we demonstrate the insights attainable for complex samples by PED. The rising availability of commercial PED solutions and the convenient applicability of the PED method enhanced through EF, demonstrated on our examples, may incentivize the broader scientific community to embrace this method for investigating metals and alloys.

Poster Group 2

Background incl. aims
We have previously presented polarisation-resolved differential phase contrast microscopy (pDPC) - a robust, low-cost single-shot open-source technique utilising "PolCam" (a polarisation-sensitive camera with a Sony Polarsens™ sensor) to simultaneously acquire 4 images from which semi-quantitative phase images can be calculated [1]. While pDPC microscopy can be easily implemented on a commercial microscope, as we have demonstrated with an automated multiwell plate fluorescence microscope (based on an Olympus IX-83 frame), the implementation of pDPC on an openFrame-based microscope [2] controlled by µManager [3] greatly widens access to phase imaging – with facile integration with fluorescence imaging modalities – at a whole system component cost below €20,000 (<€3000 for only the pDPC components). openFrame describes our specific open-source modular hardware for light microscopy that enables users to assemble a wide range of instruments with no constraints on software or other hardware components that can be self-built or commercial products. Examples of openFrame-based instruments and other open-source instrumentation can be reached through www.openScopes.com.
Here we present an improved pDPC software plug-in for µManager that performs analysis of pDPC data and provides real-time phase imaging. We also report the extension to higher magnification in a new condenser-less geometry that we have applied to imaging biological samples including mycobacteria.
Methods
An openFrame microscope stand is configured for brightfield transillumination imaging including a Köhler transillumination arm utilising a low-cost white LED and a condenser lens that provides a maximum illumination numerical aperture (NA) of 0.55. pDPC is initially implemented by mounting a diffuser and quadrant polariser (QP) mask at the condenser back focal plane. This QP utilises low-cost polarising polymer film and is implemented in a custom 3D-printed mount. Because differential phase microscopy requires a higher illumination NA relative to the imaging NA [4], this condenser-based pDPC system is limited to a spatial resolution of ~λ/1.1. To overcome this limit, we have developed a condenser-less geometry using a simple extended LED array that provides approximately uniform illumination. This approach is simpler and at lower cost compared to approaches based on electronically switched microLED arrays, e.g. [4] and enables the use of higher NA objective lenses.
The pDPC image data processing is managed by a new µManager plug-in (MM2_pDPC) that reads the four polarization resolved images from the PolCam raw images and uses a pre-determined calibration matrix to correct unbalanced illumination and crosstalk between the different polarising quadrants. The phase component of the optical transmission function of the sample is calculated, and a preview of the resulting phase image can be displayed in real time within the µManager graphical user interface (GUI).

The single-shot capability of pDPC makes it suitable for dynamic subjects including timelapse imaging of microbiology and we have extended the capabilities of openFrame-based microscopes by developing a low-cost 3D-printed stage top incubator with temperature stabilization, which we have applied to support the long-term imaging of live mycobacteria.

Results

Our condenser-based pDPC implementation on openFrame provides robust and rapid (>60 frames/s) phase imaging up to ~0.5 NA. The condenser lens efficiently couples the LED radiation to the sample and the new pDPC µManager plug-in provides real-time phase images. We have applied this to extended time-lapse imaging of mycobacteria in a low-cost (<€500 components) stage-top incubator that provided stable operation at ~34°C over >4 hours with <3°C fluctuation and rapid (~30 minutes) warm-up time.

The condenser-less pDPC system can be realised at even lower cost – we initially used a domestic LED light panel (<€20) to provide 60x, 0.8 NA imaging of mammalian cells HEK-293 and (M. smegmatis) mycobacteria. The figure shows a phase image of a HEK-293 cell acquired with condenser-less pDPC at 60x magnification. However, the highly diffuse illumination of this set-up resulted in lower illumination intensity at the sample and therefore requires longer (~500 ms) image data acquisition times. We are currently upgrading this to a higher transillumination power and higher NA pDPC system that will be optimised for imaging mycobacteria and particularly for the study of M. tuberculosis.

Conclusion

We have demonstrated that research-grade semi-quantitative phase microscopy capabilities can be realised using open-source modular hardware and software to widen access to this important imaging modality. pDPC is particularly convenient to integrate with other modalities as it is wavelength agnostic (within the detection sensitivity range of the Polarsens™ camera). The modular openFrame microscope platform supports the straightforward integration of pDPC with other imaging modalities, including fluorescence microscopy and single molecule localisation microscopy (e.g., easySTORM [2]), which can also be open-source and cost-effective. The compact size, robust design and relatively low-cost of openFrame-based microscopes make them suitable for biosafety containment facilities, e.g., for the study of infectious diseases.

Understanding high resolution protein structure in the context of the whole cell is the vision of visual proteomics. With the advent of high-throughput cryo-electron tomography and cryo-FIB milling, paired with cutting edge computational techniques, achieving such an ambitious goal is no longer a far-reaching dream. The new generation of cryo-FIB from Thermo Fisher Scientific uses plasma to generate focus ion beam, which reduces redeposition and ion beam damage, substantially improving throughput. In preparation for a large-scale effort towards visual proteomics of the model organism Chlamydomonas reinhardtii, we have prepared enough lamellae to allow for acquisition of more than 1800 tomograms of different cellular compartments (Fig 1).

Initial results indicate that the data is of sufficient quality to achieve sub-nanometer resolution for selected complexes using a fraction of the dataset. Six tomograms from the same lamella were used to determine the structure of 80S ribosome at 6Å using template matching1 and subtomogram averaging. Encouraged by this, a number of other targets were selected among the collaborators for further study such as ribulose 1,5-bisphosphate carboxylase/oxygenase (RuBisCO), ATP synthase, nucleosomes, photosystem II, and microtubules.

While some proteins were in such high abundance that template matching alone was sufficient to obtain a sub-nanometer structure, as in the case of Rubisco where we were able to determine a 7Å structure from within the pyrenoid compartment, other targets proved more of a challenge and necessitated a combination of computational techniques to achieve results. The denoising neural network cryoCARE was implemented on all datasets to increase template matching accuracy. In the case of microtubules, which are rare in C. reinhardtii, filament tracing in Amira (Thermo Fisher Scientific) was necessary to determine initial centerlines for reconstruction along individual protofilaments.

Photosystem II (PSII), which is present in very high abundance in the chloroplast, proved to be a challenging target as it is a membrane embedded protein with only a small region protruding into the lumen of the thylakoid membrane. Multiple template matching methods failed to identify most of the visible particles and unfortunately noise2noise denoising tended to blur or erase the small densities along the membrane. We therefore employed a novel approach that paired two deep learning networks to generate PSII candidate coordinates which could be further refined for classification and subtomogram averaging. The first network is a regression UNet trained on purely synthetic data2 to denoise cryo-tomographic data. The denoised data was then used to train a 2.5D UNet to segment membrane, ribosomes, and all densities that protrude into the thylakoid lumen as PSII (Dragonfly 2022.2, Object Research Systems). Coordinates (without any angular information) were extracted from the PSII class and used as particle picks, which were then aligned using the surrounding membrane. Work is ongoing, but initial results from 24 datasets are very promising.

The scale of this dataset is exciting, but the huge number of molecular complexes within living cells makes it difficult to identify, confirm the identity of, and determine each structure by just one group. Achieving a full visual proteome of C. reinhardtii will necessitate a large collaborative effort. To that end, we would like to create an open access database for C. reinhardtii to accelerate annotation and curation, enable further cell biology research, and develop new computational tools for in situ cryo-ET. Along with sharing the raw data, reconstructed tomograms, denoised datasets, and structural determinations, we will provide high quality segmentations of selected datasets created using 2.5D (Dragonfly) and 3D (MemBrain Seg3) UNets. This project has the potential to provide invaluable insights into cellular processes and will hopefully lay the foundation for other large-scale studies of other species.

PS-05 (3), Lecture Theater 3, august 30, 2024, 10:30 - 12:30

Background
The utilization of single atom catalysts (SACs) has captured significant interest due to their superior reactivity compared to nanoparticle counterparts, especially in Environmental Catalysis and Clean Energy applications [1].
SACs can be supported on non-porous structures like oxides or carbon-based materials, or within crystalline porous materials such as zeolites or metal-organic frameworks (MOFs). Their performance is heavily influenced by the local atomic environment and structural characteristics, particularly notable in non-porous materials where surface heterogeneity and defects offer diverse anchoring sites with distinct catalytic performances. Tailoring these characteristics is essential for modulating catalyst reactivity, prompting significant efforts in synthetic methods development and characterization techniques advancement [2]. Notably, High Resolution High Angle Annular Dark Field Scanning Transmission Electron Microscopy (HR HAADF-STEM) emerges as a crucial tool for directly visualizing single metal atoms. However, while its qualitative usage is widespread, quantitative extraction of structural features remains limited [3].
This gap motivates the integration of deep learning algorithms, particularly convolutional neural networks (CNNs), with DFT calculations for a comprehensive and quantitative assessment of metal-support interactions in SACs. In this study, we focus on Pd SACs anchored onto MgO (100) nanoplates, aiming to provide a detailed understanding of their structural features and interactions with the support, crucial for advancing heterogeneous catalysis knowledge and applications in Environmental Catalysis.

Methods
The synthesis of morphology-controlled MgO nanoplates involved a hydrothermal method followed by thermal treatment, resulting in $Mg(OH)_2$ nanoplates that were subsequently heated in a H_2(5%)/Ar flow. Pd-based catalysts were synthesized using two precursors: $Pd(NO_3)_2$ in acetone and an aqueous solution of the coordination complex $[H_3PdL]^{5}$+, with both catalysts prepared via semi-wetness impregnation methods and treated to remove nitrates. Macroscopic characterization included X-ray diffraction using a Bruker D8 Advanced A25 diffractometer, X-ray photoelectron spectroscopy analysis using a Kratos Axis Ultra DLD spectrometer, and electron tomography experiments conducted on a Talos FX200 G2 microscope operated at 200 kV. Transmission and Scanning Transmission Electron Microscopy measurements were carried out on a FEI Titan3 Themis 60-300 double aberration-corrected microscope operated at 200 kV. In particular, HR-HAADF images were acquired with a beam current of 30 pA and a dwell time of 1.25 µs. The Deep Learning algorithm, implemented using Tensor Flow and Keras, involved segmentation using a residual U-net structure for HR-HAADF STEM image analysis. Additionally, DFT calculations using Quantum Espresso with Perdew-Burke-Ernzerhof functional and Hubbard U parameter were performed to assess structural properties

Results

Figure 1a illustrates a representative HR-HAADF STEM images acquired on the Pd catalyst supported on MgO {001} nanoplates, recorded along <211> zone axis. In this orientation, the atomic columns comprise only either Mg or O atoms, allowing to distinguish the nature of the interaction at play.
To precisely quantify these interactions, a smart segmentation procedure leveraging Deep Learning techniques was developed, enabling the accurate discrimination of atomic columns containing Pd single atoms from those containing only Mg. The segmentation process, guided by convolutional neural networks employing the U-net architecture, effectively separates contrasts in HR-HAADF images, Figure 1b. In particular, 900 Pd-support interactions, revealing Pd species adjacency to cationic columns, suggesting substantial interaction with Mg. XPS signals indicate Pd^{2}+ oxidation state, implying Pd species may substitute Mg^{2}+ ions on {001} surfaces, contrasting previous reports of Pd atoms stabilizing on oxygen vacancies.
To unravel the mechanisms underlying Pd-support interactions, we conducted density functional theory (DFT) calculations. These calculations provide an energy differences which suggest a sequence wherein Pd first interacts with V-centers (Mg-vacancies), then likely occupies F-centers (O-vacancies), and finally resides atop the surface, aligning with experimental observations, indicating Pd species localized within Mg atomic columns.
Detailed structural analysis of relaxed models reveals that Pd atoms tend to move slightly into the surface or outside the center in the case of F-centers, while in V-centers, the displacement is subtler, highlighting distinct behaviors in Pd localization within defects. A method, using AtomSegNet, achieves sub-pixel precision, measuring displacements accurately. This approach maps displacement vectors and modulus, enabling precise measurement of shifts from 0.1 to 0.6 Å, Figure 1c. The histogram fitting reveals peaks at 0.17±0.07 Å and 0.45±0.12 Å, matching DFT-calculated values for V and F centers. A 3:1 ratio in Gaussian curve areas indicates more atoms with smaller displacement, consistent with theoretical predictions. Considering MgO support properties, metal loading, and V-to-F ratio, an estimated 1% cationic vacancies align with literature findings for powder MgO.

Conclusion

The methodology's strong validation is evidenced by the close agreement between experimental image analysis and computational predictions, providing unprecedented insights into metal-support interactions in high-surface area powder catalysts. Direct imaging reveals that Pd species preferentially stabilize within surface-located V-centers on MgO supports, a significant advancement in SAC structural analysis. The method's robustness is further underscored by alignment with macroscopic techniques like XPS, enhancing confidence in conclusions drawn from the synergistic integration of advanced AC-STEM, AI analysis, and computational approaches. Its application to diverse catalytic materials promises to uncover general principles governing metal-support interactions, advancing both fundamental and applied catalysis research.

PS-03 (3), Lecture Theater 2, august 30, 2024, 14:00 - 16:00

Background incl. aims
Dielectric and semiconductor nanostructures are garnering increased interest due to their low radiative loss properties. This makes them a promising alternative to metal plasmonic structures for manipulating light fields at the nanoscale. The flexibility to manipulate optical resonance can be further enhanced by electrically doping and gating the mobile carrier density in semiconductors. In this study, we present the experimental observation of distinct optical resonances in one-dimensional InAs nanostructures, achieved through high-energy electron excitation.
Methods
The nanowires were grown with molecular beam epitaxy (MBE) system. Their length and width were fined tuned by modifying the growth conditions. The STEM-EELS investigation was conducted using a double-aberration corrected microscope (Thermo Fisher Scientific Themis Z) fitted with a high-resolution monochromator and a Gatan 1066 continuum spectrometer. The energy resolution is approximately 200 meV.
Results
Figure 1 presents the two-dimensional EELS mapping of an individual InAs nanowire across various energy windows. It's evident that as the energy loss increases from 0.94 eV to 1.17 eV and further to 1.43 eV, the EELS intensity distributions display different nodal patterns. These patterns correspond to resonant modes from m = 2 to 4 and can be recognized as standing wave Fabry–Perot type resonances. Figure 1(b) shows the intensity line profiles along the direction of the nanowire's growth, taken from the central area. To fully understand the experimetnal observation, we applied the quasi-normal mode theory and boundary element methods to simulate the resonate excitations in siminar geometric structures. The simulated results succssfully interprate the subtle changes in the EELS reponse across different energy windows within a given geometric confinment.
Conclusion
Our STEM EELS investigation and simulation show that InAs nanostructures are a promising candidate for local light field manipulation covering the near infrared-visible-ultraviolet (NIR-vis-UV) spectral range.

Cryo scanning transmission electron microscopy (STEM) is becoming an indispensable tool for studying phase transitions in a vast range of applications in the field of quantum materials [1], magnetic materials and nanostructures, ferroelectrics [2], topological insulators, etc. at the atomic scale. A detailed characterization of a sample's structural and electronic properties across phase transitions necessitates a sample holder with double tilt capability and a continuous temperature control of the specimen while maintaining a sample stability that enables atomic resolution imaging.

In this contribution, we will share our latest developments of a combined in situ cooling, biasing, and heating holder able to achieve atomic resolution imaging in a wide temperature range [3]. The holder, cooled by liquid nitrogen, allows to set any user-defined temperature (Figure 1). The temperature control is achieved using microelectromechanical systems (MEMS)-based heating and biasing chips [4, 5] in combination with a dedicated cryo TEM sample holder. Due to the low power consumption of the microheater, it is possible to sweep the temperature of the sample from -175oC to +800oC, while maintaining the holder at liquid nitrogen temperatures. It was found that atomic resolution imaging can be attained while continuously varying the temperature over a thousand degrees with marginal focus and image shift.

We will present several application examples applied to ferroelectrics that that include thermal and electrical cycling including cooling conditions.

IM-07, Lecture Theater 2, august 26, 2024, 10:30 - 12:30

Background incl. aims
Predicting cloud formation and the arrival of precipitation has always been a hot topic in meteorology. With global warming and the many ongoing drought events, this has become a major issue. Environmental scanning and transmission electron microscopy (respectively ESEM and ETEM) can provide valuable information to understand how clouds are formed by condensation of water on submicronic aerosol particles. Indeed, Environmental Electron Microscopy allows following the structural changes during the condensation of water droplets, while controlling the relative humidity, from the dry state up to fully hydrated conditions.
Methods
Sodium chloride particles are used as model marine aerosols. The deliquescence of crystals in the size range 100 nm – 1 µm is studied in ESEM (QuattroS from TFS) equipped with either a commercial Peltier stage (SE imaging) or a home-made tomographic stage (STEM imaging in both BF and DF modes) [1]. The deliquescence of smaller crystals is studied in ETEM (Titan ETEM from FEI/TFS) using either a commercial cryo-holder from Gatan/Ametek or a home-made system based on a Peltier micro-cooler [2]. More realistic aerosols, such as (non-hygroscopic) Arizona dust decorated with (hygroscopic) sodium chloride, are then studied.
Results
The evolution of the crystal facets and corners as a function of relative humidity is studied in ESEM in the SE mode, and is compared with the literature [3]. The measurement of the relative humidity allows a calibration of the other microscopy set-ups. Interestingly, oscillating behaviors at the beginning of deliquescence could be reproduced and followed in real time in STEM and TEM on smaller crystals (see Figure 1). They were found to match 2D simulations based on local fluctuations of the solute content. The distribution of sodium chloride during hydration/dehydration cycles is also analyzed.
Electron tomography is also carried out at multi-scale, in ESEM and ETEM on hydrated samples and quantitative data can be extracted: crystal shape and size as well as water droplet shape, and the aggregate shape and compound distribution in the case of salted Arizona dust.
Conclusion
The multi-scale approach combining ESEM and ETEM enable the analysis of salt particles not only in 2D, but also in 3D, for different values of relative humidity. As irradiation damage can have large influence on the observed behavior and kinetics, the electron dose received by the sample is quantified and its effects discussed.

Poster Group 2

Background incl. aims
Transition metal beryllides, MBe_{12}, are an important material class in tokamak fusion reactors for use in tritium breeder modules as a neutron multiplier to maintain the refuelling cycle. During the neutron multiplying reaction chain, helium and tritium are also produced as well as knock-on radiation damage. Beryllium metal is a commonly used candidate neutron multiplier but develops large helium bubbles at breeder module operating temperatures which retain tritium on their inner surfaces (Zimber, et al., 2023), which complicates end-of-life recycling and would be a radiation and explosion hazard in an accident scenario. Titanium beryllide retains less tritium and is tougher (Kim, et al., 2021), so has been chosen as a candidate neutron breeder for EU-DEMO and JA-DEMO. There are still many material unknowns, however; what crystal defects develop, what do they do at high temperature, and how do helium and tritium/hydrogen behave in the microstructure?

Methods
In this study we used the University of Huddersfield's MIAMI-2 ion beam/TEM to implant 300kV He+ ions into 2µm thick sections ("bulk ex situ" sections for the purposes of containing the He peak) of TiBe12 at temperatures 387°C, 480°C, 600°C and 900°C to fluence of 10^{17} ions/cm². From this energy we expect a He peak approximately 900nm under the surface. We then re-sectioned the samples to produce cross sections parallel to the irradiation direction, with the He peak present as a horizontal band of helium approximately 900nm down the re-section. To begin investigating the effect of free surface proximity, a 100nm sample was also irradiated in-situ with 20keV He+ at 550°C. This produces a uniform low level of He (50x less than ex situ case) implantation, and a gently increasing comparable level of knock-on damage going down through the sample thickness.

Results
The thick "quasi ex situ" samples developed faults on {110} planes at temperatures up to 600°C; at 900°C the fault plane had changed to {111}. Displacement vectors were obtained using g.R analysis; some were found to be from the ½<110> or ½<011> families, some from neither previously observed displacement vector type (Banerjee, Jacobson, Zindell, & Mitchell, 1991). Bubbles of size 1-10nm were found at the He peak in samples irradiated at 480°C and 600°C. At 900°C, large bubbles (>200nm) evolved on grain boundaries and smaller (50-100nm) bubbles in grain interiors at the He peak (Sharp, et al., 2024). The {111} faults were preferentially associated with the grain interior bubbles, implying some kind of free surface or He sink effect at work.
The thin in situ sample contained some faults at room temperature before irradiation, which experienced very little change as the temperature was increased to 550°C. A high density of new faults began to appear almost as soon as He+ irradiation was started. Analysis of prior and irradiation induced faults in the in situ specimen is presented and compared with ex situ work to give an initial step to explaining the relationship between bubbles and faults.

Conclusion
Planar crystal faults are present in unirradiated $TiBe_{12}$; new faults are created on irradiation with high energy (20-300keV) helium ions. At lower temperatures, faults lie on {110} planes, transitioning to {111} planes at some temperature between 600°C and 900°C in constrained material. In the same temperature interval, helium bubbles change from single nm size, to 50-100nm in grain interiors and larger on grain boundaries. Bubbles and {111} faults created at high temperature are preferentially associated.
Next steps in the subject will be to pinpoint the fault transition temperature, and to carry out and simulations and compare with experimental results to find the atomic configurations at {110} and {111} fault types, if there is a volume change between the two types that affects their relationship with bubbles, and whether/how they are sinks for interstitial helium atoms. The same process of understanding must then follow for hydrogen in the structure.

Image caption: ADF-STEM image from sample irradiated ex situ at 900C. White lines are {111} planar faults; small black objects are grain interior bubbles. At bottom is a larger bubble on a grain boundary. Image is part of a montage presented in Sharp et. al. 2024.

Scale-Bridging Analysis of Hierarchical Mesoporous Transition Metal Foams

Jonas Frohne[1], Dr.-Ing. Julian Müller[1], Dr. Jean Marie Vianney Nsanzimana[1], Charles Otieno Ogolla[1], Prof. Benjamin Butz[1]
[1]Micro- and Nanoanalytics Group/University of Siegen, Siegen, Germany

Poster Group 1

Mesoporous materials have attracted tremendous attention in recent decades due to their unique property portfolio and potential applications in various fields such as energy storage, catalysis and sensoring. Mesoporous copper for example has proven suitable as a material for large-scale production due to its properties, cost efficiency and excellent accessibility. Mesoporous transition metals comprise an enormous surface area, high electrical conductivity, improved catalytic activity, and long-term mechanical stability. Those properties are strongly influenced by the material's morphology specifically the pore size, pore distribution as well as connectivity. The chemical composition of the surface particularly governs the material's catalytic properties.
Dealloying as a technique utilises the differences in the galvanic series. A porous structure is created by selectively etching out an element of an alloy. Dealloying has been established as a facile method to tailor hierarchical porous structures with extensive pore networks of varying sizes dependent on the depth and location in the material. It is, therefore, a robust, scalable and cost-effective approach for the synthesis of mesoporous transition metals and their alloys [1].

In this study, dealloying is applied under various process parameters to investigate their influence on the porous structures formed using a copper-manganese alloy sample. The dealloying process is conducted under acidic conditions (hydrochloric acid). To unravel structure formation dependent on the various process parameters, e.g., pore size and distribution, morphology of pores, composition etc., advanced 3D imaging techniques including micro-computed tomography (µCT), focused ion beam (FIB), and transmission electron microscopy (TEM) tomography are employed along different length scales. To gain a deeper understanding of how morphology and composition influence catalytic activity and stability, we evaluated the performance of mesoporous copper foams as electrodes for the hydrogen evolution reaction (HER).

The resulting structures exhibit systematic channel networks and variations in pore size depending on depth and location in the material. We found that even small changes in the synthesis process can have a significant impact. For example, very small concentrations (≤1 at%) of other elements may lead to strongly altered morphologies with, e.g. an order of magnitude smaller pores and higher overall mechanical stability; moreover, the catalytic properties and overall morphology were affected.

We successfully have fabricated mesoporous copper for HER reaction. Multiscale analysis of the structures of the dealloyed material from the millimetre to the nanometre range facilitate the understanding of structure formation and unravels the complex structure-property relationship. The project, therefore, contributes to the detailed understanding of the impact of the various reaction parameters of the dealloying process to the structures formed, and subsequently their impact on the performance of the material.

Intralayer modification on Ti3C2Tz MXene Multilayer by Tailoring Surface Terminations

Mr Hari Hara Sudhan Thangavelu[1], Assoc. Prof. Fredrik Eriksson[1], Asst. Prof. Leiqiang Qin[2], Assoc. Prof. Jonas Björk[2], Prof. Johanna Rosén[2], Prof. Per Persson[1]
[1]Thin Film Physics Division, Department of Physics, Chemistry and Biology (IFM), Linköping University, SE - 58183, Sweden, [2]Materials Design Division, Department of Physics, Chemistry, and Biology (IFM), Linköping University, SE - 58183, Sweden

PS-01 (1), Lecture Theater 3, august 28, 2024, 10:30 - 12:30

Background incl. aims
MXenes are a class of two-dimensional materials whose properties can be tuned by tailoring surface terminations during the etching of the parent MAX phase precursors (1). It can be affirmed that the repetition of a MXene multilayer structure is the sum of interlayer width and intralayer thicknesses. Notably, conventional measurement techniques like X-ray diffraction (XRD) do not distinguish between these dimensions. However, it is crucial to recognize that the interlayer spacing holds particular significance in numerous applications, especially those reliant on swift diffusion of species in between MXene sheets, for example energy storage, material separation and interception. Consequently, understanding the determining variables for the interlayer spacing requires a thorough interpretation of intralayer spacing. Through theoretical simulations it has been identified that the surface terminations of Ti_3C_2Tz MXene affect the sheet thickness. As is evident from a theoretical study which is shown in the graphic below, the sheet thickness varies for different surface terminations. Therefore, the aim of this study is to experimentally verify the structural changes that occur as a function of surface termination chemistry.

Methods
Ti_3C_2Tz MXene multilayer structures with a mix of Oxygen (-O), hydroxide (-OH), and fluorine (-F) surface terminations have been used in this study. It is well known from the previous studies that F desorbs from the surface at around 500 °C and is removed completely while heating upon 700 °C (2). Double aberration corrected Scanning Transmission Electron Micrsscope (STEM) was used to observe the changes occurring within the MXene sheets at the atomic scale during in situ heating, to these temperatures. Images were obtained at ambient conditions after maintaining 15 minutes at every 100 °C up to a maximum temperature of 800 °C. Electron Energy Loss Spectroscopy (EELS) was used to explore the chemistry of the MXene.

Results
Experiments were conducted under vacuum between the temperature range of 100 °C to 800 °C. For every 100 °C increment, the structural and compositional changes in MXene multilayers were investigated. As expected F starts to leaves the surface after 500 °C, which was confirmed by EELS and accordingly changes the surface termination chemistry. From High Angle Annular Dark Field (HAADF) imaging in STEM mode the MXene intralayer corresponds to 0.482 ± 0.002 nm at 100 °C. This thickness is maintained until 500 °C after which it is reduced and reaches a spacing of 0.457 ± 0.002 nm at 700 °C arises as a result of fluorine removal from the surface. These results clearly reveal the impact of surface terminations on the sheet thickness. In addition, as the intralayer spacing decreases, the interlayer spacing increases by 0.026 nm at 700 ^{o}C (0.597 nm) in comparision to the ambient MXene conditions (0.571 nm).

Conclusions

In conclusion, it is evident that the surface terminations significantly influence the MXene sheet thickness. This variation is proposed to originate as a consequence of the strength of the interaction between the electron cloud of Titanium atoms and the surface terminations. This intralayer tuning can be widely applied in any MXene applications where intercalation plays a vital role.

Analytical Phase-Shifting Electron Holography using Fresnel-corrected holograms

Augustin Nogier[1], Aurélien Masseboeuf[1], Kévin Garello[1]
[1]SPINTEC, Grenoble, France

Poster Group 2

Background incl. aims
Unlike conventional Transmission Electron Microscopy (TEM) techniques, Electron Holography (EH) gives an access to the phase of the electron wave, which makes it suited for imaging electromagnetic fields with fine sensitivity and a spatial resolution in the range of nanometers [1].
When performing a measurement, the complex wave contribution of the sample is contained in the object band of the Fourier transform of the recorded hologram. For this reason, the most common way of extracting the sample phase contribution consists in applying a circular mask around the object band [2]. This low-pass filtering cuts off excessive noise and undesirable Fresnel diffraction effects, but also limits the final spatial resolution of the recovered phase map. While this limit may not be an issue depending on the scale of interest, such a loss of precision can lead to artefacts in the phase maps realignment process when working with finer details, which remains a critical step in separating the electric and magnetic contributions.
Other approaches overcome this by combining two holograms to suppress the zero-order band [3], effectively doubling the maximum mask size available and typically getting the spatial resolution down to 2 - 3 nm. This may not be enough in some cases though. A solution to this problem is the Phase Shifting (PS) method, which uses linear combinations of a greater amount of holograms to mathematically isolate the object band [4], thus negating the necessity to apply a mask in Fourier space and allowing for a theoretical pixel precision. Implementations tend to use specific initial phase values in order to get back to an ideal diagonal matrix system, which greatly facilitates the calculation. When working with arbitrary initial phase values, it is still possible to avoid the complex matrix inversion by performing sine fittings in each pixel, using an even greater amount of hologram recordings [5]. Due to the absence of any filtering however, Fresnel modulation effects become a source of errors in the reconstruction process in both cases. However, this effect can be rendered ineffective by adjusting the hologram fringes spacing to match that of the modulation pattern [5].
In this work, we aim for the pixel-precise reconstruction of phase maps using a modification of the PS method, so that the recovered sharp atomic details can lead to better phase maps alignments. This study focuses primarily on a more general analytical solution to the PS equation in the case of arbitrary chosen initial phase values, which eliminates the need to conform to an ideal case. We also investigate the use of biprism voltage as a suitable way to minimize Fresnel modulation effects and related calculation errors. Finally, we apply these methods to both computer simulations and TEM measurements from specifically prepared magnetic samples.
Methods
The general analytic solution we derived to the PS matrix equation works for any set of non-redundant initial phases containing at least three elements. While more measurements ultimately yield less noise in the final phase map, we typically used 5 or 7 hologram recordings for each manipulation up to this point. As common as it is for this matter, we used beam tilting to tune each initial phase value. Under the small angle approximation and disregarding the Fresnel modulation pattern, this is equivalent to an overall phase offset in the fringe pattern. The experimental values

can then be extracted for each hologram from the center of the object band in Fourier space and be used as parameters in the solution expression.
Since there is no requirement regarding the fringe spacing in the holograms, we also choose to tune the biprism voltage low enough to give a sufficiently good contrast while still cancelling out the Fresnel effect. Up to this point, all of our measurements have used this particular setting.
Results
Our computer simulations use artificially generated phase and amplitude maps from which holograms are calculated. We first tested our method on square-shaped phase maps with various apodizations, noise levels and Fresnel diffraction effects. Using our analytical method on Fresnel-free holograms, we see that the reconstructed phase maps show accurate reconstructions of the initial wavefront regardless of the spatial details [Fig.1].
Additionally, we measured the Fresnel modulation effect on holograms for various biprism voltage values in order to minimize this effect. So far, all of our experimental results have thus been using a voltage of 21 V instead of the usual 200V, which corresponds to 24nm-wide fringes for an image pixel resolution of 0.12 nm.
Conclusions
We were able to reconstruct phase maps using our generalized PS analytical method for reasonable noise and Fresnel modulation levels. While this method works best on perfectly generated holograms, we also have shown that it is possible to maximize the fringe contrast and correct the Fresnel modulation effect by adjusting the biprism voltage. Likewise, other parameters such as the initial phase do not need to match ideal values since our method takes the experimental measurements into account.
Using this modified phase shifting method, we expect that further testing done on specifically prepared samples can give satisfactory results with an effective spatial resolution approaching the theoretical pixel size.

Poster Group 2

Background: InGaN/GaN quantum wells (QWs) have garnered significant attention for LED applications due to their high quantum efficiencies in the ultraviolet/visible range and emission tunability with indium content, among other factors. However, the growth of QWs with high indium content encounters issues with indium phase separation, resulting in structural changes and inhomogeneous light properties. This can be controlled via growth stopping, forming quantum dot like islands that behave as localized emitters [1,2]. Furthermore, subsequent etching reduces the strain-induced quantum Stark effect present in majority of such structures. Due to its deep subwavelength spatial resolution and broadband frequency components enabling coupling to high-energy optical transitions, cathodoluminescence nanoscopy (CL) has emerged as the ideal tool to study such high-bandgap semiconductor systems [3] and characterize their nm-scale features and defects. Despite it being a popular characterisation technique, the impact of the electron cascade on the sample, as well as the optoelectronic effects of thinning bulk samples into lamella, as is commonly performed for studies in a transmission electron microscope (TEM), have hitherto not been studied systematically. In this work we aim to confront this using a comprehensive study comparing time-resolved (TR) scanning electron microscope- (SEM) based CL, TEM-CL, and TR-photoluminescence (PL) measurements.
Methods: We utilized CL imaging with both 5 and 150 keV electron beams to acquire hyperspectral maps on InGaN/GaN QWs. Additionally, employing a beam blanked SEM with pulse lengths ranging between 30 – 100 ps, we conducted time correlated single photon counting and extracted luminescence decay maps as a function of position, temperature, and wavelength. The samples subsequently underwent preparation as lamella using Ga-based focused ion beam milling, after which the same measurements were performed. These measurements were compared to the decay maps obtained via an ultrafast photoemission TEM, along with decay traces from analogous samples acquired using TR- PL at liquid helium to room temperatures.
Results and Conclusions: We show that despite the energy density deposited by a 5 keV electron beam being an order of magnitude larger than that deposited by a 150 keV beam, the probability of exciting higher energy localized emitters, seen in the RGB fitted hyperspectral map in the graphic, is reduced due to the size of the electron cascade. The recombination dynamics of carriers, however, are comparable, with two major lifetime components of around 100 ps and 1.5 ns, as well as a delay in the rise time of the lower energy component of the emission. Interestingly, the TR-PL results indicate shorter lifetime components of 30 and 120 ps, when usually lifetimes in PL are reportedly longer than in CL. We present a model describing the recombination dynamics measured and the nuances between the different experimental techniques and respective results.

Magnetic layers reversal in new MRAM devices measured with operando Electron Holography

Augustin Nogier[1], Bernard Dieny[1], Ricardo Sousa[1], Christophe Gatel[2], Eric Gautier[1], Aurélien Masseboeuf[1], Kévin Garello[1]
[1]SPINTEC, Grenoble, France, [2]CEMES, Toulouse, France

Poster Group 1

Background incl. aims
Recent improvements in spintronics led to new types of non-volatile Magnetoresistive Random-Access Memories (MRAM) with low power consumption and short switching times, such as the current-induced Spin-Orbit Torque (SOT). So far, studies of such devices mostly rely on the measurement of their electrical and magnetic characteristics using external electrical methods [1]. However, their optimization ultimately requires a deeper understanding of the internal processes through direct observation. Given the usual dimensions of these components (<60 nm lateral, <1nm in thickness), observing magnetization textures and reversal during their activation requires the use of large-scale instruments [2].
In particular, Transmission Electron Microscopy (TEM) is a tool of choice for this matter, offering the combination of nm-scale spatial resolution and magnetic sensitivity. Indeed, Electron Holography (EH) gives access to 2D projected electric field and magnetic induction maps with a sensitivity in the nm.T range [3], which can lead to information about various electrical properties of the sample.
This work aims for a better understanding of the switching processes taking place inside these devices upon writing and reading data by performing an operando analysis (e.g the quantitative dynamic imaging of their inner magnetic structure) on electrically biased samples using EH [4]. We will present here the study of the free layer reversal process inside Magnetic Tunnel Junctions (MTJ) in both isolated and array-like SOT devices. Given that the zone of interest is a ferromagnetic layer less than 1nm-thick with weak internal fields close to the detection limit, we also chose to study the reversal process in a wider in-plane MTJ as preliminary results less sensitive to the measurement quality.
Methods
Most of the EH measurements presented here use Phase Shifting (PS) by combining several holograms recorded with different beam tilting angles as a mean to enhance both spatial resolution and magnetic sensitivity. While this method gives an exact analytical solution to the PS matrix equation, it comes at the expense of limiting ourselves to study the reversal processes in a pseudo-static regime.
In any case, separating the electric and magnetic components of the electron wave phase requires two holograms to begin with. We perform all image alignments using points with strong Mean Inner Potential (MIP) gradient and theoretical zero magnetic field in an iterative correction process.
In order to ensure the best measurement quality regardless, the device under observation must be sufficiently thinned down below 100 nm to limit the electron beam absorption through heavy materials, while remaining intact regarding its electrical behavior. Additionally, the injection of an external electrical bias on the sample inside the microscope chamber remains a technological challenge [5]; these conditions for accurate measurements require a highly controlled preparation process that will be presented.
Results

We first performed PS electron holography on a 8nm-wide in-plane double MTJ without any electrical bias, where a controlled external magnetic field acted as the trigger for the free layers switching. In this experiment, we were able to witness the reversal on phase maps approaching the pixel resolution for an external field of around 9mT [Fig.1]
We also conducted experimentations leading to a complete preparation process for the electrical connections of SOT samples inside the TEM chamber in order to perform PS on them, this time with a voltage bias for triggering the layer switching. Although the MTJ in SOT are typically smaller than that of our previous experiment, they still exceed the 0.12 nm spatial resolution limit of our image pixel size.
Conclusions
These first results on unbiased samples show that a pixel-precision magnetic induction map is obtainable through the PS method with some image realignments and additional precautions. Given our advancement on the SOT preparation, we thus expect to be able to measure the free layer switching in these particular devices with a similar spatial resolution, keeping in mind the study of domain wall motion as the next step towards a deeper understanding of the SOT mechanisms.

IM-13 (2), Lecture Theater 5, august 27, 2024, 14:00 - 16:00

Background

The structural steels used in the primary circuit of nuclear power plants are subjected to irradiation and/or temperature conditions that lead to changes in their mechanical properties. These mechanical properties are directly linked to changes in microstructure due to ageing, particularly on a nanometric scale (segregation, precipitation, clusters of point defects, etc.). To predict these changes, it is necessary to describe the nano-objects present as precisely as possible, i.e. to correlate their chemistry, morphology and crystallography. In the nuclear materials scientist community, two complementary instruments are often used to characterize nano-features: Atom Probe Tomography (APT) and Transmission Electron Microscopy (TEM).
APT enables characterization of nm-scale chemical heterogeneities in terms of size, density, composition, and morphology in the 3D of the real space. However, it does not provide a full crystallographic description.
TEM related techniques can provide access to the crystalline structure of the matrix and nano-objects, as well as their orientation relationships. Its wider field of view also allows us to quantify the number density of objects with better accuracy. Chemistry can also be studied in analytical STEM, although the matrix signal can be convoluted with that of the precipitates. Contrary to APT the collected data are only in 2D.

Methods

The aim of TEM-APT correlative microscopy is to characterize the same nano-objects using both techniques for the most complete possible description [1]. Since APT is a destructive techniques, correlative microscopy here consists in analyzing an APT thin needle with TEM first, and then to analyze the same sample by APT. It allows to remove ambiguities about the nature and/or location of nano-objects and thus provide new insights into the mechanisms involved in defect formation.
This work therefore involves developing a methodological approach that makes maximum use of the data collected from each technique (such as MultiVariate Statistical Analysis processing for chemical analysis in STEM) and combination of data accessible by only one of each technique obtained on the same sample. To this end, a thermally aged austeno-ferritic model alloy, in which the ferrite undergoes two phase transformations: spinodal decomposition and the formation of G-phase particles, was studied in an effort to optimize sample preparation for correlative microscopy and data processing. The challenges that have been faced are as follows: improving the contrast of electron microscopy analyses, improving the yields of TEM-APT correlative microscopy analyses, understanding the artefacts associated with the physics of field evaporation and 3D reconstruction for APT, and optimization of data processing of EDS through statistical methods (using Principal Components Analysis in particular) in order to improve EDS quantification and correlation with atom probe data.

Results

The aim of the first part of the study is to extract more quantitative data from TEM analysis (imaging and elemental analysis). Contrasts are difficult to interpret in TEM experiments because of the shape of APT samples, the amorphous layer induced by FIB preparation, the presence of oxide layers hindering diffraction patterns and the contribution of the background (i.e. vacuum) in images. In order to reduce the amorphous layer, the addition of a cleaning step has been investigated with the use of an Ar-beam polishing at low-voltage with a Precision Ion Polishing System II (PIPS II) [2]. In addition to a systematic plasma cleaning before and after every S/TEM analysis, this step would also permit to address the yielding of tips that have been investigated in EM by removing the high-field carbon contamination and the oxide layers simultaneously. Quantification in Analytical TEM is not straightforward when trying to isolate the signal from the precipitates from that of the matrix. Compositions of the α/α' domains as well as G-phase precipitates measured thanks to APT have been used to improve the data processing of EDS data. On one hand, EDS spectrum imaging supported by PCA denoising as well as sample preparation improvement, helped to optimize the detection of nano-objects. On the other hand, thanks to correlative microscopy and PCA, we were able to extract their composition from EDS maps.

The second part of the study is to use TEM images as additional information to obtain reliable 3D reconstructions with atom probe data, even without the presence of crystallographic poles. Through the comparison of different 3D reconstruction methods that exist on an experimental dataset from TEM-APT correlative microscopy: static and dynamic voltage-based reconstructions [3], shank angle or tip profile, we suggest a methodology to reconstruct a volume properly. This is done by adjusting the spatial distribution of the G-phase particles and their shape. This correlation also enabled to highlight distortion artefacts observed on APT volumes.

Conclusion and Perspectives

This work aims to present a methodology for extracting maximum information from samples thanks to correlative TEM/APT microscopy. Leveraging the strengths of each instrument, we addressed the limitations of the other, enabling successful characterization of particle shapes, sizes, crystallography and chemical composition. Efforts have been dedicated to improve the sample preparation procedure with low voltage ion beams, allowing improved image contrast and better identification of objects and therefore facilitating quantitative analysis. The optimization of the data processing of EDS spectrum, assisted by APT data, has been undertaken. PCA has demonstrated its effectiveness in reducing the background noise and thus improving the detection of poor signals (e.g. low counts experiments, from nano-particles embedded in the matrix).

Other future developments currently under investigation include:
- Exploring alternative methods to enhance contrast in diffraction-based EM imaging, such as through flash-polishing techniques. [4]
- Expanding application of the methodology to analyze more complex materials that contain a wider range of nano-objects, such as irradiated steels.

Poster Group 2

Background
Scanning Transmission Electron Microscopy (STEM) has been shown to be a powerful tool for observing the atomic structure of complex materials. However, the radiation damage induced by the electron beam limits imaging beam-sensitive materials with acceptable signal-to-noise ratio. Subsampled STEM [1] has recently been investigated as an approach for reducing the radiation damage without compromising the level of signal per each measurement (or probe position). It is achieved by subsampling the grid of probe positions, which results in an incomplete set of measurements. A complete STEM image is then recovered from those subsampled measurements through an inpainting process.
A myriad of inpainting methods have been introduced based on, e.g., variational [2], Plug-and-Play (PnP), and deep learning frameworks [3]. In this work, we focus on PnP methods, which have been widely used for solving various imaging problems by using an off-the-shelf denoiser as an image prior.
Methods
We propose a deep learning-based inpainting method. Inspired by the work on Deep Denoiser Prior (DDP) for image restoration [4], we utilize a pre-trained deep neural network as an implicit image prior and then integrate that pre-trained network into an iterative inpainting algorithm. We discuss how the training of a DDP can be improved using synthetic and experimental STEM images corrupted by different sources, such as detector noise, scan distortion, sample movement, and aberrations. Therefore, we also introduce a new tool for the fast generation of synthetic STEM images. Additionally, inspired by recent work on invariant priors [5], we demonstrate that enforcing equivariance to certain transformations, such as rotations, reflections, and translations, during the denoising step, improves the quality of inpainting.
Results
The results of our inpainting method are shown in Figure 1. The images tested in Figure 1 were not used for the training of the denoiser neural network. Ground truth synthetic images of SrTiO3 and Si were generated using our image generation tool. These images were then randomly subsampled with respect to 25% of probe positions. Despite slight imperfections around the boundary of the images, marked by a yellow arrow, the reconstructed images are of very high quality, with Signal-to-Reconstruction Error Ratios (SREs) greater than 43 dB.
Conclusion
This work presents an inpainting method for subsampled STEM data that leverages the power of both variational and deep learning methods. Given the flexibility of PnP methods, any neural network architecture can be used as a DDP. In the future, we plan to extend this work to inpainting subsampled data in different modes of electron microscopy, such as scanning electron microscopy and 4-dimensional STEM.

Scanning transmission electron microscopy in combination with electron energy loss spectroscopy is a powerful method which provides very local spectroscopic information[1]. The local spectroscopic data contains elemental and electronic information. However, the elemental quantification needs a rather large energy window to have simultaneous quantification on multiple elements. Whereas the electronic information needs high energy resolution which limits the size of the energy window due to the limited amount of pixels in an electron detector. This makes the simultaneous elemental quantification and fine structure analysis almost impossible when multiple elements are of interest. One possible solution would be to scan multiple STEM-EELS map and changing the drift tube or magnetic prism between each frame. The difficulty is that sample drift, damage and real time user interaction, such as refocusing, make this procedure very cumbersome. Another solution is doing DualEELS which applies two drift tube voltages at each probe position which solves the problems discussed above[2]. However only two snippets are available which is still insufficient for most materials where multiple edges occur.
A novel method was developed which overcomes these challenges by applying any number of offsets to the drift tube without adding dead time of the detector. Moreover, the defocus for the different drift tube voltages is corrected for to maintain a good energy resolution. This methodology provides easy correlation of elemental abundances with the fine structure for multiple edges in a sample.
In this work, the methodology is applied to multiple samples providing new insights into solving materials science questions. For example in Fig. 1, the core-loss edges of K-L, Ti-L, O-K, Eu-L and Ta-M together with the low loss are mapped quasi-simultaneously on the interface of EuTiO3 (ETO) and KTaO3 (KTO) which are interesting in the research on 2D electron gas systems[3]. At the top of ETO (purple box), a different oxidation state is observed from the fine structure of Ti, O and Eu simultaneously when comparing it to the fine structure of the ETO layer (red box). With this example we show the power of the new approach for quality, speed and ease of use in ELNES applications.

Figure 1. A series of 2d spectrum image maps converted into a 1d line maps across an interface between ETO (top) and KTO (bottom) where the low loss and different fine structures are shown for different positions with respect to the interface. The information from the different ELNES profiles can be directly correlated since they are acquired quasi-instantaneous.

pyEELSMODEL: python library for model-based EELS quantification

Daen Jannis[1,2], Mr. Jo Verbeeck[1,2]
[1]EMAT, Universiteit Antwerpen, Antwerpen, Belgium, [2]NANOlab, Universiteit Antwerpen, Antwerpen, Belgium

Poster Group 2

Electron energy loss spectroscopy is a powerful method used to investigate the elemental abundance and electronic structure of a material. Extracting this information from the experimental data is a complex process and multiple methods exist to get the results where each of them have their own advantages and disadvantages. Moreover, each method has free input parameters which influences the final results and can lead to experiments bias and reproducibility issues, especially in the common case where all parameters and the exact workflow is not shared.

In this work, an open-source python package (pyEELSMODEL) is presented which offers multiple alternative EELS quantification methodologies[1] . The library allows a transparent way to share a specific data processing workflow from raw data to a resulting plot that can appear in a paper. pyEELSMODEL expands upon the former EELSMODEL (c++) software which introduced the model-based philosophy in the EELS community [2]. This method attempts to describe the experimental data with a physical model and optimizes the parameters of this model via a minimization scheme such as least squares or maximum likelihood. The values of these optimized parameters can be used to estimate information on the material such as eg. elemental abundance. The new pyEELSMODEL package is written in python making it, in general, easier to integrate and extend as compared to the former c++ code. Multiple robust quantification workflows are available and can be easily used by the novice EELS user via eg. Jupyter notebooks.
This package is also particularly useful for testing and validating novel data processing methodologies since its results can easily be benchmarked against more common methodologies and could act as a test standard against which to make performance claims.

In this presentation, we will demonstrate the use of pyEELSMODEL on several experimental STEM-EELS maps showcasing the robustness and speed of the model-based quantification methodology for modern large size datasets. In Fig. 1, EELS quantification is used to get elemental maps on a mix of copper and silver nanoparticles on top of a carbon substrate. The lower plots show the resulting fitted model on silver (a) and copper (b).

Fig 1. Elemental maps of copper and silver nanoparticles on top of a carbon substrate. (a) Shows the fitted model on a silver nanoparticle whereas (b) shows a fit on the copper nanoparticle.

Poster Group 2

Background incl. aims
Scanning transmission electron microscopy (STEM) is a powerful tool for studying materials down to the atomic scale. Although qualitative STEM imaging offers plentiful information about atom locations and identification, quantitative analysis is becoming increasingly valuable for insights into composition, atom counting and thickness determination [1]. However, due to the strong dynamical scattering in crystals, directly solving the inverse problem from scattered electron intensity in STEM is nearly impossible. As a result, STEM imaging simulation is crucial for quantitative STEM analysis. In this study, we develop a new multislice algorithm that can be applied to nonorthogonal crystal structures, a task generally challenging in conventional multislice simulation [2].
Methods
For nonorthogonal unit cells, such as a triclinic unit cell, we first use an iterative algorithm to find a new unit cell. We aim to make the angles between the three new basis vectors as close to 90° as possible, while the c-axis keeps along the electron beam direction. The nonorthogonal supercell is then divided into a series of tilted slices parallel to the a-b vector plane. The Coloumb potential of the crystal is then projected onto the tilted slices based on a nonorthogonal mesh, and a tilted Fresnel propagation is performed between subsequent slices. The generated STEM image based on nonorthogonal mesh is then re-mapped into conventional format. By using this tilting-slice operation, we can effeiciently model the electron dynamical scattering in nonorthogonal structures.
Results
We implemented the method in our in-house STEM simulation code and performed high angle annular dark field (HAADF) STEM simulations on Gd2B4O9 [0 0 1], as shown in Figure 1.
Conclusion
We develop a tilted multislice approach to simulate focused electron beam propagation in nonorthogonal structures. This effectively extends quantitative STEM analysis to compound materials with more complex structures.

Poster Group 2

The tissue microenvironment has emerged as a critical determinant of immune cell function and inflammatory disease outcome. However, assessing complex multicellular niches within the intact anatomy of a tissue and linking them to cellular in-situ function with the necessary volumetric dimension and spatial resolution remains a challenge. Our goal is to develop workflows that enable quantitative and functional volumetric imaging of intact tissue compartments during the course of inflammation. We use computational reconstruction to correlate the 3D positioning of immune and non-immune cells with microanatomical patterns of tissue architecture. In this way, we seek to define functional niches and establish comprehensive phenotyping of local environments during the onset, progression and resolution of inflammatory disease.

4DSTEM-in-SEM by placing a pixelated detector below the sample

Johannes Müller[1], Christoph T. Koch[1]
[1]Department of Physics & IRIS Adlershof, Humboldt-Universität zu Berlin, Berlin, Germany

Poster Group 2

Background
Four-dimensional scanning transmission electron microscopy (4DSTEM) is a powerful diffraction-based technique to probe local crystallinity, orientation, strain, and many more properties of electron-transparent samples [1]. Furthermore, various open source Python packages exist to analyze the large amounts of data generated by 4DSTEM, for instance LiberTEM, py4DSTEM, and pyxem. 4DSTEM can also be employed in scanning electron microscopes (SEMs) for example by placing an electron-sensitive pixelated detector (camera) below the sample similar to on-axis transmission Kikuchi systems [2-5]. The lower accelerating voltage of SEMs leads to strong scattering even from monolayers. 4DSTEM-in-SEM is ideally suited to characterize 2D-like materials due to their inherent thickness of a few nms.
Compared to dedicated (scanning) transmission electron microscopes ((S)TEMs), the large sample chamber of SEMs with their various flanges as well as the large area around the sample give enough space to integrate cameras and other equipment into the sample chamber without compromising on the SEM's original functionality. The large field of view of SEMs of several mm^2 combined with their resolution in the sub-nm range are ideal to map properties on different length scales. Furthermore, using SEMs as a base platform allows for simpler, more easily customizable, and more economical experimental setups. On the other hand, the lower accelerating voltage of SEMs require thinner samples and the native spatial resolution doesn't allow STEM-imaging at atomic resolution.

Methods
We built two transmission diffraction substages that fit between the pole piece and the SEM stage, and can be mounted on top of the original SEM stage. One substage utilizes a fiber-coupled scintillator-based CMOS camera and the other substage a Medipix 3 hybrid-pixel detector with single electron sensitivity (X-Spectrum GmbH, Germany). Both substages with their corresponding cameras are shown in Fig. 1 a) and b). The compact 2.5x2.5x1.1cm^3 CMOS camera is integrated inside a hexapod stage and mounted to a linear stage, enabling us to physically adjust the distance between camera and sample (the camera length). The camera length is limited to the distance between the sample and the camera because there are no active lenses after the sample. The substages have sample holders for standard TEM grids and are kept inside an external vacuum chamber when not inserted into the SEM to reduce carbon contamination.
Hardware synchronization between each camera, the GeminiSEM 500 (Zeiss), our in-house scan generator, and the electrostatic beam blanker makes it possible to only expose the sample during a camera frame and to utilize the maximum possible frame rate of each camera. The scan generator also acquires the signals of the SEM's secondary electron (SE) detectors during a 4DSTEM scan. We integrated all hard- and software in-house, providing full control over the 4DSTEM-in-SEM systems allowing us to explore new and existing methods.

Results
Fig. 1 c) shows maps of the in-plane orientation and the coverage of both components of a C60/MoS2 van der Waals heterostructure [5]. The in-plane orientation map of MoS2 obtained by

gold-mediated exfoliation shown in Fig. 1 d) reveals the single crystallinity of the MoS2 over several mm² [5]. The data shown in Figs. 1 c) and d) were obtained using the above-mentioned CMOS camera-based system and are exemplary applications of 4DSTEM-in-SEM.

Conclusion
4DSTEM-in-SEM is feasible and adds to the SEM's wide range of applications. The large scan area of several mm² and the nm sized spatial resolution of SEMs is ideal to employ 4DSTEM in SEMs to characterize low-dimensional materials and thin bulk samples. Furthermore, SEMs are an excellent platform for method development due to their simplicity compared to dedicated (S)TEMs, their spacious sample chamber, the convenient access to the sample area, and their good imaging performance.

PS-03 (3), Lecture Theater 2, august 30, 2024, 14:00 - 16:00

Background incl. aims
Halide perovskites have recently risen into the spotlight due to their exceptional optoelectronic properties and compositional flexibility, enabling a wide range of choices for each component in the archetypical ABX3 formulation (A: cation, B: typically Pb or Sn, X: halide anion). The basic structural unit is the [BX6]4- octahedron, sharing corners in a 3D lattice. A new class of perovskites, featuring layers of corner-sharing octahedra alternating with layers of organic spacers, has been demonstrated to have enhanced fluorescent emission compared to their 3D counterparts. Understanding local composition, crystallography and optoelectronic properties is fundamental to develop an understanding of these materials and their engineering.
In this work we showcase the combination of various electron microscopy techniques (EDX, cathodoluminescence, 4DSTEM, monochromated EELS) to unravel the interplay between local compositional, structural and optoelectronic properties in layered halide perovskites. We also study systems where the halide component is replaced, obtaining a lateral heterostructure.
Methods
Materials (PEA2PbBr4, PEA2PbI4, PEA2MA2Pb3I10) were synthesised using a wet chemistry route described in [1]. The resulting materials were dispersed on silicon for CL measurements and lacey carbon or silicon nitride grids (20 nm thick) for STEM measurements. SEM-EDX was carried out in a ZEISS GeminiSEM 560 using an Oxford Instruments detector. SEM-CL was done in an Attolight Allalin 4027 Chronos SEM-CL. Spectra were acquired with an iHR320 spectrometer (focal length of 320 mm, 150 gratings per mm blazed at 500 nm, 700 µm entrance slit) and an Andor 1024-pixel charge-coupled device (acquisition time 100 ms/pixel). All the measurements were performed at room temperature under high vacuum (<10 – 7 mbar) with acceleration voltage of 10 kV and a pulsed beam with a frequency of 80 MHz, a pulse duration of ~7ps, at a current of ~100 pA as measured by a Faraday cup. STEM measurements were done in a ThermoFisher Spectra300 with probe and image correctors, a monochromated source and a dual-X EDX detector (1.7 sr total solid angle).
Results
We considered layered perovskites with different thicknesses and composition. Thick flakes were used for CL measurements. In PEA2PbBr4 and PEA2PbI4, a multivariate analysis decomposition highlights the presence of an emission originating from the bulk of the material and a blue-shifted emission visible along the edges in the CL hyperspectral maps. The analysis was extended to lateral PEA2PbBr4 - PEA2PbI4 heterostructures (for which the elemental distribution is shown in the figure), identifying emission from both the phase in the bulk (original phase of the flake) and the one along the edge (dominated by the replaced halide). The emissions were correlated with local compositional changes.
Furthermore, we have carried out a 4DSTEM analysis to verify local crystallinity in thin PEA2MA2Pb3I10 flakes at low electron doses. The flakes were good single crystals, with loss of crystallinity observed at the edges. The monochromated EELS signal was integrated over large areas

to minimise dose and used to calculate optoelectronic properties, finding good agreement of the calculated bandgap with optical measurements.
Conclusion
We were able to obtain spatially resolved CL measurements on layered halide perovskites, identifying emission heterogeneities. We also characterised local crystallinity and demonstrated the ability of measuring the local bandgap in individual flakes using EELS. These approaches will enable tailoring of the material engineering, leading to better light emitting and management devices.

Introduction

Raising the bar for weight reduction, safety, and environmental protection in modern automotive and construction materials can be barely achieved without new types of Advanced High-Strength Steel (AHSS) [1] and must be guided by in-detail structural and chemical characterization. To meet safety and durability requirements, modern AHSS products additionally need effective corrosion protection, and the galvannealing process, which involves hot-dip galvanizing in a Zn bath followed by annealing, is considered to be one of the most efficient methods for achieving this goal. Such a well-balanced but complex process of interfacial interactions can be significantly affected by alloying elements, which are added in AHSS to augment its mechanical properties and achieve a superior combination of high tensile strength and good formability [1,2]. For instance, silicon affects the steel bulk properties enhancing the Fe-liquid-Zn interfacial reaction by solute Si in the α-Fe phase. An additional effect is attributed to the formation of surface oxides on the steel sheet during annealing before immersion in the Zn bath [3,4]. One can conclude that the structural and chemical peculiarities of the steel/coating interface region including the so-called inhibition layer, e.g. [3], must be considered as a key factor governing the phase formation kinetics. Advanced transmission electron microscopy (TEM) can help us collect morphological, structural, and elemental information at the nanoscale. For a deeper understanding of phase evolution, it is necessary to study not only fully galvanized samples processed at different annealing times but also steel sheets at the outlet of the bath, coated with almost pure Zn.

Methods

We optimized various TEM sample preparation techniques and showed that low-temperature FIB is a method of choice for dependable Zn-coated steel preparation [3], which can be further enhanced utilizing a plasma P-FIB operated with, for instance, Xe ions. Cross-sectional TEM lamellae were prepared using a CrossBeam 1540 XB SEM (Zeiss, Germany) Ga-FIB using W to form a protection capping layer. The final thinning was performed at -60°C applying a Micro Heating Cooling Stage (MHCS) (Kleindiek Nanotechnik GmbH, Germany) based on the thermoelectric effect and 5 kV acceleration voltage to minimize the invasive influence of the Zn-Ga eutectic formation. The investigation was carried out in a JEOL JEM-2200FS (JEOL, Japan) operated at an acceleration voltage of 200 kV. The TEM is equipped with an in-column Ω-filter and a TemCam-XF416 (TVIPS, Germany) CMOS-based camera. HRTEM data processing was done with Gatan Microscopy Suite. Crystal structure simulations were performed via JEMS software. STEM EDX analysis was fulfilled in a scanning (S)TEM mode for qualitative elemental characterization of the specimens with an X-MaxN 80 T detector from Oxford Instruments (United Kingdom).

Results

Employing complementary TEM techniques (HRTEM, SAED, STEM EDX), we traced the formation of Zn-Fe phases in AHSS with high Si content at different stages of galvannealling process along with as-galvanized reference specimen [4]. In particular, it has been disclosed that the Si-based surface oxide layer, formed on steel during the recrystallization annealing step before dipping into the Zn bath

(460°C) remains stable, separating the coating from the reaction zone (Figure I). This efficiently hinders the desired reaction of Fe with Al in a Zn bath at the early stage of hot-dip galvanizing and complicates the formation of the Fe2Al5-xZnx inhibition layer. One can reveal that liquid Zn can penetrate local disruptions in this film forming a δ phase layer below, while Fe diffusion into the coating is suppressed. The δ layer supersaturates with Fe and Si from the steel during long-term annealing at 480°C and decomposes forming a δ phase [5] matrix with Fe-Si-Al-based nanoprecipitates with a cubic structure (Figure II). The phases were identified via HRTEM and STEM EDX. Based on experimental STEM EDX data, the achieved phase configuration was refined via Thermo-Calc Fe–Zn–Si–Al system simulation. It must be emphasized again that the observed Si-based oxide layer remains stable even after long-term annealing, thus Si, which constitutes this membrane, was not actively involved in the Fe-Zn reaction.

Conclusion

Our results indicate the following evolution of phases at the steel/coating interface of AHSS subjected to an industrial continuous hot-dip galvannealing process. During dipping in a liquid Zn bath, Zn penetrates the gaps in an existing oxide film and forms a layer below directly reacting with the Fe. This layer was identified as the δ phase. Thus, the desired Fe2A5-based inhibition layer cannot be formed as intended. Mentioned δ phase layer can grow during subsequent annealing being, however, efficiently constrained by the mixed oxide membrane. While long-term annealing, Si dissolved in the steel destabilizes the δ phase supersaturated with Fe and Al, triggering its decomposition into the δ phase and Fe-Si-Al-based nanoprecipitates. The challenges and solutions on the way toward a fruitful and dependable TEM analysis of galvanized industrial steels will be also discussed in detail.

Correlative characterization by X-ray tomography, SEM/FIB and TEM using reference markers: bridging imaging with micro-structuring

Dr Alexey Boubnov[1], Charlotte Neidiger[1], Rafaela Debastiani[1], Torsten Scherer[1], Matthias Mail[1], Di Wang[1], Christian Kübel[1]
[1]Institute of Nanotechnology, Karlsruhe Institute of Technology, Karlsruhe, Germany

IM-13 (1), Lecture Theater 5, august 27, 2024, 10:30 - 12:30

Correlative characterization is the spatial registration of several imaging modalities with the aim to combine complementary information on the same region of interest [1]. The imaging modalities are furthermore supplemented by micro-structuring tools such as focused-ion beam (FIB) technology for selective extraction of the region of interest (ROI), and femtosecond-laser milling for material removal.
Within the same length scale, analyzing identical ROIs using several modalities is well-established in electron microscopy, e.g. various STEM imaging modalities (BF, DF, HAADF) with EELS and EDX spectroscopy or also the combination of APT and TEM. Across length-scales, the analysis of identical ROIs requires combination of different instruments. Without a correlative approach, the characterization of the full length-scale hierarchy relies on statistically random sample extracts, which only provides a good representation for very homogeneous samples, with similar ROIs uniformly distributed within the sample. However, for macroscopically inhomogeneous samples, such as heterogeneous catalysts, a correlative approach is indispensable to characterize the individual components of the sample. Therefore, for linking the local micro-structure to the macroscopic level of the sample, a full correlation of all applied techniques on the part of the sample containing the ROI is desired.
We present a correlative workflow, which allows the combination of 3D analysis across several length scales from the bulk sample with defined laser pre-structuring for micro-CT at the sub-mm level, identification of regions of interest on the 10-100 µm scale in a FIB, for 2D/3D surface and tomography visualization by SEM/EDX/EBSD and light microscopy, followed by defined sample extraction and transfer to nano-CT and TEM.
For this purpose, we developed a dedicated sample carrier, enabling large tilt angles for FIB work, as well as flexibility for direct transfer to micro-CT. The carrier is equipped with global three-dimensional reference markers for accurate determination of the rotation, tilt, and translation of the carrier with the sample. Additionally, local markers, in the form of Pt-deposited or FIB-milled patterns, are placed directly on the sample in the vicinity of the ROI. These facilitate local navigation and accurate translational positioning around the ROI for FIB-extraction, after the rotation and tilt has been aligned by means of global markers.
The workflow, with the use of the correlative sample carrier, global and local markers, as well as a series of geometrical calculations, gave a two-fold result. Firstly, an accurate image correlation in 3D was enabled, overlapping 3D tomographic and 2D projection images virtually in image-processing software, e.g. Dragonfly. Secondly, step-by-step instructions, in the form of a simulated FIB projection image, were generated for real-time overlap with the FIB image, leading to an accurate FIB-extraction of the ROI for nano-CT and/or TEM. We verified this workflow on samples from metallurgy [2] and catalysis [3].

Using global and local reference markers, and tracking them at different length scales, we achieved accurate ROI-targeting for FIB-extraction, and covering multiple length scales and imaging techniques. The workflow is aimed at routine multi-scale, multi-modal correlative investigations on samples from materials science, targeting specific ROIs, thereby gaining local chemical and structural information from bulk samples.

Background incl. aims
Tungsten oxides (WO3-δ) have in the past received attention for their gas sensing, catalytic and electrochromic properties. Recently, ferro- and piezoelectric properties123 coupled to local mechanical strain and even supercondutivity45 have been reported in tungsten (tri)oxide as well, inspiring interest in the electronic properties of these materials. However, this behavior is not yet fully understood and investigations of epitaxial films of tungsten oxides are particularly scarce. In this work, we aim to provide some insight into the nature and formation of ferroelectric domains and domain walls and their structural and electronic properties.
Methods
Epitaxial films of tungsten (tri)oxide were grown by pulsed laser deposition at different thicknesses on a number of different substrates to reveal the effects of (epitaxial) strain. The substrates used are yttrium aluminate, lanthanum aluminate and strontium titanate. Atomic force microscopy and piezoresponse force microscopy were used to visualize the surface topography of the resulting films and to image the ferroelectric domain structures, respectively. In addition, conducting atomic force microscopy was utilized to show local electrical conductivity. The nanoscale structure of the films was probed using aberration-corrected scanning transmission electron microscopy (STEM). Differential phase contrast imaging enables the imaging of the lighter oxygen anions. Real-space analysis of the STEM images using an in-house developed software tool provides a sensitive means for visualizing local strain gradients and polarization.
Results
Our results suggest an intricate coupling between the epitaxial strain imposed by the substrate, film thickness and the ferroelectric domain structure in the film. Low-strain films grown on yttrium aluminate show a fairly traditional domain structure consisting of a combination of purely polar, non-ferroelastic and ferroelastic domain walls, distinct from the type of domain structure reported for thicker films on the same substrate1 in which the polar nature of the film is localized to the domain walls, as well as those reported for bulk tungsten trioxide based on theory2. Electrical conductivity is found to be enhanced in the vicinity of the domain walls. In contrast, a higher degree of epitaxial tensile strain suppresses the formation of domains altogether, favoring strain accommodation through an extended planar defect.
Conclusion
We provide some new insights into the formation of polar domain walls and strain accommodation in epitaxial thin films of tungsten trioxide under different conditions of epitaxial strain and show that there is potential for the functionalization of domain walls therein.

Background
Transmission electron microscopy (TEM) is an invaluable tool in knowledge-driven optimization of catalysts. Over the years, important mechanistic insights in chemical processes have been gained by combining the atomic resolution of TEM with miniaturized reactors. This type of reactors confines gas or liquid phase reaction environments to the vicinity of the catalyst between pairs of thin electron-transparent windows and has opened up for in situ and operando studies of catalysts during reactions conditions mimicking industrial catalysis. However, the electron beam has to traverse the reaction environment as well as the windows which, in turn, have to remain impermeable and mechanical stable to sustain pressure differences of up to several bars and therefore typically consist of 15-30 nm thick Si-based membranes. In practical terms, such membranes reduce signal contrast, and eventually resolution. Thus, thinner windows of similar strength and impermeability are needed to further improve imaging conditions.

The class of two-dimensional (2D) materials, and especially graphene, are interesting in this regard. It has been observed that graphene membranes sealing small volumes in a substrate can sustain pressure differences beyond 15 bars before delaminating from the substrate, and in addition, even a single layer of graphene is highly impermeable. 2D materials adhere to substrates via the Van der Waals force, and so graphene's ability to seal off a substrate, is of utmost importance, if graphene is to be employed as window material. At this stage, the performance of graphene-based seals at room temperature, i.e. leakage circumventing the graphene-based seal, exhibits large variation and allows gasses to leave sealed volumes through the interface between seal and substrate, making graphene-based windows impractical. Furthermore, the temperature dependence of the leakage have until now been unknown.

Methods
To investigate the leak from graphene-sealed volumes, we prepared electron transparent cavities and sealed them by mechanically exfoliating few-layer-graphene sheets on top. After exfoliation, the samples were cut to fit a GATAN heating holder. Prior to inserting the sample into the holder and subsequently the electron microscope, the cavities were filled with argon in a pressure chamber. Inside the vacuum of the TEM, the gradual decrease in argon content of the cavities was monitored as a function of time and temperature with Electron Energy Loss spectroscopy using a bottom-mounted Gatan Image Filter.

Results

At elevated temperature, the argon content of the cavities was found to decrease exponentially with time in accordance with what has been found at room temperature in previous studies. Furthermore, the exponential rate constant of the decay was itself exponentially dependent on the temperature, i.e. exhibiting an Arrhenius dependency. This indicates that the diffusion from the graphene-sealed cavities is a thermally activated process in which the argon atoms are surpassing an energy barrier. This behavior was found across different samples and cavities sealed by the same flake, showing the generality of the phenomenon. Surprisingly, repeated emptying and filling of the cavities at elevated temperature drastically improved the leak tightness of the seals, and in one case, the leak rate at room temperature improved 6 orders of magnitude from an already decent origin, as compared to previously reported leak rates. Consequently, some graphene-sealed cavities could after repeated experiments sustain pressures up to approximately 10 bars at 500 °C, while exhibiting a remarkably low leakage.

Conclusion
Our investigations reveal that graphene-based windows can be used for in situ and operando high resolution electron microscopy at elevated temperature and beyond pressures of a few bar. However, thermal engineering of the graphene seal is needed to tune the graphene-based seals' performance properly.

IM-10 (1), Lecture Theater 3, august 29, 2024, 10:30 - 12:30

Scanning Transmission Electron Microscopy (STEM) is a well-established method for looking into the physical properties of complex nanostructures. However, a major drawback is that acquiring very high-resolution images may lead to negative effects such as radiolysis and knock-on damage [1]. It has been shown that by lowering the electron beam dose, sample damage is reduced, however this leads to a lower signal-to-noise ratio (SNR) reducing the final quality of the image [2].
Convolutional Neural Networks (CNN) are a type of feed-forward neural network that is used as a powerful tool for improving image SNR through methods such as denoising. Recently, aberration-corrected STEM using CNNs has shown promising results, achieving resolutions below 0.1 nm. Specifically, improved SNR without using high-dose electron beams has been achieved by using CNNs trained on large datasets of microscopy data [3]. These methods have demonstrated the capability of CNNs to reduce damage to samples by improving image quality of low-dose STEM below 0.1 nm.
Inspired by the successful use of deep learning-based convolution for noise reduction [4] outside of STEM, we propose the use of self-supervised deep CNNs trained on both real and synthetic high-dose data to improve the SNR of low-dose data. We aim to create a robust network that is portable to methods outside of denoising by using the high-dose data to retrain the network for a variety of conditions [5] (such as hysteresis, defocus, and image blur).
This talk will present the results of utilizing self-supervised deep learning CNNs to improve the quality of low-dose data below 0.1 nm. We will also compare our proposed method to the STEM neural network autoencoder [3] and SDnDTI for Magnetic Resonance Imaging (MRI) [4] and discuss the potential of our method to improve upon on current methods within STEM as well as other domains by analyzing the SNR with the final image structural similarity (SSIM).

PS-04 (3), Plenary, august 27, 2024, 10:30 - 12:30

Lithium-ion batteries have revolutionized the field of portable electronics and electric vehicles by providing efficient and compact energy storage solutions. Despite advancements, several challenges continue to persist, such as limited battery lifespan, capacity degradation, and safety concerns. To address these issues and gain deeper insights into the underlying mechanisms, we present a comprehensive study involving an electrochemical liquid cell for in situ transmission electron microscopy (TEM) experiments. The utilization of the Dark Field technique (Figure 1) in this device enables us to directly observe the lithiation/delithiation process [1]. Through electron diffraction, we can track the modification of lattice parameters induced by the lithiation process.

In this study, we can observe the dynamic evolution of the delithiation interface between the LiFePO4 (LFP) and FePO4 (FP) phases inside a single crystal. This real-time monitoring provides valuable insights into the fundamental processes occurring during charge and discharge cycles. Additionally, we aim to evaluate the local displacement field extracted from the 4D-STEM ACOM (Acquisition of Crystal Orientation Maps) datasets [2-4]. Indeed, the lithiation process induces modifications in the lattice parameters of the FePO4 host, necessitating the calculation of the symmetric strain tensor at the LFP/FP interface and the estimation of the elastic free energy density. By integrating 4D-STEM data treatments and analysis, we can accurately characterize the strain distribution and its influence on the phase transformation dynamics.

To gain a comprehensive understanding of the lithiation/delithiation dynamics and further elucidate the underlying mechanisms, we employ phase field model to simulate the diffusion phenomena. The phase-field model has proven to be a powerful tool for studying phase transformations and microstructure evolution in materials. Here, we use an Allen-Cahn type phase-field approach to investigate the phase transition from LiFePO4 to FePO4 cathode crystals in the presence of Li-ion chemical potential difference with the surrounding liquid electrolyte. The solid-solid phase boundary between LFP and FP phases modeled as a diffuse interface of finite width [5], and its motion is implicitly governed by the phase-field variable. We numerically solve a set of partial equations describing the temporal evolution of the phase-field variable and the chemical potential [6, 12]. By incorporating the real particle morphology, obtained by TEM imaging, and considering the smoothed boundary method (SBM) [10], our phase field model provides a more realistic representation of the lithiation/delithiation dynamics within LiFePO4 crystals.

Initially, we employ a simple 2D model incorporating the chemical free energy and the interfacial free energy with a double-well potential approach [7]. By studying the kinetics of the lithiation/delithiation process within the LFP particle, which follows a one-dimensional Li-ion

diffusion path, we observe two distinct regimes known as Surface Reaction Limited (SRL) and Bulk Diffusion Limited (BDL), as described in [8]. Our simulations are obtained by varying a kinetic parameter l in our equations, this parameter is inversely proportional to the net rate of insertion R that we find in [11].
Furthermore, we extend our model by incorporating the elastic free energy to consider its influence on the phase growth direction and shape during the LFP/FP phase transition [9] within a realistic LiFePO4 single particle morphology. The elastic properties are adjusted using strain maps based on 4D-STEM data treatments and adaptative diffraction image registration.

In conclusion, this research explores the Li-ion insertion (or extraction) mechanisms into (or from) LiFePO4 crystals using in situ TEM experiments combined with phase-field simulations. The correlation between the phase-field model and the 4D-STEM results provides valuable insights into the complex dynamics of phase transformations and microstructure evolution, contributing to the understanding of key factors affecting the performance and lifetime of Li-ion batteries. Our approach contributes to the elucidation of the intricate process that drives the dynamics of lithiation inside individual cathode materials during the electrochemical process.

Poster Group 2

Two-dimensional material systems have garnered much attention since the first isolation of graphene[1]. Due to their low dimensionality, these materials exhibit interesting properties such as thickness dependent bandgaps [2] and magic twist-angle superconductivity [3], making them attractive for both experimentalists and theorists alike with much promise for industry application. In this study we focus on the utilization of electron microscopy techniques to experimentally characterise various chalcogen based 2D systems with the intent to compare it to Density Functional Theory (DFT) simulations.

Of particular interest for this study is the effect of various structural changes that influence the electronic structure. Firstly, a twist-angle induced Rashba splitting at the VBM in van der Waals heterostructures and secondly, the influence of various point defect complexes and their effect on the electronic band structure.

Herein, the angular dependence of GaS/GaSe heterostructures are theoretically studied via DFT calculations and compared to preliminary experimental studies. Electronic band structure calculations were performed on a series of twisted GaS/GaSe heterostructures with and without spin-orbit coupling (SOC) to investigate the effect of band splitting. The mobility of point defects in exfoliated PtSe2 was correlated using the climbing image Nudged Elastic Band method incorporated in the FHI-aims all-electron code. The atomistic models observed experimentally were geometrically optimized using FHI-vibes.

Bulk GaS and GaSe crystals (2D Semiconductors, Inc.) were exfoliated using the typical scotch-tape method. Flakes were carefully stacked and transferred using an all-dry viscoelastic stamping technique. In the study of point defect analysis and mobility, PtSe2 (HQ Graphene) was exfoliated through mechanical exfoliation to achieve few layer flakes. Scanning Transmission Electron Microscopy (STEM) imaging was performed using a FEI Titan 80-300 at 300 kV and a Nion UltraSTEM at 60 kV and 200 kV. STEM images were recorded with a high angle annular dark-field (HAADF) detector on a Nion UltraSTEM. Multi-frame imaging was utilised to reduced beam damage, while custom scan patterns minimised beam induced defect motion.

Results from first-principles calculations predict that GaS/GaSe heterostructures demonstrate the presence of Rashba spin splitting effects and an angular dependent band-gap shift. Rashba splitting was found to be asymmetric along different high symmetry paths. Heterostructures were fabricated at various twist angles and imaged using HAADF STEM with thickness measurements being performed via PACBED simulation. Low voltage HAADF-STEM was further utilised to investigate point defects inherent in exfoliated PtSe2. Many examples of Se/Pt vacancies and antisites were present

along with various combinations of the two. Mobile defects were observed in few layer regions. Fast frame image series were utilized to study the hopping nature of the defects to determine energetically favorable pathways.

The collaborative use of theoretical modeling via DFT and experimental characterisation through TEM was used to characterise novel 2D material systems.

Poster Group 1

Background: Telocytes (TCs) have been identified as a rather new and fascinating type of interstitial cell. Previously known as interstitial Cajal-like cells (ICLCs), these cells are now distinguished in the literature by their extremely long and thin telopods (Tp) and by the various sized vesicles they secrete into their environment. To date, these cells have been detected in several organs of humans and many other species. TCs are also found in female reproductive organs, although no data on the existence or morphological characterisation of TCs in human ovaries have been identified in the literature to yet. Furthermore, studies on human ovaries have shown the existence of many stromal cell clusters. However, there is still a significant lack of detailed research describing these cell types. This emphasizes the need for more research into understanding and identifying ovarian stromal cells, including the possible discovery of telocytes (TCs) in human ovaries. The ability of TCs for cell-to-cell signaling, plays an essential role in the regulation of homeostasis, immune surveillance and tissue morphogenesis. It has also been shown that these cells play important roles in angiogenesis, embryogenesis, and various pathologies or even tumorigenesis, under the guidance of tissue-resident stem/progenitor cell self-renewal and differentiation. Expressions or co-expressions of different markers of TCs have been reported in certain organs, but in general, CD34, vimentin, PDGRF-α and PDGRF-β, c-kit and α-SMA are primarily used in TC studies and these are so far considered as reliable TC markers. A combination of double immunofluorescence and electron microscopy is the definitive approach for identifying these cells, setting the gold standard in terms of accuracy and precision.
Aims: This research aims to advance our understanding of ovarian stromal cells and detect the presence of TCs by employing techniques such as immunohistochemistry and electron microscopy. Through the investigation of their morphology and identification of telocytes in the human ovarian stroma, this study endeavors to provide novel insights into ovarian architecture and its implications for reproductive health.
Methods: Tissue samples were obtained from women aged 18 to 65 undergoing Total Hysterectomy and Bilateral Salpingo-Oophorectomy (THBSO) for uterine reasons, excluding those who had received chemotherapy. After tissue preparation procedures for light microscopy, immunohistochemical and double immunofluorescence staining used CD34/c-kit, CD34/vimentin, CD34/PDGFR-β, and CD34/α-SMA markers for telocyte identification. Transmission electron microscopy and the immunogold technique, utilizing the CD34 marker, facilitated precise telocyte identification. This comprehensive approach aimed to illuminate telocyte presence and distribution in the ovarian stroma, offering future insights into ovarian physiology and pathophysiology.
Results: Our study confirms the presence of telocyte cells within the human ovary, characterized by their distinctive morphology. We detected telocyte cells in the ovarian stroma through

immunohistochemical analysis, labeling specifically with CD34 which is the most commonly used telocyte marker. Additionally, we utilized immunofluorescence analysis, employing double labeling with CD34/c-kit, CD34/vimentin, CD34/PDGFR-β, and CD34/α-SMA to further characterize these cells and distinguish them from fibroblasts and pericytes. We found out that TCs were strongly positive for CD34, PDGFR-β, vimentin, and weakly positive for α-SMA. On the other hand fibroblasts were found to be CD34 negative, while strongly positive for vimentin and PDGFR-β. Lastly pericytes were found to be CD34 negative and strongly positive for α-SMA and PDGFR-β. Notably, our findings delineate telocyte cells from fibroblasts and pericytes, underscoring their unique cellular identity within the ovarian microenvironment. Moreover, transmission electron microscopy provided detailed insights into the ultrastructural features of these cells, enriching our understanding of their morphology. TCs were recognized for their long and thin prolongations and small cell bodies primarily situated around blood vessels and dispersed throughout the ovarian stroma. Additionally, the use of the immunogold technique in conjunction with the CD34 marker facilitated the precise identification of telocyte cells, increasing the validity of our findings.
Conclusion: Overall, our study significantly contributes to the understanding of telocyte biology within the context of the ovarian stroma, shedding light on their presence, distribution, and morphological attributes, thus paving the way for further exploration of their functional significance in ovarian physiology and pathology.

Ptychography Optimization for Atomic Analysis of Bending Mode in Bilayer Transition Metal Dichalcogenide Translational Motion

Yunyeong Chang[1], Dr Jinseok Ryu[3], Prof Hyobin Yoo[2], Prof Heung Nam Han[1], Prof Miyoung Kim[1]
[1]Seoul National University, , Republic of Korea, [2]Sogang University, , Republic of Korea, [3]Diamond Light Source Ltd, , United Kingdom

Poster Group 2

Background incl. aims
Twisted two-dimensional transition metal dichalcogenides, have exhibited a variety of interlayer coupling phenomena and novel structural reconstructions, leading to modifications in electronic properties. However, the atomic-scale transitions within these reconstructed structures could be observed only on scales of a few nanometers, with transitional motions requiring differentiation at sub-nanometer scales. Thus, atomic scanning transmission electron microscopy-based methods are indispensable. However, due to the beam sensitivity and instability of structures, acquiring noise-free images has posed a challenge. In this study, we utilized ptychography as a fitting experimental methodology to investigate these twisted structures.
Methods
In our study, we employed suspended homobilayer WSe2 as the substrate for sample preparation. The fabrication process involved a tear and stack method, utilizing monolayers derived via the Scotch tape technique. For the analysis, we utilized ptychographic algorithms available in the abTEM and Py4DSTEM software packages. Both multislice and single-slice calculations were performed to analyze the data. This methodology allowed for a comprehensive examination of the atomic transitions within the suspended twisted 2D structures of the WSe2 samples.
Results
By adjusting various parameters for ptychography, we have identified the most stable conditions for examining suspended bilayer bending mode samples. The optimization of ptychographic conditions, including dose, focus, scan size, and other experimental parameters, has been pursued to secure the most effective imaging results. Under these optimal conditions, an atomistic analysis of the suspended bending mode twisted samples was conducted. Remarkably, the rippling domain boundaries, which had been theoretically anticipated for the bending mode, were directly observed through ptychography under low dose conditions, facilitating stable image acquisition. Furthermore, we have delineated the transition from the vertex AA core to the saddle point across varying angles, a phenomenon previously unobserved in High-Angle Annular Dark-Field (HAADF) imaging.
Conclusions
In conclusion, this study has leveraged ptychography to unveil novel insights into the atomic-scale transition of twisted two-dimensional transition metal dichalcogenides, achieving imaging clarity under optimized conditions. Our methodical approach in adjusting ptychographic parameters has enabled the direct observation of rippling domain boundaries and the intricate transition from the vertex AA core to the saddle point. These findings not only overcome previous limitations posed by beam sensitivity and structural instability but also significantly enhance our understanding of the structural and electronic properties of these complex materials, paving the way for future explorations and applications.

Comparative Analysis of Self-Supervised Learning Techniques for Electron Microscopy Images

Dr.-ing. Bashir Kazimi[1], Prof. Dr. Stefan Sandfeld[1,2]
[1]Forschungszentrum Jülich, Institute for Advanced Simulation – Materials Data Science and Informatics (IAS-9), Aachen, Germany, [2]RWTH Aachen University, Chair of Materials Data Science and Informatics, Aachen, Germany

Poster Group 2

Background incl. aims
Deep learning has revolutionized a wide array of tasks across different domains, including electron microscopy (EM) image analysis, by leveraging large labeled datasets for training. However, the scarcity of such labeled datasets in EM necessitates the exploration of alternative methods. Self-supervised learning (SSL) emerges as a promising approach to leverage unlabeled data, featuring techniques such as, e.g., masked image modeling (MIM) — which predicts missing parts of the input data, as well as contrastive learning — which learns by distinguishing between similar and dissimilar pairs of data. This study aims to investigate the impact of these SSL techniques on EM images, providing a case study on the effectiveness of leveraging unlabeled data in a domain where labeled datasets are limited and expensive to create.
Methods
Utilizing the “NFFA dataset”, which comprises 21,169 Scanning EM images across 10 categories, we established a baseline by training models from scratch with random weight initialization. We then pre-trained models using two SSL approaches: Masked Autoencoders (MAE) for MIM and Momentum Contrast V3 (MoCoV3) for contrastive learning, followed by fine-tuning on the NFFA dataset. Another pixel-based MIM technique, Multi-level Feature Fusion (MFF), was also tested. The performance of each SSL technique was evaluated based on accuracy improvements and convergence speeds relative to the baseline. Our analysis highlights the distinctions between MIM and contrastive learning approaches in handling EM images.
Results
The baseline model yielded an accuracy of 77.42%. Upon employing SSL techniques, significant improvements were observed: finetuning with MAE weights achieved an accuracy of 92.84%, MFF led to 93.86%, and MoCoV3 led to an accuracy of 92.56%. MFF, in particular, demonstrated a superior ability to enhance feature learning from unlabeled data, indicating its impact in the task of EM image classification. Furthermore, all SSL-pretrained models showcased accelerated convergence rates compared to the baseline.
Conclusion
This study confirms the viability and potential of SSL techniques in EM images. MIM, exemplified by MFF, outperformed contrastive learning in this domain, suggesting that methods focusing on reconstructing or predicting unseen parts of the image are particularly beneficial for EM tasks. The results advocate for a targeted selection of SSL strategies based on specific dataset characteristics and task requirements, highlighting a path forward for efficient model training in EM image analysis and beyond. The influence of SSL pretraining was studied in this research and experiments were conducted on SEM image classification. Further research in this direction includes investigating the influence of SSL pretraining on dense, pixel-wise classification (i.e., semantic segmentation) tasks in EM.

EDX-based annotation of biological features in large-scale EM

Peter Duinkerken[1], Dr. Ahmad Alsahaf[1], Dr. Jacob Hoogenboom[2], Dr. Ben Giepmans[1]
[1]Department of Biomedical Sciences, University Groningen, University Medical Center Groningen, Groningen, the Netherlands, [2]Department of Imaging Physics, Delft University of Technology, Delft, the Netherlands

Poster Group 2

Background
Advances in electron microscopy (EM) of bio-samples now enable ultrastructure to be inspected at biologically relevant scales. Capabilities in data analysis have however not kept pace with the throughput increase offered by novel acquisition approaches and automation. Moreover, the greyscale nature of the electron micrographs complicates a comprehensive analysis of all that is hidden within. The analysis of EM datasets is typically based on manual annotations, allowing in-depth analysis by segmenting the data into biologically meaningful features. However, such annotations are laborious and subject to the annotator's interpretation of the data. Furthermore, deep learning can used to automate segmentation but the need for manually annotated ground 'truth' remains. Energy-dispersive X-ray (EDX) imaging, or ColorEM, provides elemental context to the recorded ultrastructure, allowing variations in elemental concentrations to be reflected in color [1]. In this study we further tailored acquisitions to ColorEM and explored its potential to highlight biological features in a data-driven manner.

Methods
Pancreatic tissue composed of hormone-containing endocrine cells and zymogen-containing exocrine cells was epoxy-embedded and subjected to ultramicrotomy. A Thermo Fisher Scientific Talos S/TEM equipped with two Bruker XFlash 6-100 EDX detectors was used to interrogate the sectioned sample. The spectral richness was promoted by improving the acquisition parameters necessary for heterogenous cellular material. Greater context was provided through a mosaic acquisition of a full islet of Langerhans.

Results
ColorEM has been further improved and successfully implemented on pancreatic tissue. The high-resolution and energy-dispersed recordings allow the ultrastructure of biological tissue to be visualized in its elemental context. Various biological features such as heterochromatin, hormone- and zymogen-containing granules and lysosomes, can be readily discerned in the elemental images. The final large stitched image not only provides elemental context to the ultrastructure, but also places this in the larger context of the tissue.

Conclusions
Here we implement large-scale ColorEM, supplementing the spatial EM data with spectral EDX data. We leverage the addition of the spectral dimension to provided elemental context to the recorded biological ultrastructure, with the tiled acquisition providing the context of the tissue. Selection of which elements to visualize is based on a data-driven approach where the dissimilarity in terms of elements, and combinations thereof, amongst the biological features are identified.

Improving segmentation of FIB tomography data

Dr.-Ing. Martin Ritter[1], M.sc. Trushal Sardhara[2], Prof. Dr. med. Roland Aydin[2], Prof. Dr.-Ing. Christian Cyron[2]
[1]Electron Microscopy Unit, Hamburg University of Technology, Hamburg, Germany, [2]Institute for Continuum and Material Mechanics, Hamburg University of Technology, Hamburg, Germany

Poster Group 2

Background incl. aims
Accurate reconstruction of nanostructures using focused ion beam (FIB) tomography data is challenging due to slicing and imaging artefacts, as well as intensity ambiguities in the scanning electron microscope backscattered electron (BSE) images. We propose a multimodal machine learning approach that combines intensity information obtained at multiple electron beam accelerating voltages (multiV) to improve the three-dimensional (3D) reconstruction of hierarchical nanoporous gold (HNPG) structures. The proposed method significantly improves segmentation accuracy and leads to more precise 3D reconstructions for real FIB tomography data.
Methods
MultiV FIB tomography of epoxy infiltrated HNPG with ligament sizes of 15 nm and 110 nm was performed using a Dual Beam FEI Helios NanoLab G3 system and its ASV4 control software for automated tomography. During multiV tomography, each slice was imaged using a BSE detector three times with accelerating voltages of 1, 2, and 4 kV and a beam current of 50 pA. To compensate for drift during the process, 2 fiducial markers were prepared and positioned on the cross-section and on top of it. A ruler system was implemented also on top of the cross-section to monitor and measure the thickness of each slice. We developed 3 multimodal architectures for 3D nanostructure reconstruction with machine learning, employing different data fusion techniques: early fusion, intermediate fusion and late fusion.
Results
Our results indicate that the late fusion architecture excelled among the three options. Remarkably, the intermediate fusion architecture exhibited significantly poorer metrics than the late fusion architecture. This drop in performance can be attributed to the large size of the ML model, which posed challenges for optimization given a limited amount of training data. However, the effectivity of training data may be improved using domain adaptation. In a comparative study, confronting our ML-multiV method with a cluster-based k-means clustering algorithm and also ML models trained using individual single kV datasets, the multiV model outperformed all other segmentation techniques.
Conclusion
FIB-SEM tomography data are affected by artifacts and ambiguities in image intensities. These effects make it difficult to use cluster-based segmentation methods. More advanced ML-based methods can efficiently suppress the effects, even when trained only on a single set of synthetic FIB tomography images. The multimodal ML method with a late fusion architecture using multiV imaging data will further improve segmentation accuracy.

PS-09, Lecture Theater 2, august 26, 2024, 14:00 - 16:00

Background
Aluminate structures present phase formation anomalies irrespective of the initial stoichiometry of the oxide powder mixes. In metal oxide systems (Me2+ or Me3+), multiphases form at different cation to aluminum (Mex+/Al) ratios. Singh and his colleagues observed multiple phase formation in starting mixture ratios of CaO to Al2O3; 1:1, 1:2 and 3:1. Even if the stoichiometry started from calcium or aluminum rich compositions, CA was present in the diffractograms (Singh et al. 1990. p.873). Previous studies on calcium aluminates suggested that large cation size of Ca2+ may create a difficulty of diffusion into the Al2O3 (Tian et al. 2016. p.104). Tian and his coworkers demonstrated the distribution of Ca-rich phases with backscattered electron (BSE) images towards the outer layers of the core shell structure. In the center of this core shell structure Al2O3/CA6 was present. We observed that the first forming phase in strontium, calcium and yttrium aluminate systems is 1:1 oxide compound SA (SrAl2O4), CA (CaAl2O4), and YAP (YAlO3) irrespective of the starting Mex+/Al3+. This study claims that the Mex+/Al ratio at the interface determines the first forming incipient phase. Also, it appeared that having a single type of Al-O coordination polyhedra is facilitating the phase formation in aluminate systems.

Methods
SrO-Al2O3 binary system have 6 compounds: Sr4Al2O7, Sr3Al2O6, SrAl2O4, Sr4Al14O25, SrAl4O7, and SrAl12O19 (Fig.1). Phase pure aluminate powders were synthesized using Pechini method. Crystallization temperatures of aluminate powders were determined with thermogravimetric analysis. Phase distribution above 800-900 °C, the first crystallization, was recorded with ex-situ XRD by 50-100 °C temperature slots. Isothermal heating of 1 hour was applied to compounds. The temperature was increased until there was no change in the phase distribution of each compound. These powders were used to acquire Al-L2,3 and O-K ELNES edges of phase pure aluminate compounds with different stoichiometry to be used as a fingerprint of the compound.
Heating temperatures of deposited substrates were selected for each compound in a way that samples were XRD phase pure of desired stoichiometry. Amorphous or crystalline precursors having different Ca/Al ratio were deposited on sapphire substrates with different orientations. The effect of changing stoichiometry at the interface of the reaction couple was adjusted as a coating. Each deposited substrate was characterized with scanning electron microscopy (SEM) and X-Ray diffractometry (XRD) before the sample preparation for transmission electron microscopy (TEM). Then, the first structure to form at the interface was analyzed with the help of high-resolution TEM (HRTEM), HR-STEM, and EELS-ELNES. Different aluminate compounds at the interphase between reaction couples were compared with ELNES fingerprint of each pure aluminate compound.

Results

All sapphire substrates were analyzed with X-ray diffractometry (XRD). Four strontium aluminates were identified with ELNES edges (Fig.2 a-d). Al-L2,3 edge at an energy of 73.1 eV was chosen as the fingerprint for each aluminate compound. K edge of oxygen is at 532.0 eV. We tried to identify the incipient structures at the interface of sapphire-aluminate film with different Sr2+/Al3+ ratio with the Al-L and O-K fingerprints of phase pure compounds.

Conclusion
Our study was a first attempt to clarify what kinetic constraints are determining the incipient metastable aluminate phase in Sr-, Ca-, Y- aluminate systems.

Liver-secreted albumin is the most abundant protein in blood plasma and cerebrospinal fluid. We have previously developed liver-targeting adeno-associated viral vectors (AAV8-P3-*) that express fluorescent protein-tagged albumin to visualize blood plasma in adult mice (DOI: 10.1016/j.crmeth.2022.100302). We have also established a virally induced CRISPR/Cas9-based knock-in of green fluorescent albumin in neonatal mice (DOI: 10.1101/2023.07.10.548084). Here, we have generated a new transgenic mouse model by CRISPR/Cas9 in which the bright red fluorescent protein mScarlet is knocked into the albumin locus to produce mScarlet-tagged albumin (Alb-mSc). In adult heterozygous knock-in mice, the plasma fluorescence signal intensity recorded an order of magnitude higher than a standard AAV-expressed Alb-mSc (AAV8-P3-Alb-mSc, 2E11 vg). This strong plasma fluorescence allowed for the imaging of the entire depth of the cortical vasculature reaching to the white matter (up to ~1mm in depth) by two-photon microscopy. Thin skull preparation enabled the visualization of dura mater by “shadow imaging”, where Alb-mSc presumably infiltrated into the interstitial space from dural vessels. Furthermore, Alb-mSc mice were crossed with Prox1-eGFP mice to delineate lymphatic structures. Alb-mSc signals were subdural interstitial space were clearly attenuated reflecting the composition of cerebrospinal fluid. Nonetheless, shadow imaging was possible in the cortical parenchyma, whereby cortical neurons are detected by the relatively high fluorescence of the extracellular space. The knock-in mouse line offers multi-purpose utilities for studying morphological and functional changes in the brain and other organs.

Background incl. aims
During (scanning) transmission electron microscopy ((S)TEM), the energetic electrons used for imaging can lead to damage in the sample. Electron knock-on damage caused by elastically scattered electrons is the best known of such damaging mechanisms, and has been studied extensively also for 2D materials. In contrast, less is known about the damage mechanisms in insulating materials, such as hexagonal boron nitride (hBN) . In early studies, it was shown that extended irradiation leads predominantly to the formation of triangular nanopores. These pores and their triangular shape were suggested to arise from direct interaction between the electrons and the material, and it was shown that the dominated zig-zag edges were nitrogen terminated.
Methods
The Nion UltraSTEM 100 microscope integrated into our experimental setup at the University of Vienna allows experiments at low pressure atmosphere between ultra-high-vacuum (UHV) ~ 1x10-10 mbar and 4x10-6 mbar by carefully leaking the desired gas into the column. Measurements at varying pressures have already shown that the partial pressure of different gases can have an influence in the damage observed in graphene. Specifically, it was shown that different graphene edges dominate under an oxygen atmosphere and in UHV.
Results
Here hBN was imaged at UHV and up to an oxygen pressure of around 2x10-8 mbar. The most prominent finding was that the shape of pores that appeared under electron irradiation depends on the oxygen partial pressure. As an example, medium angle annular dark field (MAADF) images are shown in figure. In UHV the pore shape is round with no preference of either boron or nitrogen termination, whereas triangular pores emerge with rising oxygen partial pressure, with edges dominated by nitrogen atoms. The rate of pore growth also increases with increase in oxygen partial pressure in microscope column, and no any pore growth was observed when the sample was exposed to air without electron irradiation.
Conclusion
The results suggest that the shape of the pores observed in the earlier studies was determined by the composition of the microscope vacuum. The pores grow only under electron irradiation and their shape depends on the vacuum conditions.

Background
Phase change materials (PCM) are an emerging class of materials in which different phases of the same material may have different optical, electric, or magnetic properties and can be used as a phase change memory [1]. Phase-change memory materials, exemplified by (Ag, In)-doped Sb2Te (AIST) in this research, have several advantages, including high-speed read and write operations, non-volatility, and a long lifespan [2]. PCMs are able to switch between amorphous and crystalline phases when subjected to heat or electrical current. However, the full understanding of PCMs depends heavily on accurate characterization, often through techniques such as scanning transmission electron microscopy (STEM).
In the field of materials science and nanotechnology, the analysis of STEM diffraction patterns is crucial for understanding the structural characteristics of materials, especially in the context of PCMs. Accurate interpretation of diffraction patterns is essential for crystallographic analysis, phase identification, and grain visualization during an in-situ switching experiment. However, the analysis of STEM diffraction patterns in PCMs can be challenging due to the presence of noise and weak signals (Fig.1 left).
Methods
In this study, we present a solution to address the challenge of grain visualization in PCMs. We propose an unsupervised machine learning (ML) approach that employs an autoencoder to denoise STEM diffraction patterns.
Autoencoders are neural network architectures that have the ability to learn in an unsupervised manner and that are able to represent complex data in a lower-dimensional, noise-reduced form [3]. By applying this technique, we enhance the quality of diffraction patterns, improving the signal-to-noise ratio, which is highly beneficial for further analysis and visualization.
Results
Our results demonstrate a significant enhancement in the clustering and visualization [4] of crystalline grains within STEM diffraction patterns of phase change materials. By reducing noise and enhancing signal clarity, the unsupervised ML-based denoising technique allows for more precise discrimination between different crystallographic orientations and refines the identification of grain boundaries.
Furthermore, we employed clustering based on the non-zero order peak position. Nnotably, this approach yielded significantly improved results for the denoised data (Fig. 2).
Additionally, the proposed denoising enhances pattern-matching quality in commercial orientation mapping software (ACOM ASTAR), indicated by higher average index values and more visible structure in index maps, as illustrated in Fig. 3), facilitating precise analysis of crystallographic orientations and grain boundaries.
Conclusion

The proposed approach paves the way for a deeper understanding of phase change behavior, aiding in designing and optimizing PCMs for various applications, from thermal energy storage to non-volatile memory technology.

As an unsupervised method, it does not require the laborious production of specific training data and, therefore, can serve as a universal tool for STEM diffraction pattern denoising and signal enhancement. Last but not least, the proposed denoising technique is not limited to PCMs; therefore, our work can be understood as a general strategy for enhancing diffraction patterns.

Poster Group 2

Background
Since the first report of carbon nanotubes (CNTs), formidable efforts have been devoted to the synthesis of nanoscale tubular one-dimensional structures. Interest is due to their future applications, such as nanoelectronics, optoelectronic and biochemicalsensing devices. Despite their outstanding mechanical and electrical properties, CNT's success fueled the interest in alternative one-dimensional materials that can be mass-produced with high purity. Boron, positioned adjacent to carbon on the left side of the periodic table, exhibits a diverse chemistry comparable only to that of carbon. Because of electron-deficient nature of elemental boron, the BNTs can be identified as promising candidate materials. Recent experiments demonstrating the synthesis of boron nanotubes have heightened interest and expectations regarding their potential applications in various fields. The aim of our study is to develop an understanding for new process that allows the production of BNTs from boron spheres and hollows under milder process conditions.
Methods
All the chemicals were purchased and applied as received without further purification. The experimental materials used in this work were boron powder (purity ≥95%) and isopropanol (purity ≥99,5%). The Boron powder precursor was first mixed in isopropanol. The mixture sonicated with a prope-type sonicator at 400 W under nitrogen atmosphere for 4 h, followed by centrifugation at 4750 rpm for 40 min. The supernatant was collected and thermally treated at 200˚ C in the autoclave with a PTFE container for 12 h. Then 0.05 mL of this sample was dropped on a TEM grid, and the solvent was evaporated prior to transmission electron microscopy (TEM) analysis. The TEM results were obtained using the JEOL JEM-ARM200CFEG UHR-TEM (equipped with STEM, Cs corrected STEM, EDS, Gatan Quantum GIF and Digital CCD Camera) at 200 keV.
Results
When the TEM image at low magnification is examined, the presence of round-shaped amorphous particles with diameters ranging between approximately 50nm and 150 nm is observed, as well as tubes with a length of approximately 200nm and a diameter of 40nm (Fig1). The hallow-like structure can be clearly discerned from the TEM observation (Fig2, Fig3 and Fig4). We believe that, all of these happenings during the production process in the reaction vessels and by the centrifugation depending based on separation of the different structures. We are trying to understand the factors that influence the formation or transformation of different boron structures in particular boron nanotubes. EDS analysis of selected regions shows that the structures are composed of boron with some other impurities (Fig 5). When the ELNES shared in Figure 6 is examined, it is seen that the results in terms of boron element coincide with the EDS data, suggesting that boron is oxidized.
Conclusion
In the method we have developed, it has been seen that boron nanotubes can be produced by ultrasonication. However, it is clear that sonication time, sonication power, thermal treatment and centrifugation parameters should be further optimized. In addition, our studies will continue to increase the nanotube production efficiency and to realize pure production by separating from round-shaped amorphous structures. The fluorine contamination revealed in the EDS analysis is

thought to be due to the PTFE container inside the autoclave where the thermal treatment was carried out. Sodium, calcium, iron and sulfur are estimated to be impurities originating from the boron precursor used in the experiments. It is considered that there is a strong possibility that the detected Titanium may be caused by the ultrasonic probe. Based on the results obtained, the effects of the elements detected and evaluated as impurities at this stage on the formation of boron nanotubes continue to be examined.

Background incl. Aims: Recent advances in data acquisition, processing and sample preparation [1,2,3] have made cryo-electron tomography (cryo-ET) a powerful technology for investigating subcellular processes in situ. However, its usage for clinically relevant systems such as tissues, organoids and other 3D cell cultures remains limited due to the increased sample preparation complexity: With increasing sample thickness, direct milling on its substrate is not always possible. Alternatively, region-of-interests can be removed from the bulk, lifted to a new sample substrate and thinned finally to an electron-transparent lamella of less than 300 nm thickness. Both approaches, the so-called waffle [1] as well as the lift-out [2] method, are typically performed using a gallium ion beam for milling. Due to the low sputtering yield of gallium and the low ion beam currents available in conventional focused ion beam (FIB) microscopes, the throughput of both techniques is limited and the resulting slow lamella preparation poses a major bottleneck in clinical cryo-ET applications. Substantially faster sample preparation is expected with the recently introduced plasma FIB microscopes [4] because of the higher sputtering yields of the different ion beam species and the higher available ion beam currents offered. However, it is currently not characterised how the different ion species and higher currents of the ion beam might impact the sample integrity and how such structural damage propagates through the sample material. Here, we systematically investigate the structural damage caused by different ion beam species and currents. For this, we compare the structural preservation of proteins (e.g. ribosomes) with increasing distance to the impact centre for increasing beam currents by serial lift-outs [5] (see figures A, B). Our findings can be directly used to improve the efficiency of both standard as well as advanced sample preparation approaches, thereby enabling cryo-ET investigations of clinically relevant patient tissue.
Methods: To ensure uniform sample vitrification, S. cerevisiae were high-pressure frozen with a thickness of 20 µm in 20% dextran. To quantify the impact of strong ion beam currents, 100 µm long lift-out blocks were exposed to standard 1 nA and only one side was treated with a high current (15, 60, 200, 500, 1000, 2500 nA; figures A, B). The lift-out block was then cut into a series of 5 µm thin slices, therefore increasing distance to the high-current impact side with each slice. Each slice was then thinned to less than 300 nm. For detailed damage evaluation, tomograms were acquired and reconstructed followed by ribosome picking and subtomogram averaging (Thermo Scientific Tomography 5, AreTomo, crYOLO and Relion 3.1.2).
Results: We examine in total three different types of damage induced by high-current milling: 1) specimen level damage that is already evident by FIB/SEM imaging, 2) damage affecting lamella quality, such as devitrification and curtaining, that is visible by low-magnification TEM imaging and 3) structural damage on molecular level that is only apparent after tomogram acquisition and subtomogram averaging. Damage at specimen level (figure B) and lamella level (figure C) affect both the quantity and quality of lamellae that can be milled in a given time frame. The third type of damage will elucidate which currents can be used for sample preparation to still achieve high resolution after subtomogram averaging (figure D). The usage of serial lift-out allows us to trace the

expected damage gradients after high-current milling for up to 100 µm from the area of impact and gives unprecedented insights into milling-induced damage in biological samples.
Conclusion: Our research provides the first systematic analysis of plasma FIB currents and their induced damage. Having these profound insights into sample-beam interaction will be of great value for developing high-throughput sample preparation pipelines for bulk specimens.

Poster Group 1

Background incl. aims
This work aims to resolve the structure - property relationship in granular Aluminum (grAl) thin films. GrAl is currently applied in microwave kinetic inductance detectors, parametric amplifiers, fluxonium qubits, resonators and filters. The granular structure and crystallite size distribution of the Aluminum particles have been known for a long time through dark field TEM imaging. The disadvantage of dark-field TEM is that it shows a 2D-projection of a 3D-network. In order to resolve the interconnection between the Al particles, 3D-STEM tomography was applied to resolve the morphology of the grAl. Combination with accurate models for simulations will advance the understanding of granular superconductors and their properties.
GrAl is produced by physical vapor deposition of Aluminum in presence of partial Oxygen pressure. It is a so-called ‘dirty superconductor’. The emerging granular Aluminum nanostructure that is embedded in amorphous Aluminum oxide features tunable non linearity, kinetic inductance and low AC losses in its superconducting state. The Aluminum grains are assumed to form Josephson junctions between each other. A phase shift is induced on the superconducting current while tunneling through a small insulating Aluminum oxide gap between grains. Tunability of the non-linear properties is achieved by adjusting the room temperature resistivity of the film and varying the number of junctions in the network by changing the volume of a grAl component.
The critical temperature for superconductivity TC over the room temperature resistivity of the films reveals a dome shaped relationship with its maximum of 3 K at around 500 µΩcm while TC for pure aluminum is at 1.2 K. Depositing the films on cold substrates decreases Aluminum crystallite size and raises TC even beyond 3 K.
Methods
Two samples are investigated with 120 µΩcm and 25000 µΩcm resistivity. The films of 20 nm thickness are deposited on lacey Carbon TEM grids for easy nanowire templating. Gold fiducial markers are drop cast on the grid. The coated Carbon laces are investigated by energy-filtered TEM (EFTEM) on a Thermo Fisher Scientific Titan Themis Z at 80 kV with a Gatan image filter. EFTEM tomography was applied to reveal changes in al plasmon peak. The tilt series is aligned with the help of fiducial marker positions and is reconstructed using the Discrete Algebraic Reconstruction Technique (DART). Contrast levels are being estimated from an initial Simultaneous Iterative Reconstruction Technique (SIRT) reconstruction.
Results

STEM and TEM imaging show minimal contrast variations between Aluminum Oxide and metallic Aluminum due to similar atomic masses. Image corrected HRTEM shows partially polycrystalline grains in projection. EFTEM at 14 to 16 eV shows good contrast of the Aluminum volume plasmon which is confined to the Aluminum particles. Aluminum Oxide and Carbon give minimal intensity contributions. The low resistivity sample with 120 µΩcm is reconstructed as a network of interconnected 5 nm Aluminum particles with a surface oxide cover of 3 nm. An oxide barrier separating close grains cannot be resolved. The non-linear inductive behavior can be explained with constrictions in the conductive path through the grains instead of oxide barriers as initially assumed. The high resistivity sample with 25000 µΩcm is reconstructed with 3 nm grains a notably bigger surface oxide layer of 12 nm. Many grains are still interconnected but there are oxide barriers separating clusters of grains from each other. The interconnection of grains at high resistivity is either a reconstruction artefact or shows that already a small amount of oxide barriers is sufficient for high non-linearity.

Conclusions

This study provides a novel insight into the 3D morphology of granular Aluminum (grAl) thin films, challenging previous assumptions about the structure-property relationship in these materials. The advanced electron microscopy techniques have revealed that the non-linear properties of grAl are more likely due to constrictions in the conductive path through the grains rather than oxide barriers. Furthermore, the study has shown that even a small number of oxide barriers can result in high non-linearity, particularly in high resistivity samples. These findings pave the way for more accurate simulations and could potentially enhance the performance of devices that utilize grAl. Further research is needed to fully understand the implications of these results and to explore the influence of substrate temperature during deposition on the structure of these films.

PS-11, Lecture Theater 2, august 28, 2024, 14:00 - 16:00

Background incl. aims

Quantum sensing is one of the most advanced quantum technologies. Quantum sensors based on single electronic spins, or small spin ensembles, can deliver nanoscale spatial resolution in detecting magnetic fields. This property has been exploited in breakthrough experiments in the biomedical field ranging from localised detection of free radicals [1] or temperature [2] inside living cells, the demonstration of magnetic resonance imaging on picoliter samples [3], to the identification of HIV with >10^5 better sensitivity than classical methods [4]. However, we have only just started scratching the surface of the application potential of quantum technology into biomedical research and development. Our group has been developing novel nanodiamond-based quantum sensing protocols to investigate mechanoregulation of metabolism at sub-cellular level. In this study, we have focused on the mechanoregulation in the heart scar formation. The myocardial scar formation known as cardiac fibrosis is a key contributor to heart failure. Anti-fibrotic therapies are still under development due to limited understanding of molecular processes behind scar formation. The cardiac fibrosis starts with changes in the mechanical properties of a heart extracellular matrix (ECM), which leads to transdifferentiation of cardiac fibroblasts (quiescent stage) into myofibroblasts (activated stage). We have very little knowledge about how mechanical stimuli govern fibroblasts metabolic plasticity. Free radicals (FRs), a class of reactive molecules with an unpaired electron, have emerged to be crucial for intracellular signalling. However, as FRs are short lived and difficult to detect with the state-of-the art-methods, therefore their role in cardiac metabolic plasticity remained unknown. In our studies, we aimed to reveal the role of FRs in lipid plasticity of cardiac fibroblasts in response to mechanical stimuli with quantum sensors.

Methods

The experiments were performed on primary human cardiac fibroblasts cultured on stiff (Young modulus >10 kPa) and soft (Young modulus <10 kPa) substrates to stimulate their activation. All experiments were performed for young (2nd passage) and aged cells (>5th passage). We used a quantum sensing technique called T1 relaxometry [5] to detect changes in free radical generation by mitochondrial networks. Fluorescent nanodiamonds (FNDs) with NV- centers were used as sensors. We modified the surface of the nanodiamonds with antibody for targeting their delivery to mitochondria. Then we checked the uptake efficiency and colocalization of FNDs with mitochondria and transporting vesicles inside the cells. In these studies, the T1 relaxometry was for the first time combined with optical trapping of FNDs to simultaneously measure FRs and viscoelastic properties of mitochondrial networks. We further evaluated changes in lipidome with single cell lipidomics using MALDI mass spectrometry imaging and fluorescent imaging of stained lipids.

Results

Our studies have demonstrated that uptake of the nanodiamond sensors depends on the age of cells and stiffness of the substrate. We have shown successful targeting of FNDs to mitochondria, which was independent of age of cells and substrate stiffness. We have found that FR generation by mitochondrial networks shows some dependence on the age of the cells and also indicate mechanoregulation. Furthermore, the mechanical stimulation and age of cardiac fibroblasts influence heterogeneity of lipotypes and their distribution across the population of quiescent and activated cells. We have shown lipotype correlation with the FRs level and viscoelastic properties of mitochondrial networks.

Conclusion

As a result, our research shed light on the mechanobiology of the heart scarring process. We have proven that quantum sensing combined with optical trapping can be used to study mechanoregulation of metabolic plasticity of cardiac fibroblasts. Our simple quantum sensing model of mechanoregulated cardiac fibrosis could be further developed towards 3D cell cultures and serve as screening platform for metabolic drugs.

LS-07 (2), Lecture Theater 5, august 28, 2024, 14:00 - 16:00

Background incl. aims
Mitochondria are the main source of ATP and their ultrastructural features as well as their subcellular distribution depend on cell type and metabolism. In urothelial superficial umbrella cells, ATP is required for the synthesis and delivery of urothelial plaques by fusiform vesicles to the apical plasma membrane where they form a tight permeability barrier between urine and body fluids [1]. On the other hand, mechanical stretch of urothelium during bladder filling promotes ATP production and excretion into extracellular space [2]. ATP activates purinergic receptors on afferent nerves and interstitial cells in the lamina propria and on smooth muscle cells of detrusor. This ATP signalling pathway induces detrusor contraction and thus emptying of the bladder. Mitochondrial structural changes in urothelium were reported in aging organisms and some bladder disorders [3]. Our aims were to preserve the ultrastructure of umbrella cells close to native state in the living organism and to develop a method for the automatic segmentation of mitochondria.

Materials and Methods
Mouse urothelium was high pressure frozen (Balzers HPM010), freeze-substituted (Leica AFS) and embedded in Epon. Ultrastructural features of umbrella cells were examined on ultrathin sections (Philips CM100). The volumetric data from the umbrella cells was generated by Ga-ions milling and imaging in FIB-SEM (Helios NanoLab 650). For automatic segmentation of mitochondria from FIB-SEM data, we propose a pipeline based on a volumetric convolutional neural network with mechanisms that reduce the impact of noisy and inconsistent input data. The main features of the proposed pipeline are a contrast enhancement technique, usage of segmentation masks, and zero-mean convolutions.

Results and Discussion
Ultrathin sections showed numerous flattened fusiform vesicles (Figure 1a) that were composed of two parallel urothelial plaques, which confirmed superior preservation of umbrella cells ultrastructure [4]. Mitochondria with smooth outer membrane were oval to elongate (Figure 1b). Sometimes narrowing was observed (Figure 1c), which point to fissions and fusions of mitochondria [3]. Our approach produced state-of-the-art results for extraction of mitochondria from FIB-SEM volumes [5]. 3D visualization of segmented volumes presented a global distribution of numerous mitochondria within umbrella cells (Figure 1d). Some mitochondria are tubular or globular, but many of them form complex structures (Figure 1e), indicating dynamical changes possibly associated with their various functions [4].

Conclusion
We believe that our approach can be used to better understand the role of mitochondria in normal and in pathological conditions in urothelium as well as other tissues.

Figure 1: Ultrastructure of the umbrella cell and 3D model of their mitochondria. A) Cytoplasm of high pressure frozen – freeze substituted umbrella cell contains mitochondria (M) and tissue specific fusiform vesicles (FV), which could also be organized into stacks (FVs). Investigating microstructural phenomena in Additive Manufactured metals through high temporal thermal cycles in-situ heating

Dr. Alice Bastos da Silva Fanta[1], Yi-Chieh Yang[1], Christina Koenig[1], Prof. Joerg Ralf Jinschek[1]
[1]DTU Nanolab, Kgs. Lyngby, Denmark

Poster Group 2

Background incl. aims:
Additive manufacturing (AM) of metal components holds significant potential for delivering customized design, improved flexibility, and cost-effective production. However, controlling the microstructure-defined properties of AM components is a major challenge due to the inherent complexity of extreme thermal processes that form the AM microstructures. Material solidification and solid-solid phase transformation occur under far-from-equilibrium [1] conditions in cyclic layer-by-layer processes. Accordingly, established phase diagram predictions are not significantly relevant for understanding and predicting the phase formation and their consequences for the component properties. Real-time observation of microstructure evolution during AM thermal cycles at sub-µm resolution is therefore crucial for controlling microstructure related properties of AM components, as well as for exploring “unusual” microstructure formations, leading to new and exciting properties.
Methods:
In-situ electron microscopy studies offer the potential to investigate such microstructure phenomena with resolution ranging from mm down to sub-nm. However, achieving extreme thermal profiles, such as those occurring during AM process inside a microscope are not trivial.
Micro-heating devices, based on microelectromechanical systems (MEMS) combine very fast (10^3 ^{o}C/s) heating and cooling rates with high stability [2] and are potentially able to reproduce the thermal cycles of AM process. However, they were primary developed for studies of electron transparent samples smaller than 20 µm in transmission electron microscopy (TEM).
Results:
In this work we will present our efforts in exploring the high heating rates of MEMS heaters to mimic the thermal cycles of AM process inside the scanning electron microscope (SEM) and in the TEM. Supported by computational modelling (COMSOL) and indirect measurements such as Raman spectroscopy, we investigated the limits and the accuracy of MEMS heaters depending on e.g. sample size, environment, and heating rate and will discuss the prospect and limits of this approach. Furthermore, we will present the first electron backscatter diffraction (EBSD) and transmission Kikuchi diffraction (TKD) results demonstrating the potential of correlating microstructure characteristics with non-equilibrium phase transition during AM process.
Conclusion:
Our findings provide deeper understanding and highlight the potential of simulating AM thermal cycles inside the electron microscope using MEMS heater both in the TEM and in the SEM. Specially for metallic specimens, our results shows the capability of replicating ramping rates and temperature gradients inherent to AM processes within the electron microscope, thereby enabling the correlation of microstructural characteristics with phase transitions with spatial resolution varying from sub-nm to µm. This work contributes to advancing the understanding of simulating AM thermal cycles within the electron microscope, offering opportunities for enhanced characterization and analysis of materials under extreme heating conditions.

The effects of solution processing methods on halide perovskite nanostructure

Dr Alexandra Sheader[1], Dr Ryley Ratnasingham[2], Dr Nakita Noel[1]
[1]University of Oxford, Oxford, UK, [2]Eindhoven University of Technology TU/e, Eindhoven, Netherlands

Poster Group 2

Background:

Over the last decade, hybrid lead halide perovskite (LHP) materials have emerged as auspicious candidates for next-generation thin-film photovoltaics. This is largely due to both impressive optoelectronic properties and photovoltaic power conversion efficiencies, making them ideal for next-generation solar applications. Within this class of materials, formamidinium lead triiodide ($FAPbI_3$)-based perovskites are of particular interest due to their near-ideal bandgaps and improved thermal stability [1]. However, the photoactive (α-) phase of $FAPbI_3$ is only meta-stable at room temperature, and a variety of compositional tuning and additive-based approaches have therefore been employed to stabilise this phase.

While a range of methods can be used to fabricate LHP thin films, the most common of these is one-step spin coating. Precursor salts may be dissolved in a range of solvents to form a precursor ink, into which additives that improve film properties and stability may be incorporated. However, little is known about the effect of both solvent choice and additives on film nanostructure. This ultimately limits the practical application of LHPs in devices, as higher performance materials tend to be less stable. Understanding how precursor ink chemistry affects thin film crystallisation can thus inform improvements in long-term stability of films and devices, and is pivotal to improving this technology moving forward.

Methods:

In this work, we examine 'neat' $FAPbI_3$ films prepared via different solution processed routes including films prepared from the conventional precursor salts formamidinium iodide and PbI_2 and single-crystal precursors in solutions of 4:1 DMF/DMSO and 4:1 DMF/NMP, both with and without the addition of a 40% MACl additive.

High-resolution transmission electron microscopy (HRTEM) is used to elucidate the nanoscale structure of these films at the atomic scale. However, $FAPbI_3$ is highly susceptible to electron beam-induced damage; doses in excess of 100e-/$Å^2$ induce degradation into PbI_2 indistinguishable from that natively present in the film [2]. Here, all HRTEM is performed at doses below this critical threshold to ensure beam-induced effects are minimised.

Results:

While bulk characterisation data suggests that these varied approaches to $FAPbI_3$ film formation result in structurally the same material (albeit with varying levels of electronic defects and morphological film changes) [3], HRTEM shows at the nanoscale these films exhibit significant

structural and compositional differences. Figure 1(a) shows a typical low-dose HRTEM image of a $FAPbI_3$film prepared from conventional precursor salts in DMF/DMSO. The FFT of this image (Figure 1(b)) shows poor agreement with spacings expected for α-$FAPbI_3$(red rings) and the 2H-polytype of PbI_2 (blue rings). In comparison, the HRTEM image of a single-crystal precursor sample in the same solvent system and the corresponding FFT (Figure 1c,d) shows good agreement with the spacings expected for the photoactive perovskite phase. We attribute these differences to the presence of unreacted precursor material and the presence of non-photoactive $FAPbI_3$ polytypes.

It has been previously suggested that in some more structurally stable compositions, degradation in these materials occurs as a result of the inclusion of various unwanted $FAPbI_3$ polytypes during crystallisation [4]. Our HRTEM images show direct evidence of these phases, and in combination with other characterisation techniques support the suggestion that the inclusion of these undesirable phases can be controlled and ultimately eliminated through careful modulation of the precursor ink chemistry. By using a single crystal precursor we have been able to achieve better precursor ink purity, which results in films with significantly reduced structural disorder (evidenced by lower Urbach energies, as shown in Figure 1e,f). In this work, we link these observations directly to nanostructural changes visible in the HRTEM data.

Conclusions:

Precursor ink chemistry undoubtably affects LHP thin-film composition and structure. We show a direct link between these properties and laboratory-based results through the use of low-dose HRTEM. These links provide an important stepping stone on the path to truly understanding precursor ink chemistry, which ultimately may be the key to perfecting the crystallisation of LHPs.

Multimodality and correlative low-voltage electron microscopy: powerful tool for imaging in life and material sciences

Mgr. Jan Dobeš[1], Jaromír Bačovský[1], Radka Martínková[1], Jan Vysloužil[2], Zuzana Bytešníková[3]
[1]Delong Instruments, Brno, Czech Republic, [2]Pragolab, Brno, Czech Republic, [3]Department of Chemistry and Biochemistry, Mendel University, Brno, Czech Republic

Poster Group 1

Background incl. aims
Low-voltage electron microscopes (LVEMs) offer distinct advantages over conventional high-voltage instruments: visualization of samples with high contrast and resolution, and multimodal imaging and five modes available in one instrument (TEM, STEM, SEM, ED, EDS) providing an easy-to-use solution for multimodal imaging and correlation. Performing multimodal and correlative imaging on several instruments is time-consuming and expensive and increases the risk of sample damage or contamination during the transport from one analytical device to the other. LVEM combines several imaging and analytical methods available during one imaging session, which decreases this risk and allows for quick and easy analysis.

Methods
LVEMs are versatile in imaging (TEM, SEM, STEM) and analytical (ED, EDS) modes. In TEM mode, LVEMs enable the users to observe and explore thin specimens' internal structures from low magnification for a quick overview to high magnifications with high resolution. While STEM mode enhances the high-resolution imaging capability even for samples with higher-than-standard thickness and, in combination with EDS, provides the option to obtain elemental mapping of the sample. SEM mode provides surface imaging of bulkier samples, obtaining topographical information. LVEMs are equipped with backscattered electrons (BSE) detectors enhancing material contrast. Furthermore, the capabilities of ED allow researchers to obtain crystallographic information from nanomaterials and crystalline samples, lattice parameters, and information about phases present in the sample.

Multiple imaging techniques of multimodal or correlative microscopy are necessary for a more comprehensive sample understanding in the application fields such as biosensors, immunolabelling, or nanoparticles development. The LVEMs allow researchers to study the structural, chemical, and morphological properties of various material and biological specimens by correlating data from TEM, SEM, STEM, EDS, and ED modes in different magnifications, and for material science samples also the dark-field TEM and STEM, where appropriate.

Results
Analytical chemistry trends are generally moving forward, and modern scientific instruments are designed to gain more and more information as possible from the interaction between the electrons and the sample. That corresponds with the new development of 4D-STEM – a combination of imaging and ED mode.
While multimodality involves acquiring multiple signals from one analysis, correlation should find a way to find a relation between these signals. TEM-ED, STEM-EDS, and SEM-STEM correlations are quite popular and can be easily done on single instruments.

Correlation between TEM and SEM brings information about sample inner structures from TEM and morphology from SEM. If combined with EDS, we can do the elemental mapping in STEM-EDS, and if wanted, ED can be done quickly with all these modes together to see the crystallinity and lattice parameters. In addition to ED, imaging in dark-field TEM delivers other information, including inner structures, which are not achievable by SEM mode. LVEMs' uniqueness lies in connecting all these analytical modes in one device.
LVEMs also help in cases where the sample cannot be prepared as a sample specimen of one kind. For complex studies, it is very common for one part to be a typical sample for TEM, but the other part of the investigated object is more suitable for SEM mode. In this case, LVEMs offer the opportunity to perform these measurements with one instrument.

Conclusion
LVEMs represent a unique solution in correlative and multimodal electron microscopy, offering versatility and the ability to analyze life and material science samples in several imaging and analytical modes in one imaging session in one device.

Mean inner potential change of latex sphere with temperature measured using off-axis electron holography

Dr. Yan Lu[1], Peng-Han Lu[1], Dominik Biscette[2], Denys Sutter[2], Prof. Giulio Pozzi[3], Prof. Rafal E. Dunin-Borkowski[1]
[1]Forschungszentrum Juelich, Juelich, Germany, [2]CondenZero AG, Zurich, Switzerland, [3]University of Modena and Reggio Emilia, Modena, Italy

IM-03 (2), Plenary, august 28, 2024, 14:00 - 16:00

Background incl. aims
Electron-beam-induced specimen charging is frequently encountered in transmission electron microscopy (TEM), in particular when studying insulating or biological materials. Polystyrene latex is a widely-used material for immunodiagnostic reagents and is often studied using cryo-TEM. Both a highly energetic electron beam and a low specimen temperature can change the intrinsic properties of materials. The mean inner potential (MIP) is an intrinsic parameter of a material, which is defined as its volume-averaged electrostatic potential with respect to a distant vacuum reference. The MIPs of many materials have been measured at room temperature using off-axis electron holography [1]. However, few low temperature measurements of MIPs and charging phenomena have been performed.
Methods
The TEM mode of off-axis electron holography involves the use of an electron biprism to overlap a reference electron wave that has passed through vacuum with an electron wave that has passed through a sample. Analysis of the resulting interference fringe pattern can be used to recover both amplitude and phase information. In the absence of dynamical diffraction and magnetic fields, the projected phase shift of the electron wave that has passed through the sample can be expressed in the form $\phi(x,y)=C\,V(x,y)\,t$, where C is a constant that depends on the microscope accelerating voltage (6.53×10^6 rad/Vm at 300 kV), V(x,y) is the total projected potential (including the MIP V_o and the electrostatic potential V_1 induced by electron-beam-induced charge redistribution) and t is the sample thickness. For a spherical solid of radius R, $\phi_o(x, y)=2C\,V_o\,(x,y)\,\sqrt{(R^2-(x^2+y^2))}$. The contribution to the phase from the electron-beam-induced charging outside and inside the sphere are $\phi_1(x,y)=C\,Q/(4\pi\varepsilon_o)\,\ln(((x-x_o)^2+y^2)/(x^2+y^2))$ $(r \geq R)$ and $\phi_1(x,y)=2C\,Q/(4\pi\varepsilon_o)\,(\ln(\sqrt{((x-x_o)^2+y^2)}/\sqrt{(R^2-(x^2+y^2))}+\sqrt{(R^2-(x^2+y^2)}/R+(\sqrt{(R^2-(x^2+y^2))^3}/3R^3)$ $(r < R)$, respectively [2], where ε_o is vacuum permittivity, $(x_o, 0)$ is the position of image charge. In order to quantitatively measure the charge on a latex sphere, we applied a model-independent (MI) approach [3, 4], which involves the measurement of the total charge enclosed by a chosen contour (Figs 1a and 1b). In this way, the contribution to the phase shift from the MIP and charge redistribution can be separated.
Off-axis electron holograms were recorded at 300 kV on an FEI Titan G2 TEM equipped with a 4K Gatan K2 camera. Each hologram was acquired by using a total exposure time of 6 s sub-divided into 30 frames of 0.2 s. Phase reconstruction was performed using HoloWorks software. Reduced specimen temperatures were reached by using a liquid helium holder from CondenZero (down to 5 K) and a liquid nitrogen cooling holder from Gatan (98 K).
Results
Figures 1a and 1b show a reconstructed phase image of a latex sphere with a diameter of ~220 nm attached to the end of a W tip. The hologram was recorded at room temperature (RT) and the charge was measured by performing a loop integral (marked using a yellow frame). The black arrow in Fig. 1a indicates the calculation direction. The total amount of charge on the latex sphere is calculated to

be ~273 e. Figure 1c shows phase images of a latex sphere with a diameter of ~430 nm on a 50-nm-thin Au film recorded at RT and 5.3, 29 and 70 K. Figure 1d shows equiphase contours generated from differences between the RT and lower temperature phase images. The total amount of charge is calculated to be 705, 633, 600 and 555 e, respectively. The differences result from both a change in electron-beam-induced charging and a change in MIP with temperature. In the surrounding vacuum region, phase changes are present due to the charge on the sphere and the substrate. By using this approach, 20 sets of data were recorded from spheres with sizes of 220, 430 and 604 nm at temperatures of 5.3, 23, 26, 29, 70, 98 and 298 K. The MIP value at each temperature was measured from these results. Figure 1e shows the relationship between temperature and MIP, with the measurements shown as black squares and error bars and a blue curve showing a parabolic fit with an R-squared value of 0.95732. The fitted parabola gives an intercept of 5.96 ± 0.16 V. The change in MIP from RT (5.17 ± 0.18 V) to that extrapolated to 0 K is ~16%.

Conclusions

Electron phase images of latex spheres of different sizes have been recorded at different specimen temperatures using off-axis electron holography. A model-independent approach has been used to measure the charge on each sphere. The MIP is also found to change, especially at the lowest specimen temperature.

IM-07, Lecture Theater 2, august 26, 2024, 10:30 - 12:30

Background

Organic-inorganic halide perovskites (OIHPs) have emerged as promising candidates for a broad range of optoelectronic devices thanks to their unique physical properties[1]. In the current framework of energy transition, OIHPs have demonstrated great potential in the photovoltaic field with the development of OIHPs-based solar cell reaching, in 2022, a power conversion efficiency of 25.6%[2] similar to its silicon-based analog. Methylammonium lead iodide (MAPI) has been the most commonly studied LHPs due to its very promising optoelectronic properties. One of the main explored pathways for obtaining MAPI perovskite is the Ligand-Assisted Reprecipitation (LARP) approach[3]; however, this method is not totally understood from a phenomenological point of view. Especially, the use of DMF as a polar solvent for the preparation of the precursor mixture leads to the formation of intermediate DMF-solvated phases[4] before the obtention, by annealing, of the final MAPI phase.
While a large amount of the community is focused on the OIHPs' physical properties with the aim of its application in photovoltaic, very less tackles this subject with an in-situ approach for the study of its growth processes. Thus, we decided to adopt this specific research angle to provides a better understanding of the LARP approach for synthesizing hybrid perovskites.

Methods

In one of our study[5], we took advantage of the development of microchip-based systems which enabled to study dynamic phenomena in their native environment, e.g. gas or liquid, directly in the TEM vacuum column. By replicating the LARP synthesis protocol in a Liquid-Phase TEM (LPTEM) cell (Figure 1.A), we were able to dynamically track the growth in solution of an intermediate DMF-solvated phase during the LARP process. These observations were correlated with synchrotron-based X-Ray scattering measurements performed on the SWING beamline of the SOLEIL synchrotron. The second part of the study is dedicated to the study of the transition by annealing in air from the intermediate phase toward the final optoelectronically interesting MAPI perovskite material. For this purpose, we have carried out annealing at 80°C in a Gas-Phase TEM (GPTEM) cell using a similar microchip system. We correlated the TEM observations with Temperature-resolved X-Ray diffraction using a chamber dedicated to temperature measurements.

Results

First, we monitored the nucleation and the growth processes of a DMF-solvated-intermediate phase by directly visualizing the reaction medium using LPTEM (Figure 1. B-F). The LPTEM images revealed

the formation of roughly spherical objects (Figure 1. C-D) in the early stages of the process transitioning to elongated ribbon-like morphology particles (Figure 1. E-F) after a few seconds, through a crystallization process. These local observations, in direct space, were correlated with more global information brought by synchrotron-based X-ray scattering measurements (Figure 1. G and H). With excellent time consistency with LPTEM imaging (Figure 1. B-F), the X-ray scattering measurements enabled us to identify similar morphology and confirm the local observations from LPTEM. This combined analysis, conducted in real-time and in representative conditions, allowed us to decipher the structural evolution of the emerging phases.

Secondly, we tracked in-situ the transition, occurring in air by annealing at 80°C, of the as-obtained intermediate phase towards the MAPI perovskite, using a combination of GPTEM, in image and diffraction modes (Figure 1. I and J), and temperature-resolved X-Ray diffraction associated with Rietveld refinement. We provided direct and unprecedented evidence of the fragmentation of the crystals, occurring simultaneously with the structural transformation between the intermediate and final phases. While GPTEM evidenced the fragmentation of the ribbon-like crystals into platelets, the Rietveld refinement explained this morphological transition based on a crystalline structure that already exhibited a preferential orientation towards (hk0) and (0k0) family planes.

Conclusion

We have, for the first time, directly visualized the growth of an intermediate phase of hybrid perovskites in liquid media during LARP synthesis using TEM. We show that combining LPTEM observations with synchrotron X-Ray scattering measurements is particularly effective for investigating such phenomena across various scales. Additionally, we investigate the transition of this intermediate phase through annealing and demonstrate how a correlative approach, combining TEM in Gas-Phase and X-Ray measurements, provides new insights into the mechanisms underlying structural changes during crystalline transitions.

Our approach, which required the challenging development of new correlative methods, underscores the significant value of in-situ correlative studies for enhancing our understanding of the synthesis of emerging hybrid materials. There remains a gap in understanding the growth mechanism of these materials in solution and we firmly believe that in-situ TEM-based correlative studies can contribute significantly to addressing these shortcomings.

Ptychography at finite dose in SrTiO3

Dr Malcolm Dearg[1], Mr James Gilbert[1], Mr Nick Michaelides[1], Dr Laura Clark[1]

Poster Group 2

Many important materials are unstable under the electron beam and easily damaged by high-dose imaging, leading to a blurred image of a damaged sample. Ptychography is one of the most dose-efficient electron microscopy techniques currently available, providing a route to high-resolution images of undamaged samples.

The aim of this research is to develop, implement and apply new dose-efficient 4D-STEM imaging methods, based around existing algorithms for electron ptychography to improve imaging of beam-sensitive materials. Here, we lay the groundwork for an in-depth discussion of finite dose ptychography, towards the development of new low dose algorithms for ptychographic imaging to improve achievable contrast at low electron dose.

Previous studies have explored ptychographic techniques theoretically for infinite dose (Clark et al. 2023). In this study, we are investigating the thickness dependence of ptychographic imaging methods, in particular we are interested in the dependence on varied electron probe dose to see just what the dose limits are for an accurate reconstruction.

We simulate a Strontium Titanate (STO) thickness series of 1-55 unit cells (3.905 – 215 Å) along the [1 0 0] axis with a 26.6 mrad electron probe at 300 keV with a midplane focus, using μSTEM (Allen et al. 2015). We then model a dose-series across the thicknesses, by applying Poisson statistics. The resulting 4D datasets were then used to form images via a range of algorithms, including central Bright-Field (cBF), Annular Dark-Field (ADF), integrated Center of Mass (iCoM), Single Sideband (SSB), Wigner Distribution Deconvolution (WDD), and extended Ptychographic Iterative Engine (ePIE).

With these data, we then find lowest-feasible dose limits for imaging samples in realistic imaging conditions, detecting image features and atomic column positions, to provide guidelines for successful experimental data collection, advice for expected most-successful imaging approaches, and data collection parameters.

Reactivity of High Entropy Nanoalloys under O2 and CO Oxidation reaction studied by in-situ TEM

Syrine Krouna[1], Jaysen Nelayah[1], Christian Ricolleau[1], Guillaume Wang[1], Hakim Amara[2], Damien Alloyeau[1]
[1]Université Paris Cité, Paris, France, [2]ONERA, Châtillon , France

PS-05 (1), Lecture Theater 1, august 28, 2024, 10:30 - 12:30

Carbon monoxide (CO) contamination has a major input in climate change. An efficient way to reduce its contribution is to oxidize CO into CO2. Therefore, heterogenous catalysis of CO oxidation reaction has been widely studied and many noble metal nanoparticles has been proposed as efficient catalysts. However, considering the price increase of noble metals and their rarity, there is a need to come up with new catalysts that involve less of noble metals. In this perspective, High Entropy NanoAlloys (HENA) represent a new class of catalysts with promising tunable properties. The presence of 5 metals or more crystalized in a solid solution and the mix of noble and non-noble metals allow easily tuning the reactivity and significantly reducing the cost. Moreover, the existence of different reaction sites on the same NP allows HENA to simultaneously activate CO and O2 molecules. Thanks to the synergy of the different elements, these NPs seem to be active at low temperatures but the relation between their complex atomic structure and their reactivity under O2 and CO remains unknown.

In this contribution, we exploit aberration-corrected in situ STEM investigations to reveal the structural and chemical evolution of single CoNiCuPtAu NPs between 100°C and 600° C under O2. The HENA were directly synthesized on the silicon nitride membrane of a MEMS-based gas cell, using pulsed laser deposition, allowing control of both particle composition and size1. Our in-situ gas experiments performed at atmospheric pressure combined atomic-scale STEM imaging with chemical analysis performed by STEM-EDS in an aberration-corrected JEOL ARM 200F TEM, using a Protochips Atmosphere gas/heating holder.

In comparison with our previous in-situ heating experiments of the same HENA performed under vacuum, gas in-situ experiments show that the NP growth, that is governed by coalescence, is slowed down with the presence of O2 and that the NPs are more stable. Unlike NPs annealed under vacuum, under O2 no evaporation was observed and the 5 elements remain in the NPs at high temperature. Nevertheless, we reported structural and morphological changes of the NPs. At 100°C and under 1 atm of O2, we can see reshaping of NP facets as shown in figure 1a. The NPs keep their CFC structure in the core and only the external layer will be oxidized (figure 1a) but, interestingly, at higher temperatures (up to 600°C), the oxide layer will disappear (see figure 1b). The oxidation of HENA also causes the formation of nanovoids in NPs, phenomena known as Kirkendall effect, that we can see in figure 1d. This effect will still be present at higher temperatures and for some NPs, even the coalescence would not allow refilling the holes.

These preliminary results allow us to identify that 100°C is the efficient working temperature of HENA under O2 and showcase that the oxidation occurs only on the external layer of the NPs.
Besides the unexpected Kirkendall effect has motivated an ongoing study of the influence of nanovoids on NPs' reactivity towards CO oxidation.

The desire to map material structures and dynamics at intrinsic scales of ångströms and attoseconds is driving methodological advances in condensed matter science. While X-ray and electron methods provide structural detail, attosecond temporal resolution is being achieved by evolving optical spectroscopy techniques [1]. Photon-induced near-field electron microscopy (PINEM) enables the imaging of near-field intensities with nanometric resolution [2]. However, access to the evolution of nanoscale fields and structures within the light cycle requires sensitivity to the optical phase, e.g. by phase-contrast Lorentz PINEM [3], interferometric detection [4], or electron pulse bunching [5].
Here, we introduce Free-Electron Homodyne Detection (FREHD) as a universally applicable approach to electron microscopy of phase-resolved optical responses at high spatiotemporal resolution [4]. In this scheme, a phase-controlled reference interaction (Fig. 1a) serves as the local oscillator to extract arbitrary sample-induced modulations of a free-electron wavefunction. We demonstrate this principle through the phase-resolved imaging of plasmonic fields of a gold nanoprism (Fig. 1c) with few-nanometer spatial and sub-cycle temporal resolutions. The near field at a sample modulates the phase of the electron wavefunction, and this wavefunction modulation is amplified or attenuated for in-phase and anti-phase reference interactions, respectively, which allows for a coherent read-out of a position-dependent phase (Fig. 1b). The characterization of both the amplitude and phase of the near-field allows to image the electric field at different phases in a time-resolved movie (Fig. 1d).
In the area of phase-resolved near-field imaging, including scanning probe techniques and photoelectron emission, FREHD has distinct strengths. It is non-invasive, exhibits perfect linearity in response, and provides consistently high spatial resolution that is virtually independent of the sample and the optical wavelength. This resolution can be correlated with detailed structural characterization in transmission electron microscopy down to the atomic scale.
The method goes beyond imaging electromagnetic fields, and is also capable of detecting modulations imprinted on an electron beam by electronic or structural material responses. In particular, it encompasses attosecond charge density dynamics, including subtle light-induced changes in the structure factor at both the fundamental frequency and its harmonics.
In conclusion, we introduce Free-Electron Homodyne Detection that generalizes the high-resolution measurement of attosecond materials responses in electron microscopy, without a need for electron density bunching, and offers fascinating new possibilities to image local attosecond and phase-resolved responses on the nanometer scale.

Poster Group 1

Background incl. aims
Ischemic stroke stands as the second leading cause of mortality globally, necessitating innovative approaches for its diagnosis and treatment. This project delivers a validated pipeline for assessing the kinetics and dynamics of iodine nanoparticles (IoNPs) within the organism, specifically targeting critical areas like the brain, blood-brain barrier, blood, and organs like the spleen.
Understanding thrombus characteristics, including size, composition, and origin, holds significant promise in guiding treatment strategies not only for stroke but also for related cardiovascular diseases. Current imaging modalities are limited in their ability to visualize various clot types effectively, hindering precise diagnosis and tailored treatment.
Biodegradable IoNPs have the potential to become the basis of a modern theranostics (therapy and diagnostics) approach to improve the treatment. The afore-mentioned IoNPs made of monomer MAOETIB (2-(Methacryloyloxy)ethyl-2,3,5-triiodobenzoate) have been described as desired contrasting agents. Furthermore, they can be used as drug carriers.

Methods
The essential method for the characterization of nanoparticles is undoubtedly electron microscopy, offering intricate insights into nanoparticle behavior within tissue matrices. LVEM operates at significantly lower accelerating voltages compared to conventional TEM, typically below 25 kV. This lower voltage regime offers several distinct advantages, including increased contrast and gentle electron-sample interaction.
Low voltage provides improved contrast mechanisms, which are particularly invaluable for samples composed of light elements. The reduced electron energy results in increased electron scattering, enhancing image contrast and revealing finer details within specimens. This capability is especially important in imaging biological sections and generally low-contrast materials, where conventional TEM techniques may yield limited contrast.
The application of LVEM in nanoparticle characterization involves various aspects, including morphology, size distribution, crystallinity, surface properties, and interparticle interactions. Through advanced imaging techniques such as dark-field imaging and electron diffraction, LVEM facilitates a deeper understanding of NPs structure and behavior at the nanoscale level.
The unique combination of TEM, STEM, and SEM imaging modes in LVEM instruments provides researchers with a comprehensive toolkit for investigating nanoparticles integrated into the tissue structure. Furthermore, LVEM's versatility extends beyond imaging, offering advanced analytical capabilities such as energy-dispersive X-ray Spectroscopy (EDS) and Electron Diffraction.

Results

Utilizing a multimodal approach, comprehensive insights were gathered regarding the characteristics and behavior of IoNPs, spanning from initial nanoparticle characterization and quality assessment post-fabrication to their dynamics within blood circulation and targeted organs. A rat served as the model organism in this study, providing a relevant and translational platform for investigating IoNPs interactions in vivo. Nanoparticles were imaged throughout their entire lifecycle, starting from their presence in a native solution, followed by intravenous injection into the bloodstream, and subsequently deposited within the relevant organs. The examination of nanoparticles using low-voltage transmission electron microscopy was integrated to a comprehensive characterization utilizing various analytical methods.

Conclusion
The integration of LVEM into nanoparticle research promises to advance our understanding of nanoparticle behavior within biological systems. LVEM's unique imaging capabilities, particularly well-suited for biological sections, make it an invaluable tool for the development of theranostic strategies and personalized treatments. With its multimodal capabilities, LVEM emerges as a pivotal technology for the comprehensive analysis of biodegradable iodine nanoparticles, aiming towards improved healthcare outcomes.

Poster Group 1

Background
Transmission electron microscopy (TEM) has allowed for impressive opportunities to visualize matter at the atomic scale. In such experiments, the constituent atoms typically respond dynamically to the electron beam irradiation, alter the sample and, hence, modulate image contrast and intensities. While mitigation strategies have focused much on electron energy and dose variation, there is a growing emphasis on the role of the electron dose rate.

That is, for a broad class of materials, the electrons incident on the specimen is considered to cause phonon or electron excitations because the impingement rate is higher than the subsequent relaxation rate. Consequently, accumulation of energy and or charge leads to bond rupture and atom displacements. In this picture, pulsing the electron illumination seems beneficial as it enables a sharply defined maximum electron impingement rate to match the onset causing sample alterations. Here we show how a structured electron beam can suppress beam-induced alterations of a two-dimensional MoS2 by 50% compared to the continuous mode.
Method
The present experiments are conducted on a Thermo Fisher Scientific SPECTRA ULTRA microscope operated at 300 kV. An electrostatic beam blanker (ESBB) system developed by Thermo Fisher Scientific, is used to structure the electron beam with a 10 ns temporal electron delivery window with repetition rate of 1MHz. The microscope was operated in pulsed and continuous mode. In each mode, an electron diffractogram of the MoS2 was recorded at similar electron dose-rate and total dose. In pulsed mode the beam blanker was tuned to generate 1 electron per pulse. The area exposed was kept the same during acquisition to compare the behavior of the specimen in both modes.

Results
The electron diffractograms of MoS2 show for increasing electron dose and dose-rate had different evolution of the central diffraction peak intensities in pulsed and continuous modes. In continuous mode the diffraction peaks faded to ~60% of the original intensity due to loss of crystallinity caused by beam damage. In pulsed mode the diffraction peak intensities faded only by ~1%. A similar effect was observed by (1,2) delivering dose electron-by-electron and allowing relaxation time reduces beam damage. Further we found that the effect of pulsing decreased when increasing the number of

electrons per packet. This is the first time that this effect is shown with only a beam blanker and on a nanosecond time scale.

Conclusion
Thus, the comparison of pulsed and continuous electron beams suggests that the electron-induced degradation of MoS2 is a multi-electron excitation rather than a single-electron scattering event, consistent with ref. (3,4) and that excitations on the microsecond timescale must be circumvented to maintain structural integrity of the MoS2 sample. We anticipate that beam blanker pulsed electron delivery may benefit the stability of other materials and enable novel experiments with beam sensitive materials in general.(5)

Deep Learning assisted denoising of in situ liquid STEM-movies of nanoparticle nucleation and growth

Adrien Moncomble[1], Damien Alloyeau[1], Guillaume Wang[1], Hakim Amara[1,2], Riccardo Gatti[2], Maxime Moreaud[3], Christian Ricolleau[1], Jaysen Nelayah[1]

Poster Group 2

Over the recent years, the comprehension of the formation mechanism of metallic nanoparticles (NPs) has greatly benefited from in situ liquid TEM that enables imaging of the nucleation and growth of individual NPs in liquid media. However, these experiments pose challenges regarding both data acquisition and analysis. In particular, substantial scattering from the liquid around the NPs and the electron transparent SiN membranes significantly diminish the signal quality [1]. One solution would be to increase the electron dose rate, but this can lead to undesirable effects due to radiolysis. The other one is to use post-experiment techniques to remove the noise while keeping the signal of interest. Herein, we present an innovative approach that combines deep-learning (DL) and scanning transmission electron microscopy kinematic simulations [2] to denoise in situ liquid STEM-movies of NPs during their nucleation and growth in liquid media, a complex task where multiple information is intertwined.
Within a commercial liquid cell, we can visualize the formation of gold NPs, induced by the interactions between the electron probe and the precursor. We acquired a video of these events using a double corrected JEOL ARM 2100. To analyze and understand the growth mechanism, each frame was denoised by a homemade convolutional neural network similar to U-Net [3]. However, the quality of the results obtained is correlated to the quality of the training data. Hence, numerical simulations are a solution in the case of liquid electron microscopy where we cannot acquire data experimentally.
Our work consists of the development and optimization of the dataset and the CNN architecture. Besides considering the size and shape dispersions of nanoparticles, kinematic simulations account for a significant obstacle in studying NP growth by liquid cell TEM which is the formation of NPs on the opposite membrane of the cell. The latter contributes to the random background fluctuations because they are imaged way out-focus. Once we considered these challenges, our method effectively denoises low and high magnification videos, thus elevating the signal-to-noise ratio from 1 to 8 [Figure 1], above the threshold value of 5 set by the Rose criterion [4]. Consequently, our analysis pipeline facilitates the study of NP growth mechanisms with improved statistics and fewer acquisition constraints. We will show the application of this methodology to investigate surface site attractiveness on both gold nanocubes and nanorods within the context of NP synthesis.
In this work, we demonstrate the application of deep learning to the specific case of the denoising of in situ liquid microscopy. Thanks to this, we were able to get a better visualization and, thus, a better understanding of the mechanisms of the formation of nanoparticles.

In situ insights into the thermal stability of high-entropy nanoalloys

Syrine Krouna[1], Anissa Acheche[2], Jaysen Nelayah[1], Christian Ricolleau[1], Guillaume Wang[1], Hakim Amara[2], Damien Alloyeau[1]
[1]Université Paris Cité, Paris, France, [2]ONERA, Châtillon , France

PS-02 (3), Lecture Theater 4, august 30, 2024, 14:00 - 16:00

The structural stability of high entropy nanoalloys (HENA) brings hope to developing more stable nanomaterials for high-temperature applications in different fields such as catalysis or mechanics. Nevertheless, the enhanced thermal stability of nearly equiatomic nanoalloys containing at least 5 metals is nothing more than a theoretical speculation about the impact of thermodynamic contributions and sluggish diffusion kinetics on their structural properties and remains to be proven. In this context, studying the thermal behavior of HENA is a necessary first step to understand their stuctural properties and evalutate their structural stability with the view to better target their potential high-temperature applications.

In the present work, FCC AuCoCuNiPt NPs were directly synthesized on the silicon nitride (SiN) membrane of a MEMS-based heating chip, using pulsed laser deposition, allowing control of both particle composition and size [1]. Then, we used in situ scanning transmission electron microscopy (STEM), corroborated with atomistic simulations, to study in real time and at the atomic scale the structural and compositional evolution of from 298 K to 973 K. We combined atomic-scale STEM imaging with chemical analysis performed by STEM-EDS in an aberration-corrected JEOL ARM 200F TEM, using a Protochips heating holder. Molecular Dynamic (MD) simulations are performed using the open source Large-scale Atomic/Molecular Massively Parallel Simulators (LAMMPS) package. In order to investigate Cu-Au-Co-Ni-Pt NPs, the Embedded Atom Method (EAM) potential derived by Zhou et al. is used to describe the interaction between different atomic pairs [2].

The growth of FCC AuCoCuNiPt NPs is mainly driven by coalescence observable from 623 K (Fig. 1a). Furthermore, both in situ STEM and MD simulations reveal strong structural and chemical evolutions in the NPs with the formation and melting of an AuCu layer at the surface of NPs at high temperature (figure 1b and 1c). This phase separation that appears progressively with temperature is driven by surface effects and pronounced atomic diffusion that is surprisingly more active in these quinary nanoalloys than in monometallic and bimetallic subsystems. Besides ruling out the existence of sluggish diffusion in AuCoCuNiPt nanoalloys, our study allows distinguishing kinetic and thermodynamic effects on their structural properties, which is an essential prerequisite to better control the synthesis of complex nanomaterials. From a practical point of view, this study calls into question the use of AuCoCuNiPt HENA for high-temperature applications and more generally reveals the necessity to investigate the thermal behavior of HENA to determine if and how surface effects govern their structural properties, to evaluate their stability and adapt their potential applications.

LS-02 (1), Lecture Theater 4, august 26, 2024, 10:30 - 12:30

Background
Cancer cells are in close contact with healthy tissue to maintain proliferation and secure the protumorigenic microenvironment. An example of this intimate interaction is the ability of cancer cells to 'steal' functional mitochondria from surrounding stromal cells to compensate for damage to their own organelles, whether resulting from mutational burden or therapy intervention. This process, called horizontal mitochondrial transfer (HMT), occurs mostly via tunneling nanotubes (TNTs), thin membranous protrusions that connect the cytoplasm of donor and acceptor cell. Mitochondria move between cells over a distance of tens to hundreds of micrometres of TNT length using a microtubule-associated molecular adaptor and motor proteins. Here, we aim to elucidate the role of Miro1, an adaptor protein that is located in the outer mitochondrial membrane and is known to be involved in mitochondrial mobility and the HMT.

Methods
To elucidate the role of Miro1 in HMT in vivo, we have developed a mouse with inducible Miro1 knockout (Miro1KO) and with endogenous expression of the mitochondrial targeted mKate2 red fluorescence protein (mito::mKate2). We subcutaneously injected syngenic GFP expressing B16 cancer cells lacking mitochondrial DNA (so called ρ0 cells), representing a model of severe mitochondrial damage. This allows us to follow tumor growth with respect to Miro1 expression and identify HMT based on the presence of mito::mKate2 (stromal origin) mitochondria in GFP (ρ0 cancer cells) in vivo and in vitro. To further elucidate the role of Miro1 in cancer and stromal cells, we have used live cell time-lapse microscopy to capture the dynamics of mitochondrial movement as well as Sholl analysis to describe their location within cells. Finally, we have optimized cell-free reconstituted system of isolated microtubules, mitochondria, adaptor, and motor proteins, allowing us in combination with interference reflectance microscopy to track and identify alternations in movement of single organelles along microtubules.

Results
First, in vivo we observed a delay in mtDNA acquisition and tumor growth in Miro1KO mice. Furthermore, we elucidated that Miro1 is necessary for microtubule-mediated mobility and organelle relocalization toward the cell periphery and into TNTs. At the molecular level, our data suggest that Miro1 is necessary for the initial phase of mitochondrial movement, the association of organelles with microtubular tracks.

Conclusions
In summary, our results illustrate the importance of mitochondrial transfer in the context of cancer cells experiencing mitochondrial damage (e.g. as result of mutations or treatment). In particular, we have elucidated the role of Miro1 in this process, supporting the model in which it recruits mitochondria on microtubules, secures their movement towards the cell periphery and inside TNTs, and ultimately into the recipient cancer cell.

In situ insights into the thermal stability of high-entropy nanoalloys

Syrine Krouna[1], Anissa Acheche[2], Jaysen Nelayah[1], Christian Ricolleau[1], Guillaume Wang[1], Hakim Amara[2], Damien Alloyeau[1]
[1]Université Paris Cité, Paris, France, [2]ONERA, Châtillon , France

Poster Group 2

The structural stability of high entropy nanoalloys (HENA) brings hope to developing more stable nanomaterials for high-temperature applications in different fields such as catalysis or mechanics. Nevertheless, the enhanced thermal stability of nearly equiatomic nanoalloys containing at least 5 metals is nothing more than a theoretical speculation about the impact of thermodynamic contributions and sluggish diffusion kinetics on their structural properties and remains to be proven. In this context, studying the thermal behavior of HENA is a necessary first step to understand their stuctural properties and evalutate their structural stability with the view to better target their potential high-temperature applications.

In the present work, FCC AuCoCuNiPt NPs were directly synthesized on the silicon nitride (SiN) membrane of a MEMS-based heating chip, using pulsed laser deposition, allowing control of both particle composition and size [1]. Then, we used in situ scanning transmission electron microscopy (STEM), corroborated with atomistic simulations, to study in real time and at the atomic scale the structural and compositional evolution of from 298 K to 973 K. We combined atomic-scale STEM imaging with chemical analysis performed by STEM-EDS in an aberration-corrected JEOL ARM 200F TEM, using a Protochips heating holder. Molecular Dynamic (MD) simulations are performed using the open source Large-scale Atomic/Molecular Massively Parallel Simulators (LAMMPS) package. In order to investigate Cu-Au-Co-Ni-Pt NPs, the Embedded Atom Method (EAM) potential derived by Zhou et al. is used to describe the interaction between different atomic pairs [2].

The growth of FCC AuCoCuNiPt NPs is mainly driven by coalescence observable from 623 K (Fig. 1a). Furthermore, both in situ STEM and MD simulations reveal strong structural and chemical evolutions in the NPs with the formation and melting of an AuCu layer at the surface of NPs at high temperature (figure 1b and 1c). This phase separation that appears progressively with temperature is driven by surface effects and pronounced atomic diffusion that is surprisingly more active in these quinary nanoalloys than in monometallic and bimetallic subsystems. Besides ruling out the existence of sluggish diffusion in AuCoCuNiPt nanoalloys, our study allows distinguishing kinetic and thermodynamic effects on their structural properties, which is an essential prerequisite to better control the synthesis of complex nanomaterials. From a practical point of view, this study calls into question the use of AuCoCuNiPt HENA for high-temperature applications and more generally reveals the necessity to investigate the thermal behavior of HENA to determine if and how surface effects govern their structural properties, to evaluate their stability and adapt their potential applications.

Recent developments and future trends in time-resolved cathodoluminescence: measuring dynamics at the nanoscale

Dr Herman Duim[1]
[1]Delmic, Delft, The Netherlands

Poster Group 1

Background
Cathodoluminescence spectroscopy is a well-established technique utilized to extract detailed information about the optical properties of materials [1, 2] at spatial resolutions surpassing the diffraction limit of light. By employing an electron beam as a broadband excitation source, materials can be brought into an excited state. The subsequent relaxation of these excited states typically follows intricate pathways involving both radiative and nonradiative recombination mechanisms. Gaining a comprehensive understanding of these dynamic processes is essential for the design and optimization of nanomaterials and devices.

Results
We will explore various experimental implementations of time-resolved cathodoluminescence (TRCL) that are applicable for lifetime mapping or g(2) imaging. In the former, a decay trace is measured following excitation with a pulsed electron beam, enabling the determination of the excited state's lifetime [3]. In the case of g(2) imaging, photon statistics are instead utilized to observe bunching and anti-bunching effects [4, 5]. By analyzing the bunching behavior in extended material systems, it becomes possible to extract valuable information about emission lifetime and excitation efficiency. An important advantage of this approach is its compatibility with a continuous electron beam, eliminating the need for modifications to the electron microscope.

Conclusions
Here we describe the latest advancements in time-resolved cathodoluminescence and future directions, drawing examples from semiconductor research to highlight the remarkable capabilities and value that TRCL brings as an advanced nanoscale characterization technique.

PS-07 (2), Plenary, august 30, 2024, 10:30 - 12:30

Melanins, ubiquitous natural pigments found across various life forms, possess diverse biological functions such as camouflage and radioprotection. Notably, allomelanins derived from 1,8 - dihydroxynaphthalene (1,8-DHN) in Ascomycetes demonstrate robustness, offering protection against hostile environments. Despite their structural complexity and insolubility in solvents, allomelanins exhibit unique physical and chemical properties, including broad-band visible-light absorption, free radical characteristics, water-dependent conductivity, and redox behavior, albeit their exact structure remains incompletely defined[1], [2]. Thin films derived using chemical oxidative polymerization from physiologically active chemicals such as polyphenols have been studied to exhibit remarkable versatility across diverse substrates[3], [4], [5]. This study presents an in-depth investigation utilizing in-situ correlative microscopy and surface electrochemical methodologies to scrutinize thin films formed via the oxidative polymerization of 1,8-DHN molecules in aqueous electrolytes.

The study showcases the electrodeposition of 1,8 DHN onto gold electrodes and glassy carbon electrodes through cyclic voltammetry under in-situ liquid TEM using a miniaturized electrochemical cell. The resulting films demonstrate adjustable thickness and swelling properties, modulated by varying the potential sweep rate (20mV/s, 200mV/s and 1000mV/s). Analysis of the films' surface characteristics is conducted through Raman-coupled electrochemical spectroscopy and in-situ ellipsometry, complemented by cyclic voltammetry to explore their electrochemical behavior. Additionally, employing in-situ TEM provides insights at the nanoscale, in direct space into the electrochemical mechanisms occurring during the film formation.

Through the application of in-situ liquid TEM using an electrochemical cell, the real-time mechanism of thin film formation during electrodeposition has been elucidated, marking a significant advancement in the field. A proposed mechanism for the oxidative polymerization of 1,8 DHN is supported by Raman-coupled electrochemical spectroscopy, indicating dimer formation during the initial stages. Additionally, concurrent analysis with in-situ ellipsometry has allowed for the simultaneous investigation of the relationship between film thickness, scan rates, and optical properties, while quasi-in-situ impedance spectroscopy has provided insights into the electrical and conducting properties of these polymers in relation to the sweep rates. Notably, these films exhibit inherent antioxidant properties with antioxidant components distributed throughout the films' structure within a restricted energy range of -1 V to +1 V versus Ag/AgCl.

From a material point of view, this correlative study which includes in-situ liquid TEM analyses highlights the considerable potential of employing mild electrochemical conditions to fabricate

electropolymerized thin films via the Chimie-Douce mechanism utilizing fundamental organic constituents. Moreover, combining several in-situ techniques including electrochemical TEM, Raman coupled electrochemical spectroscopy, and ellipsometry, we bring new insights into chemical oxidative polymerization at different scales and more generally a structural evolution during electrochemical phenomena. Given their insolubility in commonly used solvents and favorable mechanical properties, these films hold promise as protective coatings. Moreover, their electroactive and antioxidant properties render them highly suitable for a wide range of applications, including environmental remediation, biomedicine, and catalysis.

LS-04 (2), Lecture Theater 4, august 29, 2024, 14:00 - 16:00

Visualizing the metabolism within its structural context is key to understanding the biological phenomena at stake, especially at the subcellular scale. While biochemical purification may function for specific organelles of model species, this is tedious and often impossible for atypical or less studied organisms. Time-of-flight secondary ion mass spectrometry (TOF-SIMS) enables the combined visualization of elements and molecules and is becoming more and more popular in the field of life sciences, especially for the investigation of tissue samples. Even though the ultimate lateral resolution of TOF-SIMS ought to be sufficient for subcellular imaging, very few studies have yet pushed the lateral resolution that far. In this context, we have investigated how the subcellular architecture and molecular composition of microalgae thriving in extreme environments is affected by the harsh conditions they live in.
For this purpose, we have performed TOF-SIMS imaging, combining both high lateral resolution (up to 100 nm) and high mass resolution (up to 9,000) over resin-embedded specimen. We also performed over the same zone correlative SEM (10 nm) in order to identify subcellular compartments and used this image to segment the hyperspectral TOF-SIMS dataset. We are thus combining the strength of both techniques and increasing the resolution of TOF-SIMS imaging using SEM-derived information.
We investigated the snow alga Sanguina nivaloides that blooms over lasting snow in the spring season and was recently been identified in the Alps, as well as the uranium-tolerant Coelastrella sp. PCV that has been shown to tolerate extremely high doses of uranium. In these algae, we have been able to perform molecular profiling of several subcellular features, including cell walls as thin as ~ 100 nm, nuclei, pyrenoid, starch granules and platelets and chloroplasts. In the case of S. nivaloides especially, the environmental samples hint at a likely interaction between the alga, mineral particles and bacteria that could explain how the alga is able to collect micronutrients in its hostile snow environment. Coelastrella on the other hand is able to remodel its compartments and their metabolic content when submitted to uranium-related stress.
Our TOF-SIMS images almost meet NanoSIMS images (that is however restricted to purely elemental mass spectrometry imaging) in term of resolution. Correlative TOF-SIMS/SEM allows a remarkable enhancement of the comprehensibility of TOF-SIMS images by adding in extra structural information. We reveal for every different organelle a different metabolic footprint and hints into their adaption to their specific environment.

Poster Group 1

Two-dimensional layered materials, such as transition metal carbides or nitrides, known as MXenes, offer an ideal platform to investigate charge transfer processes in confined environments, relevant for energy conversion and storage applications, such as supercapacitors and Li-ion batteries. Their rich and tunable surface chemistry plays an essential role in the pseudocapacitive behavior of Ti3C2Tx MXenes, where Tx=O, OH, F, Cl etc. However, the local distribution of surface functional groups over single flakes and within few- or multilayered flakes remains unclear. In this presentation, we introduce synchrotron-based scanning X-ray microscopy (SXM) with simultaneous transmission and electron yield detection (EY), enabling multimodal nanoscale chemical imaging with bulk and surface sensitivity, respectively, of individual MXene flakes. Soft X-rays absorption spectroscopy (XAS) allows the probing of fine electronic structure of the metal valence electrons and light elements present in the layered transition metal compounds and electrolytes. Specifically, for transition metal structures with termination groups found in MXenes, the crystal field interaction determines the shape, strength, and occupancy of electronic orbitals. Transmission imaging techniques with soft X-rays are ideal for monitoring changes in the local chemistry of few-layered materials, with guest-species between the interlayers or exposed to different environments. Microscopy techniques, other than SXM, offer limited spatial resolution (optical microscopy), only surface sensitivity (Scanning probe microscopy, XPEEM), only bulk sensitivity (TEM, TXM) or lower energy resolution (EELS). Single and few-layered Ti3C2Tx MXenes, synthesized with hydrofluoric acid (HF-etched), and multilayered Ti3C2Tx MXenes, synthesized via the molten salt route (MS-etched) [5], are imaged by multimodal SXM at the Ti L- and O K-edge using the BESSY II synchrotron light source. Transmission detection mode is used for bulk sensitivity, required to probe the surface chemistry in the MXene interlayer, while EY mode allows high surface sensitivity for probing the top MXene layer. SXM allows the monitoring of MXene flake thickness and electron emission properties at the sub-flake level. Local XAS measurements have a high chemical sensitivity to the Ti and O bonding configurations, hence to the surface chemistry of MXene. The Ti chemical bonding differs dramatically between HF-etched and MS-etched Ti3C2Tx MXenes explained by the larger content of O-termination in MS-Ti3C2Tx. Thus, different surface chemistry and electronic properties are identified for MXenes, synthesized via different routes. SXM also enables the chemical identification of the different components found in post-mortem analysis of battery components cycled in a Li-ion battery with Ti3C2Tx MXene, as working electrode. Adsorbed electrolyte (surface) and electrolyte-electrode interaction (bulk) can be probed with high chemical sensitivity. Changes in the chemical bonding configuration of electrochemically cycled MXene electrode are recorded in the bulk of MXene, related to interaction of MXene with intercalated lithium cations, and its top layer, due to interaction with the electrolyte. Specifically, upon comparison of XA spectra at Ti L- and O K-edge between cycled and pristine MXene in bulk, we identify increased Ti oxidation state in cycled MXene, related to the bonding of lithium cations with oxygen surface termination groups. Furthermore, surface-sensitive TEY measurements

hint at surface reactions between the MXene and the electrolyte during the electrochemical cycling process. This distinction underscores the complex interplay of bulk intercalation and surface phenomena in these materials. Multimodal SXM can be applied to other laminated materials, such as graphene, layered transition metal dichalcogenides, thin film solar cells and multilayered polymer films, thereby opening new insights into intercalation and surface redox processes.

Poster Group 2

Background incl. aims
In contrast to possibilities arising from electron correlations in condensed matter systems, stochastic Coulomb interactions in free electron beams are usually considered detrimental. In electron microscopy, electron repulsion leads to stochastic longitudinal and transverse emittance growth and limits the brightness of state-of-the-art electron sources. However, in a regime where few-body interactions dominate, Coulomb interactions can also have beneficial effects based on strong inter-electron repulsion, such as non-Poissonian electron beam statistics [1]. A powerful approach to induce such strong electron-electron interactions is femtosecond-triggered photoemission from nanotips [2, 3].
In this work [4], we characterize the strong Coulomb correlations of multi-electron states from a laser-triggered nanoscale field emitter, with applications in correlated probing applications, shot-noise reduction, and electron heralding schemes.

Methods
The experimental work is carried out in transmission electron microscopes that are modified for photoexcitation of the electron source [4, 5]. A laser pulse train with 2 MHz repetition rate and 160 fs pulse length generates ultrashort electron pulses by close-to-threshold laser-triggered Schottky emission [5]. The photoelectrons are analyzed with an event-based electron detector, which is mounted behind an imaging energy filter and characterizes the spectral and spatial properties of the electrons. The detected electrons are matched to the generating photoemission laser pulse, and the number of electrons n=1,2,3,4 is assigned to each pulse (see Fig. a).

Results
The single electron state spectrum exhibits a single peak at the beam energy of 200 keV (see Fig. b). Strikingly, the electron pulses with n>1 exhibit a distinctive spectral shape with the number of peaks identical to the number of electrons in the pulse (see Fig. c-e), indicating a strong interaction between the electrons in the pulse. The n=2,3,4 -states are plotted with respect to the state-averaged energy. For n=2, a projection of the energies of electrons A and B onto a two-dimensional energy pair histogram (Fig. f) shows a characteristic pair-correlation energy of about 2 eV. The strong inter-particle energy exchange is caused by acceleration-enhanced inter-particle Coulomb interaction, as confirmed by trajectory simulations. State-sorted beam caustics reveal a discrete increase in virtual source size, a longitudinal source shift, and a pronounced angular distribution of the few-electron states compared to single-electron pulses. As the correlation primarily emerges in the initial acceleration stages of the electron gun, controlling the electrostatic configuration enables control over the ratios of transverse and longitudinal Coulomb correlations. Using apertures along the optical axis, which limit the maximum transverse momentum of electrons transmitted into the

column, we can decrease the current-current correlation function by lowering the extraction voltage applied to the nanotip cathode.

Conclusion
The high fidelity of few-electron pulses in conjunction with single-particle detection enables the preparation of distinctive electron states for correlated probing, as well as enhanced microscopy and lithography. Specifically, we propose schemes to generate an electron beam with sub- or super-Poissonian two-electron statistics. By means of spatial filtering with an annular aperture or spectral filtering with either a slit or a beam stop, the two-electron state is suppressed or enhanced, resulting in a shot-noise- (annular aperture, slit) or singlet-state-reduced (beam stop) electron beam, respectively. Applications of the two-electron state-enhanced electron beam include heralded single-electron sources and may foster new developments in free-electron quantum optics and quantum-enhanced electron microscopy.

Operando TEM Reveals Oscillatory Surface and Bulk Dynamics of Nickel Nanoparticles in Ethylene Partial Oxidation

Dr. Claudiu Colbea[1,3], Prof. Jeroen Anton van Bokhoven[1], Prof. Marc-Georg Willinger[2,3], Dr. Milivoj Plodinec[1,3]
[1]Department of Chemistry and Applied Biosciences, ETH Zürich, Zürich, Switzerland, [2]Department of Chemistry, Technical University of Munich, Münich, Germany, [3]Scientific Center for Optical and Electron Microscopy, ETH Zürich, Zürich, Switzerland

Poster Group 2

Background

Heterogeneous catalysis, particularly employing transition metal nanoparticles as catalysts, has emerged as a promising avenue for facilitating the partial oxidation (POX) of hydrocarbons (methane, ethane, propane) to syngas.[1] Syngas, a mixture of carbon monoxide (CO) and hydrogen (H_2), serves as a crucial precursor for a wide range of industrial processes including the synthesis of methanol, ammonia, and various other essential carbon based chemicals.[2] Recent efforts have focused on unravelling the catalytic mechanisms at play in these reactions aiming to improve efficiency and selectivity while minimizing unwanted byproducts. One intriguing phenomenon observed in such catalytic systems is the self-sustained oscillatory behaviour, where the catalytic activity undergoes periodic fluctuations over time.[2] These oscillations can lead to enhanced reaction rates and selectivity, offering specific insights into the dynamic nature of catalytic processes. This phenomenon have been observed in many heterogenous catalytic systems including oxidation of hydrogen or ammonia, oxidation or reduction of carbon monoxide, dry reforming of methane, nitric oxide, various saturated and unsaturated hydrocarbons and alcohols.[2] In the context of transforming ethylene to syngas, POX presents one of possible pathways for production of valuable chemicals and fuels. Our study investigates the role of nickel nanoparticles (Ni NPs) as catalysts in the POX of ethylene, aiming to understand the oscillatory dynamics observed during the reaction. Utilizing operando transmission electron microscopy (TEM), we attempt to gain valuable insights into structural and morphological changes of catalyst at high spatial (sub-nm) and temporal resolution (milliseconds), thus contributing to the development of more efficient and sustainable catalytic systems.

Methods

For this study, Ni NPs were sputtered onto the heater of a Microelectromechanical Systems (MEMS) chip of the nanoreactor.[3] The operando TEM experiments were conducted using an aberration-corrected JEOL GRAND ARM Vortex TEM microscope, operating at 300 kV, combined with a DENSsolution Climate gas system and a HIDEN quadrupole mass spectrometer (QMS) 3F PIC for real-time gas analysis. Before the gas mixture for the POX of ethylene was introduced, the Ni NPs underwent reduction in a gas mixture of H_2:He (1:4 ratio) at 500°C for 3 hours. The POX of ethylene was then carried out at a pressure of 1 bar, with a gas ratio of C_2H_4:O_2 = 1:1, and at a temperature of 950°C.[4]

Results

Using operando TEM, we were able to directly observe the structural and morphological changes of Ni NPs in a self-sustained oscillatory regime during the POX of ethylene to syngas. Despite the Ni NPs varying in shape and size, ranging from several tens to up to 200 nm (Figure 1a), mass spectrometry (MS) data have demonstrated that the vast majority of Ni NPs exhibited synchronized behaviour, oscillating between a high activity (metallic state) and a low activity regime (nickel-oxide state) shown in Figure 1b.[4] More importantly, the MS data allows direct correlations between the structural and morphological changes of the NPs and alterations in the gas phase, thus providing a comprehensive understanding of the catalytic process at play.[4]
Furthermore, the observed dynamics of Ni NPs, though some of them unsynchronized, can be categorized into two distinct types: bulk dynamics and surface dynamics.[4] In bulk dynamics, as depicted in the Figure 1c, the entire particle undergoes a structural transformation when transitioning between the high activity and low activity regimes. On the other hand, the nanoparticles that exhibit surface dynamic only show minor morphological changes to their overall shape.[4] The time-lapse series of TEM images (Figure 1c) showing a single Ni NP undergoing bulk dynamics under specific reaction conditions. The transition period between the Ni and NiO states varies, ranging from 2 to 100 seconds within a single cycle. The sequence initiates with the particle in a metallic, high activity regime. Within approximately 1 second, it swiftly transitions to the oxidic state, low activity regime, indicating a rapid structural change. Ultimately, as one cycle concludes, the particle returns to the high activity regime, during which it shifts from an irregular oxide shape to a more rounded, metallic configuration.[4]

Conclusions
In conclusion, our investigation into the POX of ethylene using Ni NPs as catalysts reveals intricate dynamics underpinning the catalytic process. Utilizing advanced operando TEM, we observed both the structural and morphological transformations of Ni NPs in a self-sustained oscillatory regime. Through detailed analysis and characterization by operando TEM, we pave the way for optimizing catalyst design and operational parameters, aiming for enhanced efficiency, selectivity, and a deeper mechanistic understanding of catalytic processes at the nanoscale.

Figure 1: Oscillatory dynamics of nickel nanoparticles during ethylene partial oxidation. (a) Overview TEM image highlighting size and shape variations of Ni NPs. (b) Mass Spectrometry (MS) data depicting a complete cycle, illustrating the catalyst's high and low activity regimes. (c) Time-lapse evolution showcasing morphological changes in a single Ni NP under reaction conditions: C_2H_4:O_2 gas mixture ratio of 1:1, at a pressure of 1 bar and a temperature of 950°C.

Background incl. aims
Four-dimensional scanning transmission electron microscopy (4D STEM) measures 2D reciprocal space scattering information from an electron probe laterally shifted across a 2D real space specimen area [1]. This high-dimensional dataset allows much richer information to be retrieved than conventional STEM, ranging from crystallographic orientation and phase, strain, short and medium range ordering, to differential phase contrast (DPC), ptychography as well as other new imaging modes. The past decade has particularly witnessed the advance of this technique because of the introduction of fast direct electron-counting detectors. These detectors usually run at 1-10 kHz continuous readout, which corresponds to 1000-100 µs pixel dwell time in 4D STEM measurements, while the conventional STEM usually runs in few µs pixel dwell time. Such a 2-3 order-of-magnitude gap in speed would limit the application of the versatile 4D STEM measurements to at least two fields, including low-dose atomic-resolution high-contrast imaging of sensitive specimens as well as in situ time-resolved studies of dynamic behaviour upon external stimuli.
Methods
In order to tackle this challenge, we installed an event-driven CheeTah T3 detector with 2x2 chips (in total 512x512 pixels) from Amsterdam Scientific Instruments (ASI) on a monochromated and probe-corrected Thermo Fisher Scientific Titan STEM for 4D STEM applications. This detector retrieves precise timing of scanning line trigger signal from the microscope with the same clock as the electron impact events on the detector, which facilitates a reliable assignment of the electron events to each scanned pixel. Thanks to its 1.56 ns Time of Arrival resolution, this detector also permits recording electron events continuously in an effectively much higher frame rate for 4D STEM. Due to its inherent sparse nature, this high-dimensional data can be compressed and computed in real time efficiently in the compressed sparse row (CSR) format based on the collaborative development between ASI and LiberTEM team [2].
Results
4D STEM measurements at effectively MHz frame rate with live image reconstruction has been demonstrated based on these developments (see one example in the enclosed figure). This unique workflow enables the user to navigate the specimen, adjust focus or astigmatism, and eventually visualise sensitive specimens or dynamics without changing between different detectors or optical modes. A few application examples will be discussed during this presentation. This includes, but not limited to,
- Fast and low-dose phase-contrast imaging at nanometer to atomic resolution based on integrated centre-of-mass imaging, ptychography, and other 4D STEM modes,
- In situ 4D STEM measurement of both electromagnetic fields and strain/orientation/phase on magnetic and semiconductor specimens under tensile loading and unloading conditions,

- In situ 4D STEM mapping of electron-beam-induced charging on dielectrics and vitrified ice.

Conclusions

Effectively MHz frame rate event-driven detector has been successfully demonstrated for low dose and in situ time-resolved 4D STEM characterization. Sparse-array data format was implemented for real-time feedback and efficient analysis with compact data size. Versatile applications on low dose imaging of sensitive specimens and time-resolved studies of dynamic processes will be presented during this contribution. Further improvement and other potential applications for this workflow will also be discussed.

Background incl. aims
Layered Li-rich nickel-cobalt-manganese (LRM) oxides are promising materials for applications as cathodes in next-generation high-capacity power batteries.[1] However, the commercialization of LRMs is challenging due to their cycling instability, which originates from their intrinsic structural characteristics and deterioration processes.[2] Until now, neither their structures, which can comprise two-phase nanocomposites or only single-phase solid solutions, nor their degradation pathways, have been clarified. It is noteworthy that existing studies are based on assumptions and inferences regarding the structure under specific conditions and do not truly reflect the actual structural evolution of LRM cathodes under operational conditions.[3-5] Moreover, due to the lack of systematic research on typical failure structures in LRM cathodes, the structural evolution throughout the entire lifecycle of LRM cathodes remains obscured. Therefore, it's of great importance to reveal the actual evolution process of the structure and the degradation mechanism of LRM cathodes unfer operational conditions comprehensively. The aim is to unveil initial lattice structure and the complete structural evolution process, encompassing transition metal rearrangement, phase structure evolution, defect structure growth, and ultimate structural failure, throughout the entire lifecycle of rich lithium manganese cathodes, with the hope of providing insights for the design of LRM materials.
Methods:
This study employs in operandon neutron diffraction technology with characteristics such as sensitivity to light elements and resolution of TMs. the study combines advanced pression-assisted 4D-STEM technology with comprehensive phase analysis capabilities, supplemented by atomic-resolution aberration-corrected electron microscopy (HAADF-STEM), focusing on both short and long-range structures of LRM cathode materials.
Results:
In this work, We prepared a LR-NCM | graphite full cell and carried out both in operando neutron diffraction and low dose and precession-assisted 4D-STEM to map spatially-averaged structural evolution in real time over a large field of view and visualize light (O, Li) and heavy (TM) atoms simultaneously with atomic spatial resolution before, during and after cycling. Our work provides detailed insights into dynamic nanostructure evolution and local structural interactions through multiscale characterizations. The structure of pristine LRM is demonstrated to be a solid solution based on C2/m symmetry, resembling a thin layer of spinel. In the initial cycling, irreversible extraction of Li ions from the transition metal layers leads to the formation of vacancies within the layers, causing irreversible structural transformations within the material. The in operando neutron diffraction technique further tracks the formation of oxygen vacancies after the first discharge.

Despite surface coating with a spinel layer to prevent oxygen loss, the effectiveness is limited. In subsequent extended cycles, continuous loss of excess Li ions and migration of TMs within the layers result in the irreversible transformation of the internal structure from a lithium-rich phase to a conventional layered phase. This transformation leaves numerous vacancies within the layers, leading to the formation of internal nanoscale defects. These defects obstruct the channels for Li-ion transport within the layers, consequently causing a decline in material performance.
Conclusion:
Our work provides a new perspective on material failure mechanisms, emphasizing the importance of intrinsic modification methods in stabilizing the internal structure of layered high-energy cathodes, beyond conventional surface modifications.

In-Situ insights into Multivalent Metal Energy Storage: A model system for calcium sulfur batteries

Marco Kögel[1], Prof. Jannik C. Meyer[1,2]
[1]NMI Natural and Medical Sciences Institute at the University of Tübingen, Reutlingen, Germany,
[2]Institute of Applied Physics, University of Tübingen, Tübingen, Germany

Poster Group 1

As we globally realize large-scale electrical energy storage coupled with the rapid increase in global electromobility, the challenge of securing a consistent supply of critical raw materials utilized in lithium-ion batteries (LIB) continues to grow. Consequently, the search for alternative systems delivering comparable energy densities has become an important topic. Multivalent metals, renowned for their long-term stability, emerge as promising candidates in this regard.

The combination of calcium and sulfur represents a potent alternative, attributed to their abundant availability and recent research delineating the appreciable stability of their electrolyte system. [1] Nevertheless, to enhance fabrication efficiency, performance, and stability, a deeper understanding of the electrochemical dynamics at the anode surface, where the electrolyte interfaces with calcium, is essential. The work in the Casino project [2] aims for an understanding and optimization of key aspects towards its application.

The electrochemistry happens at the surface between the electrodes and electrolyte system. Understanding the details is what makes improvements possible. A novel in-situ model system is developed to mimic the behavior of the macroscopic symmetric Ca-Ca battery system while allowing atomic-level observations. Direct transfer of 2D materials enables the formation of liquid pockets and therefore high-resolution studies. [3,4] Calcium and electrolyte solution is encapsulated between 2D materials, and In-situ investigations are employed combined with EELS and EDX to uncover key mechanisms.

Poster Group 2

Nuclear fusion provides a safe and abundant source of energy for a long period of time and offers several important additional advantages. These include: fusion does not contribute to greenhouse gas emissions or global warming (a), reduction of long-lived radioactive waste compare to the nuclear fission reactors (b) and inherent safety features (c). Tungsten (W) is considered a promising plasma-facing material for future fusion reactors since it has number of advantages such as high melting temperature, excellent thermal conductivity, high strength and low sputtering yield. Its application in the International Thermonuclear Experimental Reactor (ITER), which is being built in Cadarache, France, and in the future Demonstartion Power Plant (DEMO) has significantly increased interest in W behavior under neutron irradiation. Knowledge about the defect formation and their evolution in neutron irradiated W is essential not only for assessing its applicability as a structural material in fusion reactors, but also for understanding numerous irradiation experiments in fission reactors.
ITER grade W was neutron irradiated in the BR2 material test reactor (Mol, Belgium) at 600°C, 800°C, 900°C and 1200°C to a damage dose of 0.1 dpa, 0.2 dpa, 0.5 dpa and 0.8 dpa. The microstructure of the irradiated material was analyzed using the Talos F200X transmission electron microscope (TEM), which is equipped with four energy-dispersive X-ray detectors (Super-X). The precipitates were detected either by high resolution TEM or by EDX elemental mapping, where they are visible in elongated shape.
The detailed TEM characterization of the radiation-induced materials shows the formation of three types of defects, e.g. voids, dislocation loops and nano-sized precipitates. The source of the precipitates are the transmutation-induced elements such as rhenium (Re) and osmium (Os), which accumulate with the damage dose [1]. In addition, a dose-dependent segregation of Re and Os, i.e. the formation of clusters around defects, was observed [2].
The results of the TEM analysis are summarized in Figure 1. The parts (a) and (b) show the voids and dislocation loops formed in W under neutron irradiation. The voids have a round or almost round shape, but in a few cases faceted voids with a size of 3-4 nm have been observed (a). Dislocation loops are typically visible in DF images obtained using a defined g-vector with a “coffee bean” contrast (b). Most loops are between 3 and 10 nm, but individual loops can be up to 20 nm. The number density of dislocation loops at 0.1 dpa and 0.2 dpa is comparable to the number density of voids (about 1022 m-3), while for material irradiated to 0.5 dpa and higher, the number density is reduced by about two orders of magnitude.
Spatial distribution of Re and Os segregation was studied by STEM-EDX element mapping in the TEM, where their local presence was visualized by intensity variations of the different colors. The part (c) demonstrates the distribution of Re (green) in representative areas in the material. The clear segregation was observed at the grain boundaries, line dislocations and radiation-induced voids and loops. At 0.1 dpa and 0.2 dpa, the Re distribution was detected only around the voids, while the Re signal at the dislocation loops was seemingly below the detection limit. There was no Os signal

detected in 0.1 dpa damage, while a weak Os signal was detectable in the material with 0.2 dpa. At 0.5 dpa and 0.8 dpa, Re and Os were detected around voids and loops.
The detailed analysis of Re and Os segregation on defects in the sample irradiated to 0.8 dpa is shown in Figure 1d-g. The distribution of Re (green) and Os (blue) are visualized in corresponding elemental maps (d and e) and shown overlapped in the part (f). The overlapping clearly show that Os tends to form small rich areas inside Re clouds which mostly have a spherical shape. Os-rich areas often have a needle-like shape, indicating the formation of precipitates or their precursor. These Os-rich areas are formed on both voids and dislocation loops.
To provide a detailed visualization of the Os distribution, the intensity profiles were recorded across voids and loops. The example of segregation around a void marked by a yellow arrow is shown in part (d-e). The profile (g) was taken through the void marked with the arrow. It shows the typical reduction in Re-intensity at the void position and the formation of elongated, Os-rich regions adjacent to the void on one side. In the few cases the crystallinity of the precipitate was detected. The atomic spacing of 0.23 nm could correspond to the [111] atomic plane of the □-WRe2 phase.
The study includes a detailed TEM characterization of the radiation-induced defects, which can be divided into three types, e.g. voids, dislocation loops and precipitates. In addition, a dose-dependent segregation of Re and Os, i.e. the formation of Re rich clusters around defects, was observed.

Figure 1: Extensive TEM analysis of radiation damage in W. TEM images of voids and dislocation loops a shown in parts (a) and (b) correspondingly. Part (c) visualize the Re-segregation on defects, dislocations and grain boundaries. Parts (d-g) demonstrate the analysis of Re- and Os-segregation on defects.

IM-08, Lecture Theater 2, august 28, 2024, 10:30 - 12:30

Background incl. aims
Coherently controlling the electronic and structural properties of new generation materials and devices down to the sub-nm level with femtosecond precision is one of the ultimate challenges in quantum technology, and has the potential to engineer novel states of matter with exceptional macroscopic functionalities. Here, we respond to such pressing need by introducing a new paradigm where the interaction between light and free-electrons can be exploited for coherently manipulating electron beams [1,2], enabling dynamical investigation of materials with enhanced sensitivities to specific materials degrees of freedom, unattainable using conventional schemes. We develop innovative ultrafast electron microscopy (UEM) methods based on light-induced electron modulation aiming to observe, understand, and control the non-equilibrium behavior of low-dimensional systems at such ultrasmall and ultrafast scales, which would be otherwise hidden in standard UEM observations.

Methods
The playground for these experiments is a modified Ultrafast Transmission Electron Microscope (UTEM) with multiple optical accesses for: i) electron pulse generation, ii) electron wavefunction modulation, and iii) sample excitation. Arbitrary longitudinal and transverse modulation of a free-electron wave function is obtained using light fields properly modulated in space and time. In particular, a femtosecond electron pulse interacts with the chosen configuration of the optical distribution as generated via a spatial light modulator (SLM) (see schematics in the left panel of the figure), and the energy-momentum quantum exchanges between electron and photons resulting from such coupling are mapped in the electron multidimensional phase space. [3]

Results
In this contribution, we will first demonstrate how to coherently modulate the spatial, momentum, energy, and temporal distributions of the electron wave function with high versatility on different modulation basis. This derives from the technological development of a new device: a photonic-based modulator for dynamic multidimensional control of electrons. Then, we will show how our approach for versatile transverse and longitudinal electron modulation at the fs-timescale is crucial for the first time implementation of new imaging techniques (see schematics in the right panel of the figure), such as Ramsey-like holography [4] – for phase- and time-resolved imaging of hybridized low-

energy modes in strongly-correlated systems – and Single Pixel Imaging [5] – that has been only recently proposed for optical detection and now is possible also in electron microscopy permitting lower electron doses, faster acquisition rates for individual nanoscale objects in their natural environment.

Conclusion
In conclusion, we report on the realization of an all-optical rapidly-programmable phase mask for electrons, which allows us to implement new electron imaging approaches with enhanced sensitivities and performance, thus radically changing how matter is investigated in electron microscopy. This is based on a specific sensitivity to materials' inner coherence when light-modulated structured electron waves are adopted. Our results pave the way for achieving unprecedented insights into new generation materials and their dynamic behavior, impacting also future photonics and electronics applications. More generally, unlocking this potential will play a decisive role in our ability to address the grand challenges that the world is facing nowadays, especially regarding 'energy', 'information' and 'health'.

Poster Group 2

The technique known as four-dimensional scanning transmission electron microscopy (4D-STEM)1 has recently emerged as a potent tool for the local characterization of crystalline structures in various materials, including cathode materials for lithium-ion batteries and perovskite materials for photovoltaics.
This 4D-STEM data analysis method based on the ACOM system of NanoMegas (Astar)2,3 uses pattern matching of a scanning nano-diffraction dataset with libraries of diffraction patterns simulated from known structures extracted from CIF files. This method enables to construct crystalline phase and orientation maps to determine crystallinity4,5, microstructures6, structural deformation7, and grain boundaries8 using scanning nano-diffraction with precession mode in a nanometer resolution9,10. However, the utilization of new detectors specifically designed for electron diffraction patterns and other advanced techniques necessitates the continuous adaptation of methodologies to address the challenges associated with crystalline materials.

The goal of the data preparation methods proposed here is to improve the quality of Astar pattern-matching using a dataset of diffraction patterns acquired with a CMOS Oneview camera. The high sensitivity of the CMOS camera and the data filtering developed here modify the diffraction images leading to a compromise between improving image quality and optimizing template-matching results11.

Our strategy employs a data reduction technique that utilizes registration methods to identify electron diffraction spots within patterns. By doing so, we are able to filter and capture the diffraction signal and subsequently reconstruct the patterns. These reconstructed patterns are then inputted into the Astar suite pattern-matching software. This process allows us to record the essential information of each reflection in a dataset, including intensity, size, and position, with a high level of accuracy (sub-pixelar) for the position, typically on the order of 10-3px. Additionally, this technique achieves a significant reduction in data size, typically by a factor of 103. This means that the essential information of the diffraction pattern is stored on a disk with 100 to 1000 times less space required. The adaptative nature of this method not only reduces noise and compresses nanodiffraction scanning data for ACOM and strain mapping analysis but also extends its applicability to other techniques such as 3D electron diffraction (3DED).

To evaluate our approach, we employ dedicated metrics that clearly demonstrate a substantial improvement in phase recognition. Our results indicate that this data preparation method not only enhances the quality of the resulting image but also boosts confidence levels in the analysis of crystal orientation and phase determination outcomes. Furthermore, it helps mitigate the potential impact of user bias that may arise when manipulating parameters during the application of this method.

Firstly, modifications on inside diffraction patterns are estimated through image quality metrics such as peak signal-over-noise (PSNR), structural similarity index measure (SSIM), and root-mean-square error (RMSE). Secondly, the quality of the pattern-matching process on filtered and reconstructed images obtained by the proposed experimental data preparation method is evaluated using index and orientation reliability, as defined in the Astar software. We demonstrate that the experimental data preparation helps to improve the pattern-matching quality result, as it reduces noise overfitting, improves structural similarity index measure, and increases the orientation reliability.

In situ ESEM study of supported noble metal nanoparticles dynamics under reaction conditions

Birger Holtermann[1], Jan-Christian Schober[2], Dr. Philipp N. Plessow[3], Prof. Dr. Andreas Stierle[2], Prof. Dr. Yolita M. Eggeler[1]
[1]Karlsruhe Institute of Technology (KIT), Laboratory of Electron Microscopy (LEM), Karlsruhe, Germany, [2]Centre for X-ray and Nano Science, Deutsches Elektronen-Synchrotron (DESY), Hamburg, Germany, [3]Karlsruhe Institute of Technology (KIT), Institute of Catalysis Research and Technology (IKFT), Karlsruhe, Germany

PS-05 (1), Lecture Theater 1, august 28, 2024, 10:30 - 12:30

Supported noble metal nanoparticles (NPs), including Pt, Pd, and PtPd alloys on Al2O3 or CeO2, are pivotal in heterogeneous catalysis for processes like the water gas shift reaction, methanation, and hydrocarbon oxidation/partial oxidation. Maximizing the economic efficiency of these costly metals necessitates catalysts with high activity over their lifetime. A primary challenge to maintaining activity is thermal deactivation via sintering. Two fundamental sintering mechanisms, namely Oswald ripening (OR) and particle migration and coalescence (PMC), have already been identified in the literature. However, recently there has been an ongoing debate about surface vs gas-phase mediated sintering pathways [Ple-16][Oh-23]. To help address this open question we aim to capture real-time, statistically significant data to provide insights into the dynamics of chosen NP/support systems under reactive conditions on a broad micrometer scale using electron microscopy.

While in situ catalysis experiments using electron microscopy were previously carried out only in transmission electron microscopes (TEM) equipped with special holders for heating or gas experiments, allowing the study of single nanoparticles with atomic resolution, recently environmental scanning electron microscopes (ESEM) have become a popular tool to study dynamic catalytic behavior on a broader micrometer scale [Bar-19].
In this work we will introduce our novel in situ experimental setup inside an ESEM using a heating stage, capable of temperatures of up to 1000°C and a self-build gas injection system, thereby enabling the study of large populations of supported NPs and their reaction to experimental stimuli. This experimental setup coupled with an automatic post-processing routine based on computer vision algorithms allows the analysis of long time series of recorded images and permits a statistical evaluation of the NP motion trajectories, thus providing insight into the sintering behavior of these NPs as a function of temperature and gas atmosphere.

Figure 1 shows the main steps of our post-processing routine, which is based on computer vision algorithms and an approach developed by Faraz et al [Far-22] for the environmental transmission electron microscope (ETEM). After acquiring long time series in step 1, NPs are detected in each frame and segmented in step 2. To overcome signal-to-noise limitations, the shape and center of mass of the nanoparticles are approximated in step 3 to better compute motion trajectories by comparing differences in nanoparticle positions from frame to frame in step 4. Not only the motion trajectories can be analyzed in step 5, but also the evolution of the NP size distribution over time.
In contrast to the work of Faraz et al., our routine works on a larger length scale and processes more nanoparticles under the additional constraint that the nanoparticle support has a more homogeneous contrast, making drift compensation based on background registration more difficult.

We will present the first preliminary results of our experimental setup under simplified oxidation conditions of 10mol-% O2 in N2, as well as reduction conditions of 5mol-% H2 in N2 at various temperatures for different NP/support systems. Following up from a previous study in which we analyzed the redispersion mechanism of Pt/CeO2 under alternating oxidation/reduction cycles ex situ, we will present the results of this redispersion experiment in our new ESEM setup, as well as ex situ characterization of the CeO2 support substrates used in this work [Sch-24]. In addition, we will present our data post-processing routines and discuss some challenges.

PS-03 (3), Lecture Theater 2, august 30, 2024, 14:00 - 16:00

Background incl. aims
Electronic materials have garnered significant interest due to their potential applications in a wide array of important electronic devices, including transistors, sensors, solar cells, and more. Achieving high-performance devices and developing new electronic materials for future technologies relies fundamentally on understanding electronic processes through advanced characterization techniques. Currently, the characterization of the active layer in a device can offer either global functional information, such as with the most current-potential methods, which only demonstrate the impact of defects on performance without detailing the quantity and distribution of defects, or provide localized details, as seen with techniques like atomic force microscopy and conventional scanning electron microscopy (SEM), which may not capture the entirety of the case. Therefore, we present a novel characterization method capable of acquiring both kinds of information from the active layer, which would be highly beneficial for comprehending the structure-morphology-performance relationship.

Methods
The use of Ultra-low voltage (ULV) SEM has become increasingly crucial for investigating beam-sensitive materials, particularly organic molecules and polymers, due to its ability to significantly suppress beam damage. Additionally, the charging behavior under ULV conditions becomes more material-characteristic compared to conventionally used beam energies (e.g., < 500 eV). Fine-tuning the beam energy within the range of 10-200 eV can result in either negative or positive surface charging [ref.1], depending on factors such as beam energy, beam current, charging density, and the conductivity of the materials. This capability allows us to simulate the working state of a p- or n-type transistor by in-situ generating the required charge type. Moreover, the surface potential resulting from charge flow anomalies enables us to visualize morphological defects along the pathways. Through post-imaging processing, we can calculate the real working pathway for charge-carrier transport, subsequently correcting the charge-carrier mobility [ref. 2].
Furthermore, under ULV conditions, we can collect the energy distribution spectrum of emitted electrons, which can be transformed into a surface charging map. The gradient of the charging attenuation provides structural information within (poly)crystalline domains [ref. 3].

Results
Utilizing the first method mentioned above, we successfully corrected 11 organic thin-film transistor devices, resulting in highly reliable mobility values that accurately reflect the material's charge transport capability. With the latter method, we can estimate the charge-carrier mobility from polycrystalline thin films, which align well with the calculated values. Of particular interest is our ability to distinguish between various crystalline domains with different molecular orientations. Furthermore, we can determine molecular orientation by observing the gradient of the charging

attenuation, a technique which, to the best of our knowledge, represents the first application of SEM for this purpose.

Conclusion
By employing in-situ charging and charging maps via ULV-SEM, we can gather information regarding various morphological phenomena. This enables us to directly correlate device performance with the chemical structure of the active material and its morphology, thereby facilitating the design of novel structures and the optimization of the active layer in electronic devices.

PS-04 (1), Plenary, august 26, 2024, 10:30 - 12:30

Over the last decades, with increasing energy demand along with the shift towards greener energy solutions, Li-ion batteries have gained attraction for energy storage applications.[1] Due to the high complexity in the hierarchical architecture of composite electrodes, it is extremely challenging to ensure a homogenous electrode structure. The non-uniform distribution of phases, leading to microstructural heterogeneities, has been shown to induce a non-uniform electrochemical behavior, which can deteriorate the performance, and cause macroscopic failures.[2,3] Therefore, the identification of these microstructural heterogeneities and understanding their effects on the dynamics of (de)lithiation is crucial to improve electrode design.

Lithium compositional distributions in composite electrodes can also be investigated using various techniques such as Raman microscopy,[4] X-ray diffraction (XRD),[5] or 2D X-ray absorption near-edge structure spectroscopy (XANES).[6] However, these methods have been restricted to low spatial resolution or spatially integrated signal along the depth direction. These methods hence cannot accurately capture the spatial distributions and can lead to a limited interpretation of the mechanism. Recently, Finegan et al.[7] used Operando X-ray diffraction-computed tomography (XRD-CT) for characterizing, in 3D, the dynamic crystallographic structure between and within LMO particles during electrochemical operation.

Several works have combined XANES and X-ray tomography to generate a rich data set that allows a direct correlation of the chemical information and the microstructure. Meirer et al.[8] used 3D XANES to probe the conversion of NiO to Ni metal in a partly reduced electrode. They found significant inhomogeneities in terms of chemical states across particles as well as evidence of fracturing caused by volume expansion during the reaction. More recently, Wang et al. [9] collected a 46-point spectrum across the iron K-edge of a LiFePO4 cathode particle and developed a run-out correction system to enable automated tomography.

Here, we perform XANES coupled with transmission X-ray computed tomography (TXM-CT) at nanoscale in Operando mode to investigate LiNi0.5Mn0.3Co0.2O2 (NMC) positive electrodes[12]. The ability to probe battery materials in an operando mode provides significant advantages over ex situ approaches and allow characterizing the microstructure evolution while capturing the electrochemical reaction kinetics inside electrode and active materials (AM). In this work, we demonstrate that Operando XANES-TXM nanoCT allows access to the Li distribution (local Li concentration) at nanoscale within the LiB electrodes during the operation. We also proposed a method that relies on just three energy levels located at pre-edge, edge, post-edge for minimization of radiation damage to the sample. Also, a specific electrochemical cell and a sample preparation process were introduced, which make the use of electrodes typical to those used in real-life applications possible.

Our experimental results unveil the non-uniformity of the Li repartition throughout the LiB porous electrodes during operation [10]. As a result, there are regions being more active than the others as well as preference spots on the particle surface where the reactions are more likely to occur. The Li repartition across the electrode depth is adequately uniform, which indicates a negligible effect from porous electrode. This is expected as we used EC:DMC solvent-based electrolyte at 1.2 M which reduces the limitation from ionic transport in liquid phase within the porous electrode. Thus, we can conclude that mass transport in the electrolyte is not rate limiting factor in this electrode under the applied cycling conditions. In addition, some of the reconstructed slices also revealed that the lithiation process could also happen from internal pores of the AM particles. This observation also implies that the electrolyte along with the carbon conductive can penetrate some internal pores through the AM grain boundaries and allow the (de)lithiation process to occur from the inside of the NMC secondary particles.

Finally, we expect that our analysis technique will provide a direct method to unveil the effects of the electrode microstructure on its electrochemical performance [11,13]. This multiscale insight can shed light to the optimization of the electrode design to improve the electrode performance.

Coherent inelastic scattering probed by holographic scanning transmission electron microscopy

Dr. Nora Bach[1], Tim N. Dauwe[1], Dr. Murat Sivis[1], Prof. Dr. Claus Ropers[1]
[1]Max Planck Institute for Multidisciplinary Sciences, Göttingen, Germany

IM-03 (2), Plenary, august 28, 2024, 14:00 - 16:00

In today's nanoscale technology, a detailed understanding of the structures and induced fields is fundamental. Electron microscopy has proven a powerful method for quantitative phase-contrast imaging of electric fields in nanostructures. One successful approach is based on off-axis holography which employs the interference of a complex object wave with a reference wave. However, this technique requires a wide, coherent electron beam emitted from a highly coherent electron source, and cannot be transferred straightforwardly to access ultrafast dynamics in the femtosecond-nanometer range.
Nonetheless, phase-resolved measurements of local optical responses have recently been revealed using Lorentz microscopy [1] and free-electron homodyne detection [2]. These measurements rely on the inelastic scattering of electrons off optical near-fields in so-called Photon-Induced Near-field Electron Microscopy (PINEM) [3,4]. Pulsed electrons generated in an ultrafast transmission electron microscope (UTEM) gain or loose energy upon interaction with the optical field of the driving laser pulse. While both approaches for phase-resolved measurements have proven powerful in terms of resolution, sensitivity and robustness, their stringent requirements on electron beam coherence or a designated sample holder, respectively, render the general experimental implementation challenging.
In this contribution, we present a method based on scanning transmission electron miscroscopy (STEM) with spatially separated coherent probes [5], that yields holographic information on inelastic interactions at reduced electron beam coherence requirements. Specifically, we insert an amplitude grating in the electron microscope condenser system and can, thereby, prepare a tailored electron probe composed of a coherent superposition of spatially separated STEM foci corresponding to given diffraction orders. The far field of these probes interferes to form an image of the grating pattern. Distinct elastic and inelastic interactions experienced by the separate probes will modify the interference condition and affect the recorded far field distribution.
Experiments are carried out in a UTEM based on a Schottky field-emission JEOL JEM-F200 instrument, which we modified to allow for a laser-triggered photoelectron mode and optical sample excitation. As a first application of STEM holography, we perform 2D-raster scans at nm-scale spatial resolution to visualize elastic and inelastic interactions at an optically excited heterostructure.
In the simplest case of only elastic interactions, a difference in, for example, sample thickness between the separate probes would lead to a translation of the interference pattern for different scanning positions. Imaging of inelastic scattering processes is achieved by employing a single-electron-sensitive hybrid pixel detector behind an energy filter. Moreover, by adjusting the electron microscope imaging spectrometer to collapse one of the momentum space dimensions on the detector and adding energy dispersion along this direction, we anticipate recording two-dimensional images simultaneously, encoding holographic information both on relative phases between the probes and on the energy spectrum.
In conclusion, we demonstrate STEM holography adapted to the characterization of coherent inelastic scattering. A particular advantage of this technique is the relaxed coherence requirements,

which could be central to overcoming common challenges in ultrafast transmission electron microscopy and improving time-resolved imaging of electric and magnetic fields on the nanoscale.

Poster Group 1

Background incl. aims:
Mesoporous silica structures are widely used in the field of nanotechnology, e.g. as substrate in heterogeneous catalysis [1] and as stationary phase material in size-exclusion chromatography [2]. To understand and improve the material's properties, a precise characterization of the pore network is indispensable. Common approaches to quantitatively analyse the mesoporous space are averaging sorption/intrusion techniques [3] and three-dimensional imaging techniques such as electron tomography in high-angle annular dark-field (HAADF) scanning transmission electron microscopy (STEM) mode [4]. While the first mentioned techniques lack the localized spatial information, HAADF-STEM tomography resolves the mesoporous structure with a spatial resolution in the nm-range, but suffers from poor contrast between pore space and network in case of low atomic number (Z) materials, since the imaging contrast scales with ~Z^2 [1]. In this study, we uniquely combine Ga intrusion of the pore space in mesoporous silica with HAADF-STEM tomography to enhance the Z-contrast between pores and silica significantly by a factor of ~9x. This enables a reliable quantitative analysis and visualizes localized information about the pore network and the process of Ga intrusion. In particular, we apply 360° HAADF-STEM tomography on pillar-shaped specimen prepared from the intruded mesoporous silica. This allows for precise 3D reconstruction of the tilt series without missing-wedge artifacts to accurately obtain important pore characteristics such as size distribution, tortuosity, and connectivity [5].

Methods:
Mesoporous silica with an average pore size of 20nm is intruded with Ga up to different filling degrees (50%, 100%) by a modified Hg intrusion porosimetry technique. From the intruded sample systems pillar-shaped specimen are prepared on a tip by scanning electron microscopy (SEM)/focused ion beam (FIB) techniques using a Helios NanoLab 660 DualBeam SEM-FIB. The samples are analysed by 360° HAADF-STEM tomography in a double Cs-corrected FEI Titan³ Themis at 300 kV.

Results:
Backscattered electron (BSE) imaging on a FIB prepared cross-section of the fully intruded silica reveals that the method of Ga intrusion leads to a homogeneous filling of the pore space in a representative volume required for STEM tomography (Figure 1a - left). The homogeneous distribution of the infiltrated Ga phase is crucial for a reliable quantitative analysis by STEM tomography. If the pressure during the intrusion process is reduced, a partial filling (50%) of the porous network can be achieved with the empty pockets being evenly distributed in the entire

sample (Figure 1a - right). This finding resembles the homogenous and narrow pore size distribution of the material and hints towards smaller pore channels being present within the unfilled spaces, since the infiltration of smaller pore channels requires in general higher pressures.
From the fully- and half-intruded silica, pillar-shaped specimen can be prepared on tomography tips by common FIB lift-out technique (Figure 1b). In contrast, imaging and pillar preparation from pure silica is challenging, since the material is electron-beam sensitive and non-conductive. This leads to sample charging and causes sample drift and uneven milling during FIB preparation. Therefore, a charge neutralizer is indispensable in case of silica, which is, however, not available on any FIB instrument. Also during STEM tomography, charging effects occurring on pure silica easily cause complications resulting in bending and structure deformation, which strongly worsen the 3D reconstruction quality. Moreover, the build-up of carbon contamination during tilt series acquisition worsens the image contrast over time, due to the low atomic number difference of Si, O, empty space and C contamination in HAADF-STEM imaging mode. In contrast, specimen intruded with Ga feature a ~9x stronger contrast, so that C contamination is negligible and the pore and silica space can clearly be resolved throughout the entire tilt series (Figure 1c). As outlined, Ga intrusion of mesoporous silica features multiple advantages: (1) it improves the imaging contrast in HAADF-STEM mode, (2) increases the sample integrity, (3) mechanically stabilizes the pillar, and (4) forms a conductive pathway through the sample eliminating charging effects during preparation and STEM tomography. These benefits improve significantly the reconstruction quality of the tomographic tilt series in the fully intruded specimen (Figure 1d - left), facilitate the phase segmentation between Ga and silica (Figure 1d - middle) and enable a reliable quantitative analysis of the porosity and pore size distribution by the method of maximum sphere inscription (MSI) (Figure 1d - right, Figure 1e). For a benchmark comparison, the mesopores of the silica structures were investigated with N_2 physisorption, evaluated with the non-local density functional theory (NLDFT) method. Moreover, we investigated the 3D reconstruction of the half-intruded silica specimen (Figure 1f) to improve our knowledge regarding the Ga intrusion process and to study contrast differences of pores, Ga and silica in more detail. While the filled channels are clearly visible, the unfilled channels, which indicate bottlenecks in the pore pathways, are weakly distinguishable from the surrounding silica network (Figure 1f - left). The respective segmentation is challenging, but helps to identify bottlenecks in the pore pathways (Figure 1f - right). In sum, the findings from electron tomography can further elucidate the gallium intrusion process on the nanoscale and contribute to the development of methods for textural characterization based on liquid intrusion.

Conclusion:
This study highlights the potential of Ga intrusion for contrast enhancement of the pore space in mesoporous silica during 360° HAADF-STEM tomography to study quantitatively important pore characteristics. Vice versa, the study further helps to understand the process of Ga intrusion. The intrusion process leads to a homogeneous Ga distribution and enhances the mechanical stability of the non-conductive silica during both FIB sample preparation and acquisition of the STEM tilt series by minimizing electrical charging. The Ga intrusion process can be regarded as a potential common technique to improve electron tomography not just on mesoporous silica but also on various other porous materials.

The significance of the phonon polarization vector in vibrational EELS

Paul Zeiger[1], Jan Rusz[1]
[1]Uppsala University, Uppsala, Sweden

Poster Group 1

Background incl. aims
Phonons are the quasiparticles of lattice vibrations. They influence a variety of material properties such as for example the heat conductivity and play a major role in physical effects of technological importance such as for example superconductivity and the phonon Hall effect. Phonons are thereby wave excitations of the entire lattice of a material in the solid state, so-called normal modes, which can be distinguished by the wave vector q and the phonon branch v. Each mode (q, v) has a definite frequeny ω(q,v) and phonon polarization vector e(q,v). Knowledge of both of these quantities fully characterizes a phonon mode (q, v).
Vibrational Electron Energy Loss Spectroscopy (EELS) is establishing itself as an important tool to characterize phonons at the nano- and atomic-scale [1]. In this contribution we discuss the role of the phonon polarization vector in vibrational EELS from different perspectives.
Methods
As the first step we consider the analytical expression for the vibrational EELS cross section in first-order Born approximation, which scales with the phonon frequency ω(q,v) in a simple manner and depends on the scalar product of the momentum transfer Q and phonon polarization vector e(q,v). Here we focus on the richer dependence with respect to the phonon polarization e(q,v). In the second step we consider explicit simulations of vibrational EELS with the Frequency-Resolved Frozen Phonon MultiSlice method and comparison with experiments.
Results
The scalar product dependence of vibrational EELS is the key to the phonon polarization vector. It governs the visibility of phonon modes and is responsible for an interesting modulation of the intensity of the phonon EELS as a function of the detector placements, both for small and large off-axis detectors. The effects have been observed in recent experiments [3,4].
Conclusion
The phonon polarization vector leads to an intricate modulation of vibrational EELS, which can be exploited to gather information on the direction of the phonon polarization vector.

Direct imaging of deformation in metallic glasses using precession nanodiffraction mapping

Dipl.-Ing. Simon Fellner[1], Dipl. Ing. Lukas Schretter[1], Univ. Prof. Dr.-Ing. Habil. Dr. h.c. Jürgen Eckert[1,2], Dr. Christoph Gammer[1]
[1]Erich Schmid Institute of Materials Science, Austrian Academy of Sciences, Leoben, Austria, [2]Department of Materials Science, Montanuniversität Leoben, Leoben, Austria

PS-02 (3), Lecture Theater 4, august 30, 2024, 14:00 - 16:00

Background:
Despite having unique attractive properties, non-crystalline/amorphous materials suffer from catastrophic failure after reaching their yield strength. The ability to improve the mechanical and functional properties of metallic glasses depends on understanding their inherent strain state. Recently, nanoscale strain mapping was used to unravel shear band formation in a monolithic metallic glass [1]. The effect of structural changes induced by the introduction of secondary crystalline phases, highly rejuvenated regions or other defects renders transformation mechanisms in metallic glasses even more complex. Due to the emergence of novel dedicated specimen holders, in-situ transmission electron microscopic measurements are a powerful tool allowing to directly measure the deformation behavior of these tailored nanocomposites [2].
Aim:
In this work, we want to directly image the local elastic strain fields at heterogeneities in metallic glasses using precession nanodiffraction mapping.
Methods:
The study was carried out on a CuZr-based metal alloy, which is a well-known glass former. The introduction of heterogeneities included thermal processing techniques and solid state amorphization. Nanosized specimens with an electron transparent window were fabricated through focused ion beam milling. A unique push-to-pull device, which is a micro-electromechanical systems-fabricated flexure device from Bruker was used for in-situ tensile testing in the transmission electron microscope. Precession nanodiffraction mapping was integrated with an in-column energy filter and a direct electron detector from QuantumDetectors. This combinatorial approach enabled rapid acquisition of high quality diffraction patterns. It also allowed us to follow the structural response during in-situ deformation on the nanoscale.
Results:
The results of precession nanodiffraction mapping were able to describe local events of cooperative shear in metallic glasses. From acquired in-plane atomic level strain maps the interaction between heterogeneities could be described quantitatively. Different enthalpy states of the metallic glass showed different shear band mechanisms, which contradicts the model of a uniform disordered material after processing. It was shown, that high interfacial stresses between heterogeneities cause complex strain concentrations preventing strain localization in a single shear band. We were also able to show that crystalline phases strongly influence the stress field in the amorphous phase. Recorded strain maps from elastostatic loaded samples and during in-situ tensile deformation revealed early stages of shear nucleation and propagation on the nanoscale. As a result, a direct link could be established between the structure and properties of these tailored metallic glass composites.
Conclusions:
We demonstrated the experimental measurement of local quantitative strains on the nanoscale. For this purpose, structurally altered metallic glasses were investigated. It could be shown how

heterogeneities influence the deformation behavior and mechanical properties. These new findings will improve the understanding of the interplay between structural heterogeneities and carriers of plastic deformation. With these conclusions, our work contributes significantly to the development of new high-performance materials.

Poster Group 1

Complex correlated oxides are quantum materials characterized by unshielded d-electrons. Their interaction across competing energy scales leads to diverse functionalities, which can be altered by slight changes of their structure, composition, or boundary conditions [1]. In this context, recent studies on ferroelectric oxides have shown the formation of complex polar topologies, which are related to a delicate interplay between the intrinsic tendency of the material towards a uniform polarization and the electrical and mechanical constraints placed upon them [2]. However, the cube-on-cube epitaxial structure of these materials forces the use of single crystalline substrates for their growth, which restricts the possible mechanical boundary conditions and, therefore, the formation of new topological structures. To overcome this limitation, we have isolated the ferroelectric materials from their parent substrate by a selective chemical exfoliation method, thus obtaining freestanding layers of just a few unit cells in thickness. This new approach vastly increases the potential for novel hetero-integration approaches by stacking various freestanding layers and avoiding the chemical, structural, or thermal limitations of conventional synthesis and growth processes [3].

In this work, we show how a polar vortex pattern is induced by stacking twisted freestanding ferroelectric $BaTiO_3$ layers [4]. We study the formation of these topological polar structures in relation to the twisted angle and layer thickness by aberration-corrected scanning transmission electron microscopy and density-functional theory calculations.

These results show an exciting opportunity to create novel polar topologies using the unique modulations that are possible in moiré bilayers and pave the way for potential applications in future high-density ferroelectric memory devices.

PS-09, Lecture Theater 2, august 26, 2024, 14:00 - 16:00

Background incl. aims
The interactions between the spin, charge, orbital and lattice degrees of freedom in transition metal oxides (TMO) give rise to a wide range of emergent phenomena, such as high temperature superconductivity, colossal magnetoresistance, or metal-insulator transitions, to name a few. Small variations in local chemical or electronic doping resulting from the presence of O vacancies can lead to drastic changes in these physical properties, since the macroscopic response is ultimately determined by the interplay between the oxygen s-like and transition metal d-like electrons. Thus, the in-depth comprehension of such phenomena relies on being able to quantify the presence of very reduced densities of these elusive defects. However, the detection of very low O vacancy concentrations remains extremely challenging. Aberration-corrected electron probes in the scanning transmission electron microscope (STEM) can bear on this task. In this work we propose a new method aimed to detect single O vacancies in a TMO such as SrTiO3 (STO), exploiting the capabilities of 4D-STEM techniques.
Methods
Density-functional theory (DFT) calculations were used to obtain reference relaxed STO supercells containing a single oxygen vacancy per 3x3x9 unit cells in order to mimic very low deoxygenation levels. Simulations of 4D-STEM data based on these models were carried out using the py_multislice code. Convergent beam electron diffraction (CBED) patterns of fully oxygenated O columns and columns with a single oxygen vacancy were obtained. Simulations have been performed implementing the multislice method in combination with the frozen phonon approximation, to account for multiple and thermal diffuse scattering. Analysis of the scattered intensity distribution, as a function of scattering angle and specimen thickness, allows identification of the characteristic fingerprints associated with the presence of single oxygen vacancies in atomic resolution diffraction images. A virtual detector can be used post-acquisition to generate images from 4D-STEM datasets. The imaging geometry was optimized here by selectively picking a distribution of inner/outer angles of annular detectors. Angular ranges were chosen to maximize intensity variations when comparing individual O atomic columns, and a virtual imaging mode was engineered to maximize the contrast between fully oxygenated columns and atomic columns where single O vacancies were present. Such simulations were then used for comparison with experimental 4D-STEM data obtained from ultrathin, freestanding SrTiO3 membranes 16 nm thick with O vacancy concentrations bellow the sensitivity threshold of complementary techniques such as electron energy-loss spectroscopy (EELS).
Results
The contribution to the electron scattered intensity distribution associated with O columns where a single oxygen vacancy is located can be quantified by subtracting the CBED pattern from a fully oxygenated column to a vacancy containing column, as illustrated in Fig. 1. The analysis of the resulting scattered intensity distribution reveals two angular regions of interest: (1) a central region

inside the bright field disk where fully oxygenated columns scatter in a more intense fashion due to beam channeling and (2) an external region in the bright field disk where the scattering intensity is increased due to a dechanneling effect. This behavior is robust and easily interpretable upon sample thickness variations. Such well-defined angular dependence of the scattered intensity constitutes a characteristic fingerprint of single oxygen vacancies.
Experimental data can be then examined with these features in mind. Experimental 4D-STEM datasets were analyzed using the virtual detector previously discussed in order to track spatially any O column intensity variation. Optimized detector images were produced by integrating the relevant angular ranges in experimental data. The resulting images exhibit, indeed, variations in O column intensity that are consistent with small amounts of O vacancies, which can be identified well above the noise threshold. Results will be shown to prove that both image contrast difference and single CBED pattern features demonstrate single vacancy detectability. The contrast difference between fully oxygenated and vacancy containing columns in the optimized virtual detector imaging mode will also be discussed in the light of conventional annular dark field (ADF) and annular bright field (ABF) images.
Conclusion
We demonstrate the detection of single oxygen vacancies in SrTiO3. Combining DFT calculations, atomic resolution 4D-STEM simulations and data analysis, the characteristic fingerprints of single oxygen vacancies can be identified in both simulations and experimental data, which indeed replicate the predicted fingerprints both in image intensity and CBED patterns. This capability enables for the first time the experimental identification of single oxygen vacancy columns in a freestanding STO membrane. This method opens a new path in the field of advanced materials characterization by electron probes, highlighting the advantages of 4D-STEM techniques and the unique insight they provide.

Poster Group 2

Background incl. aims
Soft x-ray tomography (SXT) uses low energy x-rays to image frozen-hydrated biological specimens such as entire mammalian cells or thick tissue slabs with a few tens of nanometers of spatial resolution. The technique takes advantage of the biological water window whereby water is relatively transparent to x-rays from 284 to 543 eV (2.34 to 4.4 nm) but carbon-based organelles are absorbing. This native contrast imaging allows high resolution imaging of bulk specimens with minimal sample preparation. While SXT has traditionally been confined to synchrotrons the recent development of a laboratory scale SXT microscope opens the possibility of integrating this novel technique into light and electron imaging workflows. The SXT microscope features an integrated light microscope for overview imaging and fluorescence targeting, allows for swift acquisition of 2D and 3D x-ray images covering extensive areas on the specimen, and enables efficient and rapid identification of cells of interest. The utility of the microscope is currently being demonstrated through 2 EU-funded consortia (https://cocid.eu/ and https://clexm.eu/). Recent case studies have included correlative imaging of whole, virus infected cells treated with anti-viral drugs; imaging the 3D distribution of therapeutic-laden nanoparticles in whole cells; and the development of correlative workflows for tissue imaging across scales. An alternative sample carrier in the form of a thin-walled glass capillary was also developed, further enhancing the novelty of the lab-based microscope.
Methods
Integrated cryo fluorescence was used to screen an entire EM grid for cell selection and correlation with SXT. Low magnification/large field of view 2D x-ray mosaics were then acquired over large areas of the grid before acquiring tilt series from ±60° on selected targets. Data from both modalities were then overlaid to provide the location of fluorescent proteins in the context of whole cell ultrastructure. For cells suspended in glass capillaries the tilt series was acquired over ±90°.
Results
Resulting cryo-SXT tomograms and fluorescent light images of cellular organelles and nanoparticles provide proof of concept for the lab-based microscope and associated workflows.
Conclusion.
Workflows of correlative light, electron and soft x-ray microscopy combines the strengths of each modality. The recent availability of a compact soft x-ray microscope will accelerate the development of novel workflows and biological imaging applications that can benefit from this technique. We will present our microscope workflows and application data.

LiNi1/3Mn1/3Co1/3O2 (NMC-111) is one of the most promising cathode materials in Li-ion batteries. However, structural and chemical instabilities of the electrode / electrolyte interface at high charge cut-off voltages lead to capacity fading. It is necessary to study the structure and chemistry of electrodes and electrode / electrolyte interfaces in Li-ion batteries since the interfaces determine the local Li-ion transport kinetics and the electrochemical performance. Surface modification using metal oxides is one of the best approaches to suppress capacity fading. In this work, a systematic study on the degradation mechanism of an uncoated NMC-111 powder electrode was presented. Moreover, the effect of an Al-doped ZnO (Al:ZnO) coating layer on the chemical and structural stabilities of NMC-111 electrode cycled at high charge cut-off voltages was analyzed using scanning electron microscopy, analytical transmission electron microscopy, and X-ray photoelectron spectroscopy. The objective of this work is to study the effect of electrode / electrolyte interface on the degradation mechanism and also the effect of coating layer on the stability of electrode / electrolyte interface. The coating layer was applied to commercial NMC-111 powder using a microwave-assisted sol-gel synthesis method. High-resolution TEM imaging, STEM imaging, nano-beam electron diffraction (NBD), electron-energy-loss spectroscopy (EELS), and energy dispersive X-ray spectroscopy (EDX) were carried out using a FEI Titan Themis G3 60-300 TEM. Cross-sectional TEM samples were prepared using a ZEISS cross-beam 340 FIB-SEM. In the case of uncoated NMC-111 electrode, cation mixing, pitting corrosion due to hydrofluoric acid attacking the electrode surface, and an irreversible phase transformation from a trigonal layered to a rock-salt phase occurred, leading to capacity fading. While, in the case of Al:ZnO – coated NMC-111 electrode, cation mixing, pitting corrosion, and the irreversible phase transformation were mitigated. Therefore, the rate capability and capacity retention were improved since the coating layer protected the electrode surface from the direct electrolyte exposure.

Momentum-resolved STEM Tomography of Gold-Silver core-shell Nanoparticles

Sebastian Sturm[1], Dr. Felizitas Kirner[2], Prof. Dr. Elena Sturm[2], Prof. Dr. Knut Müller-Caspary[1]
[1]Ludwig-Maximilians-Universität München, Department of Chemistry, Munich, Germany, [2]Ludwig-Maximilians-Universität München, Department of Earth and Environmental Sciences, Munich, Germany

Poster Group 1

Background
Precisely tailored Gold-Silver core-shell (Ag@Au) Nanoparticles (NPs) can have outstanding optical properties due to localized surface plasmon resonances, making them suitable candidates for advanced senors or for application in photothermal therapy [1]. Exact control over the nanocrystal growth however, demands for suitable analytic methods to confirm the quality and reproducibility of the synthesis. Facetted core-shell NPs like this especially benefit from techniques like Electron Tomography and STEM Tomography in particular, which are able to reconstruct their nanoscopic structures in all three dimensions, via acquisition of a tilt series of projections [2].
Depending on the detectors used, STEM offers a great variety of suitable signals for these projections [3]. For example the commonly used Bright-field (BF), annular dark-field (ADF) and high-angle annular dark-field (HAADF) signals each cover rings with different radii, corresponding to certain magnitudes in momentum space. However, the exact radii of the detector in momentum space additionally vary with the chosen camera length and the choice of those radii in the experiment has significant impact on the fidelity of the tomographic reconstruction, since most techniques rely on the linearity of the signal during projection and might even have different optima for detecting different materials. To understand the impact of the detector choice and to overcome its limitations, Momentum-resolved STEM (MR-STEM or 4D-STEM) has been applied, where for each scan position of a 2D scan raster an individual 2D diffraction pattern is recorded with the help of a fast direct electron detector and signals for each magnitude of momentum have been extracted from this data set. This allows to apply and compare arbitrary virtual detectors post-experimentally. In combination this enables MR-STEM Tomography, where the best suitable signal with respect to its performance in tomographic reconstruction of the Ag@Au NPs can be determined in hindsight.

Methods
The MR STEM experiments were conducted using a probe corrected FEI Titan Themis operated at 300kV and equipped with a Quantum Detectors MerlinEM direct electron detector (based on Medipix 3).
Acquisition of the 4D tilt series has been done using an in-house developed software written in python, utilizing the FEI Scripting COM interface. A 4D tilt series with a tilt range of -75° .. +72.5° in 2.5° steps has been recorded with 256 x 256 scan points and 256 x 256 pixel diffraction patterns at an semi-convergence angle of 18mrad. For reconstruction, a WSIRT reconstruction algorithm has been used with 5 to 10 iterations.

Results
The performance of different detector radii in momentum space in regards of tomographic reconstruction has been investigated on reconstructions of selected slices. Additionally an magnitude of momentum resolved WSIRT reconstruction of the whole volume has been explored, leading to a

4D dataset (x, y, z,|k|), which can then be evaluated e.g. using Principal component analysis (PCA). Furthermore the second moment in momentum space has been calculated, where ring segments with radius k have been weighted with k^2, summing up from a chosen minimum radius to a cut-of radius. Figure 1 exemplary shows the reconstructed Second Moment tomogram (c) of four self-assembled Ag@Au NPs (b), clearly depicting the octahedrally faceted Au cores encapsulated by truncated cubically faceted Ag shells.

Conclusion
Momentum-resolved STEM has been explored to find the most suitable signal for STEM Tomography, comparing different ADF / HAADF signals. For the Ag@Au NPs, the second moment has proven to quickly converge to similar results as the HAADF signal reconstructions, if the outer detector radius is chosen large enough, however the less strict dependence on the inner radius might still be advantageous for some applications.

Phase Stability and Evolution of Defect Structure in (CoCuMgNiZn)-Entropy Stabilized Oxide

Mr. Saptarshi Mukherjee[1], Professor Nilay Krishna Mukhopadhyay[1], Dr. Joysurya Basu[1]
[1]Department of Metallurgical Engineering, Indian Institute of Technology (BHU), Varanasi, Varanasi, India

Poster Group 1

Continuously diminishing fossil fuel resources, growing environmental concerns and changing geo-political scenario has incentivized the search for new energy resources and technologies. It has been well understood that future sustainable and green energy innovations will be mostly driven by the innovations of materials. Multicomponent high entropy oxides (HEOs) are perceived to have the potential to bring about a paradigm shift in catalysis, electro-chemical energy conversion and storage, electronics etc. HEOs may be looked at as a recent vintage of the high entropy alloys (HEAs), which was brought into existence by innovative thinking with a dash of serendipity by Profs. Cantor and Yeh independently. High entropy oxides were discovered following the line of high entropy alloys, however much later. The first high entropy oxide, redefined as entropy stabilized oxide (ESO), was discovered in 2015 in CoCuMgNiZn-oxide by Prof. Maria and coworkers. Since then a number of HEO/ESO systems have been discovered, and concept extended to carbides, borides, nitrides etc. HEOs are slightly different than HEAs as in HEOs there are more than one cation and anion sublattices and substitutions may happen in either of them. The calculation of configurational entropy is also different and much more robust than HEA counterpart. In addition, these systems are sensitive to environment in order to sustain its defect equilibria and electrical neutrality. It has been believed so far that all HEOs are single-phase solid-solutions where cations randomly fill up a disordered sublattice while oxygen decorate the ordered anion-sublattice, with little or no reference to their stability.

CoCuMgNiZn-oxide was synthesized using powder metallurgy route. The pure (>99.9%) precursor oxide powders were taken in stoichiometric proportions, mixed thoroughly in mortar and pestle, consolidated to a green compact of 12mm dia. pellets, which were sintered at 1323K for 10hours. Couple of other sintering schedules were also adopted to address phase stability and subsequent microstructural evolution. The processed pellets were metallographically polished for SEM and XRD analysis. TEM of the pellets were done from both the bulk and its crushed powder. Powders from the pellet were sonicated in ethanol before drop-casting it on carbon-coated copper grids, whereas chunks taken out of the pellet were mounted on a 3mm dia. hollow steel tube, dimpled and ion-milled to produce electron transparent thin foils.

The as-synthesized pellets produced clean hyperspectral maps when subjected to SEM-EDS, and formation of micron-sized grains separated by grain boundaries. The XRD pattern from high-resolution diffractometer also gave a clean signature of a cF8 rock salt phase, however with finite peak broadening and shoulder peaks to the principle reflections. Moreover, the ratio of intensity of the (111) and (200) reflections were reversed when the same composition was examined, one in its bulk (pellet) form and other in its powder form. Prolonged holding time at 1323K resulted in the fall of intensities of all the reflections along with broadening of peaks. Low-temperature ageing treatment revealed highly broadened and asymmetric peaks, with significant deviation in intensity ratios. Systematic TEM experiments were carried out to probe the system. The ion-milled samples

occasionally show nano-crystalline regions with spotty-ring diffraction pattern along the edge of the thin foils. However, tweed-contrast in the grain interior can clearly be discerned which show streaking in the reciprocal space. Powder TEM warrants the exact same clue where fine scale tweed-contrast could be seen in dark-field imaging from the [001] zone axis pattern. Moreover, fine parallel fault lines can be seen in the matrix phase and its corresponding diffraction pattern from [011] show spot-splitting and diffused streaking. Upon ageing, the tweed-contrast develops into an orderly arrangement of defect structure and sharp streaks centered around primary reflections appear. Centered-dark field imaging with s>o under two-beam condition clearly reveal the defect structure. Along with this, several regions in the matrix reveal a superimposed diffraction pattern where a major rock salt phase shares its signatures with high and low-symmetry phases of the spinel crystal structure, hence developing an orientation relationship with each other.

In conclusion, there seems to be an unexplored energy landscape where the system likes to jump from one local minima to another. There also seems to be oriented growth of phases, structurally derived or similar but chemically separate. The tweed morphology may act as template for growth of the defect structures under suitable conditions. Minimization of strain in the geometrically frustrated sublattices seems to drive such microstructural nuances. Models of such transformation will be presented in detail.

The study of spatial relationship between Restrictor complex and RNA-Pol II through Expansion Microscopy

Dr Simona Rodighiero[1], Dr Marta Russo[1], Dr Mattia Marenda[1], Carolina Borriero[1], Dr Danilo Polizzese[1], Dr Gioacchino Natoli[1]
[1]Department of Experimental Oncology, European Institute of Oncology, Milan, Italy

LS-03 (2), Lecture Theater 4, august 27, 2024, 10:30 - 12:30

Background incl. aims
In recent years, there have been continuous research efforts to optimize the experimental Expansion Microscopy (ExM) protocol for studying spatial correlation among different proteins. Our focus has been on developing an effective method to relocate the same cells acquired in pre-expansion onto expanded gels, enabling precise calculation of expansion and deformation factors. We then applied ExM and colocalization analysis to uncover the spatial relationship between the Restrictor complex and RNA-Pol II. The Restrictor complex, comprising ZC3H4, a putative RNA-binding protein, and WDR82, an adapter protein that interacts with RNA-Pol II Ser5-p, terminates extragenic transcription arising from active enhancers and promoters, thereby mitigating the pervasive capacity of transcription of the genome, which may lead to genomic instability (1). However, the exact molecular mechanism of action of the Restrictor complex remains poorly understood.

Methods
HCT-116 WT and HA-WDR82 HCT-116 cells were seeded on 35 mm MatTek dishes before being processed for indirect immunofluorescence. ZC3H4, WDR82, and RNA-Pol II Ser5-p or RNA-Pol II Ser2-p were fluorescently labeled. A scratch with no symmetry for rotation and reflection on adhered cells, together with a pre-expansion overview of the sample, were used to identify pre-expansion imaging areas. Samples were then processed for ExM according to (2). After expansion, the same areas were identified under a stereo microscope based on their relative position with respect to the scratch (Fig.1). Both pre- and post-expansion images were acquired using a Yokogawa spinning disk confocal system (CSU-W1, Nikon Europe B.V.). Colocalization was assessed using Pearson's coefficient calculation and object-based colocalization analysis.

Results
Expansion factor, deformation, fluorescence intensity decrease upon expansion, and both 2D and 3D colocalization were evaluated. Across three experiments, an expansion factor up to 6 and an average deformation factor of 9% were obtained. Overall, the colocalization results obtained with ExM revealed a stronger spatial correlation between the Restrictor complex and RNA-Pol II Ser5-p compared to RNA-Pol II Ser2-p, consistent with molecular, genomic, STocastical Optical Reconstruction microscopy (3) and Structured Illumination Microscopy observations previously obtained in our laboratory.

Conclusion
Our ExM imaging workflow efficiently facilitated the acquisition of identical areas both before and after expansion, thus providing essential control over the expansion protocol. Considering that the expansion factor directly influences the ultimate resolution of any ExM experiment, it is crucial to consistently account for the precise expansion factor of each sample to ensure fair comparisons among different samples. The colocalization analysis of ExM images further supported the concept

that Restrictor-mediated transcription termination primarily affects initiating and early-elongating RNA-Pol II complexes.

Developing cryo-Volume Electron Microscopy using the JEOL 4700 cryo-FIBSEM to address biological ultrastructural questions

Ms Maryna Kobylynska[1], Professor Pippa Hawes[1], Professor Roland Fleck[1]
[1]King's College London, London, United Kingdom

IM-12, Lecture Theater 5, august 26, 2024, 10:30 - 12:30

The Focused Ion Beam Scanning Electron Microscope (FIBSEM) is well suited for site-specific sectioning where the FIB milling exposes a surface that can be imaged either with the FIB or SEM to examine the microstructure within each layer and the interfacial structure between layers. By collecting ultrastructural data from a large volume, to be interrogated in silico; novel understandings of the interconnectivity between many individual cell types can be deduced. These volume Electron Microscopy studies (vEM) overcome two principal limitations of EM: the loss of 3D understanding of ultrastructure and the possibility of "missing" rare ultrastructural events through the limited volume of tissue examined. However, to date, this has only been successfully applied to chemically processed tissue, with their associated artefacts. Non-chemical fixation using low temperature allows cells and tissues to be studied close to their native biological state and has been applied to cryo electron tomography (cryoET) of thin sections of cells and tissues. With cryo lamellae produced from vitrified material by controlled milling using focussed ion beam milling in a dual beam scanning electron microscope at cryogenic temperatures (cryoFIBSEM).

Here we develop cryo vEM (cvEM) to generate larger 3D volumes than possible with cryoET by a sequence of sectioning in a cryo FIBSEM at high resolution and close to the biological native state. By successfully overcoming the high beam sensitivity of vitrified material, lack of heavy metal contrast and significant challenges to the generation of sufficient signal to noise it has been possible to demonstrate the potential of cvEM as a complementary approach to cryo ET capable of generating larger volumes (e.g., an entire cell), and at the same time retaining resolution sufficient to clearly define ultrastructural details at the level of the membrane bilayer (Figure 1). We have incorporated novel scan approaches and evaluated in-painting techniques to manage charge and improve signal to noise (1,2). We also show the workflow can be successfully extended to multicellular volumes by increasing vitrification depth with high pressure freezing, the "waffle" method. By integrating a cryo correlative capability (cryoCLEM) into the workflow, we are able to target regions of interest for cvEM. Data detailing differences between two Euglenoids at the subcellular level has been generated. Clear differences between Eulgena longa and Euglena gracilis Paramylon storage granules and key organelle were observed.

Future development aim to incorporate lamella lift out with cryo CLEM, cvEM to a predetermined region of interest with cryoET of recovered lamella. A complete and flexible full cryo FIBSEM workflow, the circle would be completed for cryogenic samples for complex biological studies.

Femtosecond extreme-ultraviolet imaging of magnetic domains during ultrafast demagnetization

Dr. Hung-Tzu Chang[1], Sergey Zayko[1], Timo Schmidt[2], Murat Sivis[1,3], Manfred Albrecht[2], Claus Ropers[1,3]
[1]Max Planck Institute for Multidisciplinary Sciences, Göttingen, Germany, [2]Experimental Physics IV, University of Augsburg, Augsburg, Germany, [3]4th Physical Institute, University of Göttingen, Göttingen, Germany

PS-08 (2), Lecture Theater 2, august 27, 2024, 14:00 - 16:00

Background incl. aims
Understanding femtosecond dynamics of magnetic domains such as photoinduced ultrafast demagnetization and magneto-optical switching is important for the development of optoelectronics such as ultrafast optical-magnetic memory devices. Despite intensive research, the extraction and elucidation of those ultrafast magnetization dynamics remains highly challenging due to the multitude of the electronic, phonon, and spin processes involved. Direct observation of nanometer magnetic domain dynamics in real space, in particular, the domain wall profile, can yield valuable information for determining the mechanism of magnetization dynamics (1, 2) yet it remains elusive due to the simultaneous requirement of nanometer and femtosecond spatiotemporal resolution. In this work, we utilize femtosecond extreme ultraviolet (XUV) imaging with high-harmonic light source (3) to visualize the magnetic domain dynamics during the demagnetization of a Co0.75Tb0.25 ferrimagnetic thin film in real time and extract the local changes of the domain walls at each wall position.
Methods
Coherent diffractive imaging of the Co0.75Tb0.25 thin film produced with magnetron sputtering is conducted with circularly polarized femtosecond XUV pulses at 59 eV (Co M2,3 edge), which is time-delayed with a 35 fs laser pulse centered at 800 nm exciting the sample. The circularly polarized XUV pulses are produced with high harmonic generation of bi-circular 800 nm and 400 nm laser pulses in He with a MAZEL-TOV configuration (4). The amplitude and phase of the transmitted XUV field is reconstructed using an iterative phase retrieval algorithm and the local magnetization is extracted from the phase difference between the left and right circularly polarized field exiting the sample (5).
Results
Using femtosecond imaging at the Co M2,3 edge with circularly polarized XUV pulses we obtained images of the magnetic domains in Co0.75Tb0.25 thin films with 13.5 nm spatial resolution, which is confirmed with analysis of the phase retrieval transfer function. The positions of the domain walls are determined by the local maxima of magnetization gradient. At each domain wall position, the wall width is extracted by fitting the magnetization as a Bloch-type domain wall function of a cutout perpendicular to the domain wall. By fitting the domain wall profile as a function of time delays between the optical pump and XUV probe, we show that while the domain wall height exhibits a subpicosecond decrease and recovery due to demagnetization, the widths of the domain walls remain largely unchanged throughout 0-20 ps delays with an average of approximately 25 nm.
Conclusion
In summary, we demonstrate femtosecond XUV imaging of magnetic domain dynamics of a Co0.75Tb0.25 alloy thin film with 13.5 nm spatial resolution and for the first time extract the real-time changes of domain wall widths. The observed real-space domain dynamics can be further utilized to elucidate the mechanisms of the demagnetization process. Our method can be readily

applied to other magnetic thin film materials to understand and control ultrafast magnetization dynamics.

Evaluation of SXES on different kind of materials : successes and failures

Jean-Louis Longuet[1]
[1]CEA Le Ripault, Monts, France

Poster Group 1

First, a brief reminder of the main aspects of wavelength dispersion spectrometry (WDS) will be given, with examples illustrating the contribution of WDS analysis compared to EDS analysis. Then, we will introduce the problem of detecting low energy X-ray photons (less than 1 keV) and the useful information on the sample that can be derived from it.
Among others, the “SXES” type detector (Soft X-ray Emission Spectroscopy) is one of the technical solutions developed by manufacturers to enable the detection and analysis of X-ray photons in this energy range. Their principle is based on the use of a variable pitch array (VLS) and a CCD camera instead of the analyzer crystals and proportional counters of traditional WDS spectrometers. The lithium detection capacity, getting information on the chemical environment at the local scale or even the very good detection sensitivity for light elements are the main advantages of this device. Examples, successful (or not!) will be presented and compared to data accessible by WDS crystal spectrometry.
To conclude, other technological solutions (already marketed or in development) will be presented such as new EDS spectrometers or new WDS analytical crystals for the detection of Li, as well as RZP (Reflective Zone Plate) type grating spectrometers for example.

Nanowire Triple-Junction GaInP/InP/InAsP Solar Cells Realized

Prof. Reine Wallenberg[1,2], Dr Lukas Hrachowina[2], Prof Magnus Borgström[2]
[1]national center for HREM, Lund University, Lund, Sweden, [2]NanoLund, Lund University, Lund, Sweden

PS-04 (1), Plenary, august 26, 2024, 10:30 - 12:30

Background
Planar multi-junction solar cells, based on III-V semiconductors, matched to the solar spectrum, are today's world-record efficiency solar cells1. Multi-junction III-V nanowire (NW) solar cells with equal performance would require significantly less material and is more sustainable at lower cost than planar solar cells. The NW geometry allows more material combinations along the NW axis than for current multijunction solar cells. We report the design and proof-of-principle demonstration of axially defined GaInP/InP/InAsP triple-junction photovoltaic NWs optimized for light absorption exhibiting an open-circuit voltage (VOC) of up to 2.37 V. The open-circuit voltage amounts to 94% of the sum of the respective single-junction NWs.
Methods
Hexagonal Au seed particle arrays on 2 inch InP:S (111)B wafers were defined2 using displacement Talbot lithography, Au evaporation, and lift-off. We grew the NWs in a MOVPE reactor at 440°C. We used phosphine (PH3), arsine (AsH3), trimethylindium (TMIn), and triethylgallium (TEGa) as precursors, and hydrogen sulfide (H2S) and diethylzinc (DEZn) as n- and p dopants, respectively. Throughout NW growth, hydrogen chloride (HCl) was used to prevent tapering in situ. HAADF-STEM and XEDS was used to verify the composition and structure of the 12 different segments constituting the triple-junction solar cell, together with a LED-illuminated EBIC.
Results and conclusions
We used an EBIC set-up with a tungsten probe to electrically contact single NWs. The NWs can be excited by a LED source. For the triple-junction NWs, their voltage is the sum of the subcell voltages. We measured an average VOC of the triple-junction photovoltaic NWs of 94% of the sum of the VOC of single-junction photovoltaic NWs. The highest measured VOC of the triple junction photovoltaic NW, 2.37 V, corresponds to the same value as by adding the highest measured VOC of the single junctions.

Machine Learning-Enabled 3D Visualization for Microstructural Risk Assessment in Creep Strength Enhanced Ferritic (CSEF) Steels

Dr. Xiyu Zhang[1], Dr. Mark Jepson[1], Dr. Simon Hogg[1], Dr. Stuart Robertson
[1]Loughborough University, Loughborough, United Kingdom

Poster Group 1

Background incl. aims
Modern power plants, especially coal-fired and combined cycle facilities, rely heavily on Creep Strength Enhanced Ferritic (CSEF) steels for their thick components. These components face extreme stress due to operating temperatures reaching 650°C. CSEF steels excel in this environment because their unique tempered martensite microstructure offers exceptional strength. However, the long-term creep resistance, which refers to a material's ability to resist deformation under constant stress, can be a challenge for CSEF steels. Factors like nitrides, inclusions, and uncontrolled particle formation within the steel can significantly weaken it. These disrupt the carefully designed microstructure, creating potential weak spots for cracks to start and grow.
Introducing Tantalum (Ta) into the steel's composition offers a solution. Ta forms tiny MX precipitates within the microstructure. These strategically placed precipitates act like roadblocks, hindering the movement of dislocations (defects in the crystal structure) and migration of grain boundaries. This ultimately slows down the creep process and extends the time it takes for the steel to deform. While Ta is beneficial for creep resistance, achieving optimal performance requires precise control over the size and distribution of these Ta-containing precipitates. Large Ta-rich particles or inclusions have the opposite effect, introducing weak points within the microstructure. These weak points become prime locations for cavities to form, which further accelerate creep and compromise the material's integrity.
Understanding how damage develops in these steels requires a multi-faceted approach. We need to link pre- and post-testing conditions, assess damage in the base metal, develop consistent testing procedures, and gather statistically relevant data. This will allow us to optimize the use of Ta and ensure the long-term strength and reliability of CSEF steels in power plant applications.

Methods
Microscopic analysis of as-received and creep-exposed CSEF steel samples utilized a suite of complementary techniques: focused ion beam (FIB) microscopy, field emission gun scanning electron microscopy (FEG-SEM), transmission electron microscopy (TEM), and electron backscattered diffraction (EBSD). To further enhance microstructural risk assessment, a framework integrating machine learning with 3D visualization was also developed for analysing the microscopic data.

Results
A meticulous investigation employed various characterization techniques, including focused ion beam (FIB) serial sectioning and electron microscopy, to track and quantify the distribution of second-phase particles and inclusions in CSEF steels. The key focus was on the interactions between these features and creep cavities, particularly during the early stages of creep.
Our findings reveal a critical link between Ta-containing particles and creep damage. The close association suggests these particles act as preferred sites for cavity nucleation, potentially impacting the overall creep behavior of CSEF steels. Conversely, no significant correlation was observed between Laves phase particles and creep damage. The adoption of 3D tomography proved to be

instrumental. It provided a detailed and accurate analysis of the spatial distribution of microstructural features, particularly the interactions between Ta-containing particles and cavities. This 3D perspective offered a deeper understanding of the mechanisms governing creep behavior in CSEF steels.
This research underscores the critical role of advanced characterization techniques like 3D tomography and machine learning in understanding the intricate relationships between phases within materials. By leveraging 3D analysis, we were able to identify the crucial role of Ta-containing particles in creep damage initiation. These insights pave the way for targeted interventions in steel design and processing to optimize the performance of CSEF steels under creep conditions in power generation applications.

Conclusion
This study investigated the role of Tantalum (Ta)-containing phases in creep behaviour of CSEF steels used in power plants. By employing advanced microscopy techniques, including 3D characterization, we identified a strong correlation between the presence and size of these phases and the formation of creep cavities at early stages. This finding highlights a potential metallurgical risk factor for creep in CSEF steels. These insights pave the way for targeted interventions in steelmaking practices. By optimizing Ta content and processing techniques, we can potentially improve creep resistance across various steel alloys. Furthermore, the established methodology using 3D characterization offers a valuable tool for future research and development of high-performance CSEF steels for power generation applications.

PS-01 (2), Lecture Theater 3, august 28, 2024, 14:00 - 16:00

Background
Single-layer transition metal dichalcogenides (TMDs) exhibit remarkable light-matter interaction, making them prime candidates for next-generation optoelectronic devices. When thinned down to a single monolayer, the bandgap of TMDs changes from an indirect to a direct bandgap, resulting in efficient light emission. However, harnessing their full potential requires a deep understanding of their nanoscale optical properties. Probing these properties is challenging due to the highly confined nature of excitons in TMDs [1]. Advanced techniques like cathodoluminescence (CL) and electron energy loss spectroscopy (EELS) offer powerful tools for such investigations, but successful implementation hinges on meticulous control over sample preparation. Integration with hexagonal boron nitride (hBN) encapsulation offers a promising solution, potentially leading to improved optical properties and the emergence of moiré potentials for further functionalities [2, 3].

Results
This work addresses the aforementioned challenges in studying excitonic processes within single-layer TMDs. We leverage meticulous sample preparation techniques, including polymer-assisted stamping and encapsulation in hBN flakes, to ensure well-defined interfaces and controlled heterostructure thickness [4]. This meticulous approach paves the way for reliable analysis using advanced microscopy techniques.
We employ a multimodal approach, combining Scanning Transmission Electron Microscopy (STEM)-CL and STEM-EELS for comprehensive characterization. While STEM-CL allows for precise mapping of excitonic recombination processes, STEM-EELS measurements with monochromated electron beams provide information about the absorption mechanisms within the heterostructure at a high spatial resolution. Our investigation highlights the crucial role of hBN encapsulation in enhancing the intensity of cathodoluminescence. By comparing SEM-CL and STEM-CL on the same sample across a wide range of acceleration voltages, we directly assess the effectiveness of each technique. Additionally, we explore the impact of different substrates like SiO2/Si on emission characteristics and spatial resolution, emphasizing the importance of substrate selection for optimal analysis.

Furthermore, we leverage Monte Carlo simulations to understand the relationship between energy deposition within the heterostructure, influenced by acceleration voltage and sample thickness, and the resulting CL intensity. We observe a proportional relationship between these parameters, further validating our experimental findings.
Conclusions

This study offers valuable insights into the influence of material interfaces and heterostructure thickness on the optical properties of TMD monolayers. By elucidating the role of hBN encapsulation in enhancing CL intensity, we pave the way for the development of high-performance optoelectronic devices. Furthermore, our multimodal approach, combining STEM-CL and STEM-EELS, provides a comprehensive understanding of excitonic processes in TMD monolayers. This knowledge is crucial for the future design of complex nanostructures with tailored optical properties and the development of controlled quantum emitters. The ability to correlate CL and EELS measurements offers an unparalleled perspective on light emission processes, laying the groundwork for fundamental advancements in understanding excitons in 2D materials.

Figure caption: Results from SEM-CL and STEM-EELS. (a) Normalized SEM-CL intensity map integrated over the spectral range from 775 to 805 nm, as indicated by the dashed lines in (b). Bubbles corresponding to residues from sample preparation can be observed as dark patches in the intensity map. (b) Normalized CL spectrum extracted from the SEM-CL intensity map in (a) exhibiting a single CL peak originating from the A-exciton (XA) of the TMD monolayer. (c) Monochromated STEM-EELS spectra taken at a beam accelartion of 100 keV. The EELS spectra are displayed for different dispersion so that absorption features from both the TMD monolayer as well as the hBN encapsulation layer can be observed.

Atomic Resolved In situ mechanical Microscopy leads to realize the negative mixing enthalpy solid solutions

Dr. Zibing An[1], Dr. Ang Li[2], Prof. Shengcheng Mao[2], Dr. Wei Li[2], Prof. Lihua Wang[2], Prof. Xiaodong Han[1]
[1]Southern University of Science and Technology, Shenzhen, China, [2]Beijing University of Technology, Beijing, China

Poster Group 2

The advancements of atomic resolved in situ mechanical microscopy (ARISMM) helped to understand the grain boundary sliding mechanisms [1], the grain boundary phase transformation mechanisms [2] and the grain boundary migration as well as rotation [3]. Recently, by ARISMM, it was uncovered that a face-centered cubic (FCC) disordered solid solution AuCu alloy nanowires (NWs) exhibit superplasticity of ~260% and ultrahigh strength of ~6 GPa, overcome the trade-off between strength and ductility [4]. With these, we further propose the concepts of ultra-high strength and ductile metals by leveraging negative mixing enthalpy solid solutions. Mixing enthalpy, a pivotal parameter in the thermodynamic state of materials, reflects the chemical affinity among distinct atoms and plays an essential role in quantifying the internal energy of a system. The introduction of elements characterized by negative mixing enthalpy disrupts this entropic solid solution framework, leading to the formation of localized negative enthalpy chemical affinity clusters, characterized by compositional fluctuations and local ordering. Aberration corrected atomic resolved microscopy helps us to realize the distribution of configurational mixing entropy and enthalpy in a solid solution. Pursuing the proposed strategy, we incorporated Al into the nearly ideal solid solution alloy HfNbTiV, thereby modulating the solid solution architecture of alloy. Given that Al and other alloying elements (Al-M, where M = Hf, Nb, Ti, V) exhibit negative mixing enthalpies, the integration of Al fosters the emergence of multilevel nanoscale heterogeneous structures within the alloy, culminating in the creation of the HfNbTiVAl10 negative enthalpy solid solution alloy. Finally, the HfNbTiVAl10 alloy shows remarkable tensile ductility (~ 20%) and ultrahigh yield strength (~ 1,390 megapascals) [5].This study highlights the importance of atomic resolved in situ mechanical microscopy for designing advanced structural materials.

Poster Group 1

The development of new promising cathode materials for lithium-ion batteries and sodium-ion batteries must go hand-in-hand with the development of new, more efficient, and more environmentally friendly synthesis routes. Several strategies have been reported in the literature to try to overcome the current limitations that prevent a broader deployment of promising cathode materials for intercalation batteries. Among them, the synthesis of electrode materials via an emulsion procedure demonstrated to be beneficial to obtain materials with controlled morphology [1].

In particular, a novel synthesis route [2], which involves the use of metal acetates, water, and oleic acid to form an emulsion is specially promising since only organic precursors are used, and the side reaction products are not contaminant,which makes it significantly more environmentally friendly.

Here we present a structural and electrochemical characterisation of the cathodes synthesised using a modification of the aforementioned route. This modification reduces the mixing times of all the precursors required down to a few minutes, which is a very significant improvement compared with the tradicional sol-gel or ball-milling routes used at the laboratory levels. Furthermore, the modification makes this route very easily upscalable at the industrial level.

We have synthesised a large variety of promising cathodes for the families of lithium-ion and sodium-ion batteries. Transmission electron microscopy and related techniques were used to evaluate the quality of the particles fabricated using this novel synthesis route, and the results are compared with particles fabricated using the more stablished synthesis methods. The particle size and distribution were characterised by means of conventional transmission electron microscopy, while X-ray energy dispersion spectroscopy maps in scanning-transmission electron microscopy (STEM) was used to visualize the elemental distribution in individual particles. Aberration-corrected STEM corroborated that the expected atomic structure had been achieved in individual particles.

In a subsequent step, the particles were analysed at the fully charged and several-times cycled states to visualize the atomic rearrangements and chemical changes that may lead to battery failure. In those cases, the electron dose was carefully controlled to avoid irreversible beam damage, especially in the charged particles. Additionally, multi-frame acquisition followed by non-rigid registration and averaging was used to further reduce the damage due to exposure to the electron beam.

All the results obtained using the ultra-fast synthesis route described here are in very good agreement with those obtained for the same materials using the more conventional sol-gel or mechanical dry-mixing methos, whereas the times involved are considerably reduced.

Evaluating spherical models of EBSD patterns for forward modelling indexing

Dr René De Kloe[1], William Lenthe[2], Stuart Wright[2], Matt Nowell[2]
[1]EDAX-Gatan, Tilburg, The Netherlands, [2]EDAX-Gatan, Pleasanton, USA

Poster Group 2

The application of full pattern matching-based forward modelling indexing techniques of EBSD and transmission EBSD patterns has shown significant improvements over conventional indexing methods that are based on the detection of individual bands in the EBSD patterns [1,2]. Forward modelling provides superior robustness on poor quality patterns, improved orientation precision, and can resolve common indexing challenges including pseudo-symmetry, non-centrosymmetric point groups (polarity), and overlapping patterns. Furthermore, new GPU implementations of spherical harmonic indexing and real space orientation refinement can both achieve speeds of thousands of patterns per second on modest hardware making its application accessible for routine EBSD analyses.
A remaining challenge for these indexing methods, both dictionary indexing and spherical indexing, is that they rely on detailed knowledge of the crystal structure of the phase(s) that are being indexed. The dynamic simulations that are the basis of the forward-model indexing methods are critically dependent on the crystal symmetry, atomic positions, occupancy, and electron scattering parameters. This is especially important in more complex phases such as solid solutions, intermetallic phases, and minerals. In many cases this detailed information is not available.
Alternative master patterns that do not require the same detailed knowledge of the crystal structure can be created using a kinematical model or using actual EBSD patterns. For these methods the information that is already available in the more basic EBSD structure files that are used for Hough transform-based indexing is sufficient. With the lattice parameters, the point group symmetry, a list of expected reflectors or bands, and the relative intensity of the bands in the EBSD patterns a kinematic spherical intensity model can be constructed. Alternatively, Kikuchi spheres may be created using actual EBSD patterns, provided that their phase and orientation is known by conventional EBSD indexing [3]. These spheres can then be applied as experimental master patterns for spherical indexing.
The advantage of using the experimental master patterns is that the required calculation time is less than 1 minute while dynamic simulations may take multiple hours to generate. Experimental patterns will also exhibit the same contrast range as the experimental patterns which may change with specific pattern image processing methods. With a closer match between the experimental patterns and the master pattern, improved indexing results may be expected. In this presentation the requirements for successful generation of master pattern simulations for pattern matching will be discussed together with application examples.

The role of atomic displacements in high-resolution scanning transmission electron microscopy imaging of strained nanoparticles

Prof. Dr Roland Kröger[1], Dr Shuayl Alotaibi[1]
[1]University of York, York, United Kingdom

Poster Group 2

Background
Strain in nanoparticles (NPs) plays an important role in the control of catalytic or chemical reactivity and its impact on the atomic level structure is essential for applications in many areas such as biomedicine or soil remediation. Hence, atomic level displacement analysis is greatly important with Z-contrast imaging in high-resolution scanning transmission electron microscopy (HRSTEM) being at the forefront of its exploration [1]. However, analyzing atomic level strain in NPs with HRSTEM or HRTEM faces numerous challenges such as the impact of strain on the image formation since strain induces modifications of column intensities and intensity distributions and hence affects the interpretation of image contrast and apparent column positions. Thus, knowledge of the 3D strain distribution in NPs is required. To investigate this, we employed a workflow combining finite volume strain calculation and image simulation to study the impact of strain on image formation for an iron oxide (magnetite) segment like those found in cluster source deposited cubic and partially oxidized iron NPs to be compared with experimental Z-contrast images.

Methods
Our approach was inspired by our previous work which shows that lattice strain is induced by stress at the oxide domain boundaries in iron-iron oxide core-shell NPs [1]. To investigate how strain affects Z-contrast image formation, we constructed an atomistic model of the oxide shell, then applied a finite element calculated strain field to this model to be used for simulating HRSTEM images of such strained domains employing the QSTEM simulation software [2] including thermal diffuse scattering. Subsequently we compared our findings with experimental data obtained using aberration corrected Z-contrast imaging.

Results
We find that lattice strain has various effects on the HRSTEM images including a significant change of Fe(II) column intensity distribution within the domains in comparison to the unstrained as well as streak formation due to strain-induced atomic displacements, which is in-line with our experimental observations. We further compared the atomic displacement fields derived from experimental images with those resulting from our image simulations showing a significant maximum displacement at the oxide surfaces and a linear strain gradient between the core/oxide boundary and the oxide surface, which is in good agreement with experimental observations with high-resolution STEM.

Conclusion
Overall, we find that atomic level displacements due to strain fields strongly affect HRSTEM image formation and need to be carefully considered when quantitatively analyzing such data e.g. for the extraction of strain field information. We find that strain mapping from 2D images cannot necessarily be taken at face value but require a sufficient understanding of the 3D strain field distribution. Furthermore it becomes evident that evaluation of atomic column intensities for e.g. atom number determination is non-trivial in the presence of strain fields since the column intensities and positions

determined from HRSTEM images can be strongly affected by atomic displacements in beam direction leading to significant local variations of electron scattering.

Unravelling the collagen mineralization using multiscale in situ X-ray-scattering/Raman spectroscopy and ex situ electron microscopy/nano-Xray-fluorescence

Prof. Dr Roland Kröger[1], Dr Julia Parker[2], Ms Emma Tong[1]
[1]University of York, York, United Kingdom, [2]Diamond Light Source, Harwell, United Kingdom
IM-05 (2), Lecture Theater 3, august 26, 2024, 14:00 - 16:00

Background
The process of collagen mineralization is key to numerous biological processes including bone and tooth formation, arteriosclerosis as well as tendon and cartilage calcification and other forms of ectopic calcification. Therefore, understanding the processes that govern the formation of a hard inorganic calcium phosphate phase (usually hydroxyapatite) within a soft matrix of collagen is central to identify the physico-chemical processes involved in collagen calcification, which occurs in close interaction with the collagen template. E.g. for bone it is known that the hydroxyapatite mineral is organized, like collagen, in a hierarchical fractal-like fashion [1]. A key problem in this context is the dynamics of the mineralization and the possible presence of intermediate phases before a full mineralization with hydroxyapatite occurs. Using the polymer-induced liquid precursor (PILP) method for in vitro collagen mineralization [2], we employed state-of-the art characterization techniques, a combination of in situ X-ray scattering, in situ Raman spectroscopy, nano X-ray fluorescence (nXRF) with 50 nm resolution and transmission electron microscopy (TEM) to monitor the mineralization process at different length scales. In our studies we focused on the impact of mineralization on the collagen response and the possible occurrence of intermediate phosphate phases apart from hydroxyapatite.

Methods
A combination of in situ characterization with Raman spectroscopy and small and wide-angle X-ray scattering (SAXS, WAXS) was used with the same flow cell, which was heatable and kept at 37 ˚ C during the mineralization process. We applied PILP using osteopontin, fetuin-A and poly aspartic acid as active protein polymers to mimic this process in vitro using rat-tail derived collagen type I fibers. Raman spectroscopy enables a molecular level analysis of the mineralizing collagen, SAXS provides information on the particle evolution and impact of mineral growth on the collagen D-banding (a periodic pattern caused by repeat sequences of overlap and gap regions in the staggered collagen molecule organization) and WAXS permits the study of the time dependent evolution of crystallinity monitoring the {002} lattice planes in the hydroxyapatite mineral phase. The resulting mineralized collagen fibers were subsequently analyzed using nano - XRF microscopy to map the distribution of Ca and P within the fibers and TEM and electron diffraction for microstructural investigations and analysis of the mineral phases.

Results
In situ Raman spectroscopy reveals intermediate phosphate phases during the initial mineralization stage confirmed by electron diffraction in TEM. In accordance with these findings, we observe three stages of mineralization with SAXS showing an initial expansion of the collagen D-spacing, associated with the infiltration phase, a subsequent contraction of the D-spacing, associated with the beginning of nucleation and crystallization and finally a continuous growth phase, correlated with an expansion of the D-spacing. Analyses of the mineralized collagen ex situ using TEM and nXRF indicates the

presence of two morphological features, which we associate with octa calcium phosphate and hydroxyapatite, respectively, and an inhomogeneous pattern of tessellation in accordance with reported patterns for bone mineralization [3].

Conclusion
Our in vitro studies of collagen mineralization shows a remarkable resemblance of observations made in biological systems indicating that the PILP process is an excellent proxy to study relevant physico-chemical processes e.g. in bone formation. The joint application of multiscale and multiplatform methods to monitor the progression of mineralization as well as the resulting mineralization patterns allows for unique insights into the evolution of the mineral phase and the interaction between the hard mineral phase with the soft collagen template.

Poster Group 1

Background and aims
Aqueous processable binders, such as a sodium carboxymethyl cellulose (CMC) - styrene butadiene rubber (SBR) mixture are crucial constituents in composite battery electrodes ensuring good adhesion properties, high elasticity as well as improved cyclability and thermal stability (Alvira et al. 2022). The uniform distribution of the binder, active material, and conductive carbon is a prerequisite. Inhomogeneous distribution that may occur during the fabrication and processing of the electrode, such as coating, drying, and calendaring can lead to segregation, delamination or solidification which directly influence the overall battery performance (Jaiser et al. 2016). Therefore, its crucial to assess the distribution of the constituents, particularly the binder as agglomeration or segregation of the binder during longer cycling may lead to capacity loss.
The aim of the study is the visualization of CMC and SBR binder components next to hard carbon (HC) and conductive nano carbon particles using osmium tetroxide (OsO4) and uranyl acetate (UA) staining. OsO4 stains the double bonds present within SBR (Lee et al. 2022), whereas UA reacts with the carboxy groups (Stoeckenius 1961) of the CMC. As CMC is soluble in water, the sample preparation techniques must be adapted. In this study, we applied the embedding procedure introduced by Eswara-Moorthy et al., where Pt is deposited within a several µm deep volume of the sample using a 30 kV electron beam. This method avoids mechanical polishing using aqueous solutions and provides excellent contrast within the sample.

Methods
HC electrodes were prepared by doctor blading of a water-based slurry consisting of 80 wt.% HC, 10 wt.% SuperP, 5 wt.% Na-CMC and 5 wt.% SBR. The sample was first stained with OsO4 vapour by placing the sample in a sealed container together with a couple of droplets of 4 % aqueous OsO4 solution for 6 days, whereby the droplets were replenished after 3 days. In a second step, a droplet of 2 % uranyl acetate dissolved in ethanol was placed on the sample, removed after 30 min, and the sample was then rinsed with ethanol. The samples were investigated using a Helios Nanolab 600 and a Quanta 3D FEG (both Thermo Fisher Scientific Inc., USA). To achieve better contrast, avoid shine through artefacts, and reduce curtaining effects during FIB milling, the samples were embedded in Pt using electron beam induced deposition (EBID) with methylcyclopentadienyl trimethyl platinum as precursor and an electron beam operated at 30 kV, 32 nA. EDX mapping was conducted using an Element EDX detector attached to the Quanta and Apex standard software package (both EDAX Inc., Germany). The microscope was operated at 6 kV and 16 nA with a dwell time of 50 µs and 64 frames.

Results
Compared to the non-stained sample, secondary electron (SE) images of FIB cross-sections of the EBID Pt embedded region of the stained sample show reasonable contrast between the binder, HC particle and Pt (Fig.1 a & b). The contrast is sufficient to easily segment the 3 phases in FIB-SEM

tomography data sets. It is also possible to distinguish between the binder matrix and conductive carbon nano particle within the binder. Although pores larger than approximately 1 m in diameter were not completely filled with Pt, the delicate structure of the binder phase was well preserved. Regions containing binder material are completely embedded and therefore provide volumes suitable for FIB-SEM tomography studies due to the enhanced contrast. EDX maps reveal the successful staining of both components, SBR with OsO4 and CMC with UA (Fig1. d & e). However, it should be noted, that remnants of the UA staining procedure may occur within the sample, but UA particles can be clearly distinguished. They appear brighter than the binder components in the SE images (e.g., Fig1 c & d, marked with red star) and in EDX measurements, as they contain less C but significant amounts of Na.

Conclusion

In this contribution, we show the potential of OsO4 and UA staining of SBR and CMC binder mixtures to reveal the 3D distribution of the binder phase within HC composite electrodes. EBID Pt embedding results in improved contrast and avoids artefacts as well as protect the delicate binder structures. The here described sample preparation method is suitable for FIB-SEM tomography studies and EDX mappings of FIB cross-sections, as the Pt surrounding the binder also limits the extend of the excitation volume compared to epoxy resin embedding. As both binder components react with different staining agents, namely CMC with UA and SBR with OsO4, both components can be tracked individually using EDX. For TEM-tomography studies EBID Pt embedding may not be suitable and should be replaced by classic epoxy resin embedding.

Fig.1: SE images and EDX maps of FIB cross-sections of EBID Pt embedded HC composite electrodes, red arrows point at binder components, hard carbon particles are exemplarily marked with “HC” a) SE image of non-stained electrode; b) SE image of the stained electrode with the stained binder components revealing clear difference in grey value relative to the HC particle and Pt embedding; c) SE image of ROI for EDX mapping; d) Os distribution; e) U distribution, red star marks possible UA remnant from the UA staining step.

Analysis of molecular packing and nanoscale atomic variation in polymer semiconductors

Sang Pham[1], Sean Collins[1,2]
[1]Bragg Centre for Materials Research & School of Chemical and Process Engineering, University of Leeds, Leeds, United Kingdom, [2]School of Chemistry, University of Leeds, Leeds, United Kingdom

Poster Group 2

Background incl. aims
Conjugated polymers are an important class of organic light emitting diodes (OLEDs) and organic solar cells (OSCs). These materials are predominantly semi-crystalline or amorphous with intricate molecular packing and mixed variety of structural orders and disorders [1]. The susceptibility of these materials to 'burn-in degradation' [2] can induce blend-demixing and photo-induced ordering/disordering [3], thereby resulting in the performance losses of the devices [4]. Controlling this performance degradation during operation necessitates an understanding in changes in chemical structures and structural disorders at the nanoscale – the length scale commensurate with the transport of charge carriers. Yet direct nanoscale characterisation is limited for polymer semiconductors and their associated devices due to the irreversible changes in these materials structure when exposed to high-energy ion and electron beam conditions [5]. Here, we advance the structural characterisation of polymer semiconductors, whether in the form of free-standing films or cross-sectioned lamella, using low-dose four-dimesion scanning transmission electron microscopy (4D-STEM), enabling the analysis of the molecular packing, crystallinity, and atomic arrangement in the polymer semiconductors in response to temperature and ion milling-induced damage.

Methods
Low-dose 4D-STEM analysis was conducted using established nanobeam scanning electron diffraction alignment at electron Physical Science Imaging Centre (ePSIC), Diamond Light Source. In particular, Merlin-Medipix detector and <1 mrad convergence semi-angle with 1-2 pA in probe current at 300 kV were used to minimize radiolytic damage. We obtained data at a range of camera lengths to enable both mapping of crystalline domains from Bragg scattering as well as reciprocal space (variance measures) and real space electron Pair Distribution Function (ePDF) analysis of disordered and amorphous regions. The materials under examination were free-standing polymer films (F8:F8BT, 1:1), prepared by spin-coating onto PDOT:PSS/ITO/Glass substrates. Subsequently, the multi-layered sample was submerged in deionized water, and the F8:F8BT films were floated onto carbon support films for 4D-STEM analysis. Additionally, we developed cryo-Focused Ion Beam (cryo-FIB) protocols to facilitate the structural examination of the cross-sectioned device model, Glass/ITO/PDOT:PSS/F8:F8BT (1:1).

Results
The developed techniques reveal the formation of nano-crystalline domains in the F8:F8BT films after heat treatment. These domains are attributed to the crystallisation of F8 polymers, as evidenced by indexing some diffraction patterns aligning along the zone axis. Additionally, ePDF analysis allows us to characterise the atomic structures in amorphous areas with varying contrast. The analysis indicates that there were no chemical changes in the F8:F8BT blends induced by temperature. However, partial phase segregation occurred, as also supported by low-dose EELS analysis. We extended these analyses to a cross-sectioned device model prepared by cryo-FIB, and the findings

demonstrate that our cryo-FIB protocol preserves the crystalinity of the polymer blends. ePDF shows that cryo-FIB milling does not alter the chemical structures of the films, i.e. intramolecular structure, but does affect the intermolecular arrangement.

Conclusion
The developed electron microscopy techniques enable the characterisation of microstructures and nanoscale atomic arrangements in beam-sensitive polymer semiconductors, paving a pathway for examining phase segregation and chemical changes resulting from the burn-in degradation. By doing so, effective strategies can be developed to minimise structural degradation in polymer semiconductors, thereby preventing performance losses during operation.

Poster Group 1

Background incl. aims
Proton Exchange Membrane Fuel Cells (PEMFCs) are being developed mainly for transport applications. Significant progress has been made over the last decade, leading to the commercialization of the first generation of fuel cell cars. More recently, R&D efforts have shifted to heavy-duty vehicles, where PEMFCs are more competitive with Li-ion batteries. However, their cost and durability are still the two barriers limiting the expansion of this market. To overcome these obstacles, we still need to optimise the components and structure of the electrodes and better understand their degradation mechanisms.
PEMFC electrodes are a nano-porous material composed of carbon particles (30 nm) supporting platinum nanoparticles (3 nm) - the catalysts of electrochemical reactions - and linked together by ionomer (proton conducting polymer).
Scanning and transmission electron microscopies (SEM and TEM) are widely used for investigating the microstructure of PEMFC electrode. They have played a significant role in the improvement of electrode components and the understanding of their main degradation mechanisms. However, the currently available descriptions of the electrode microstructure do not allow yet to unambiguously identify the key microstructural parameters that limit gas and proton transport within the electrode. These factors are crucial as they govern PEMFC performance, especially at high current densities, and are therefore the subject of numerous studies, using either fine electrochemical measurements or modeling approaches.
The aim of our work is to provide an improved description of the electrode microstructure in 3D to give quantitative information on its porosity, Pt nanoparticle (NP) spatial distribution and ionomer distribution. For this purpose, we are developing 3D characterization techniques applied to the PEMFC electrodes, such as electron tomography and 3D FIB-SEM.
Methods
The studied cathode electrode was prepared using TEC10E50E catalyst from Tanaka that is 50 wt % loading of Pt deposited on high-specific area carbon (HSAC), and Nafion D2020 as the electrode ionomer. The Pt loading of the electrode is 0.2 mgPtcm-2 and the ionomer/carbon ratio is 0.8.
The electrode was analyzed using electron tomography and 3D FIB-SEM.
Results
As a first step, electron tomography analyses were performed on the Pt/HSAC powder to determine the distribution of Pt NPs which can be located either on the carbon surface (outer NPs) or inside the carbon porosity (inner NPs)[1-2]. Our strategy is to record tilt image series by using two annular detectors: i) a high angle annular detector avoiding Pt NP diffraction contrast for the 3D image reconstruction of Pt NPs (without diffraction artifact) and ii) a lower angle annular detector that enhances carbon contrast for the 3D image reconstruction of the carbon phase. These two segmented images were then combined (Figure 1), allowing the calculation of the NP size histogram but also of the volume and the surface area of the two NP populations (inner and outer NPs).

On the second step, the porosity of the electrode was analyzed by 3D FIB/SEM. A volume of around 10 X 10 x 5 µm3 was imaged with a cubic voxel size of 5 × 5 × 5 nm3. The solid phase (carbon, Pt NPs and ionomer) segmentation was based on a composite image created from two electron detectors (secondary and backscattered electrons) and using a machine learning software. Quantitative data such as the total porosity and the pore size distribution were extracted from this volume. Figure 2a shows a 2D slice of this segmented volume where the solid phase is in black and the porosity in white.

In order to analyze the electrode porosity with a higher spatial resolution, electron tomography experiment was also performed on a 150 nm thick slice of the electrode cut by ultramicrotomy after being embedded in an epoxy resin. The tilt image series were recorded with a pixel size of 0.5 nm and a field of view of 2 x 2 µm2. The 2D slice of the reconstructed volume (Figure 2b) shows that the largest solid agglomerates detected on the 3D FIB/SEM image can be identified as an agglomeration of numerous carbon particles. The challenge now is to quantify the porosity created between these carbon particles, which cannot be detected by 3D FIB-SEM.

Finally, the distribution of the ionomer was analyzed within the electrode similarly to [3]. For this analysis, a 150 nm slice of the electrode was cut by cryo-ultramicrotomy without embedding in epoxy resin as described in [4]. TEM images show that the ionomer is not homogeneously distributed on the surface of the entire carbon particles but is often observed in the concave surface created between the carbon particles (Figure 3). These observations suggest a ionomer distribution in agreement with the heterogeneous ionomer coating model proposed by Inoue et al. [5]. We also suggest that a part of the ionomer could be localized in the small pores located inside the large carbon agglomerates described in the previous paragraph. This could explain why the ionomer is so difficult to detect on TEM images.

Conclusion

The different 3D electron microscopy techniques make it possible to obtain information on the distribution of the different components of the PEMFC electrode. This 3D description of the electrode can then be incorporated into recent models that calculate electrochemical performance as a function of microstructural parameters, in an attempt to identify the key parameters that limit cell performance. Similar studies are also being carried out on aged electrodes after the fuel cell operation.

This work has been done in the frame of the FURTHER-FC project. This project has received funding from the Fuel Cells and Hydrogen 2 Joint Undertaking (now Clean Hydrogen Partnership) under Grant Agreement No 875025. This Joint Undertaking receives support from the European Union's Horizon 2020 Research and Innovation program, Hydrogen Europe and Hydrogen Europe Research.

Correlating atomic-resolution structure to the properties of transition metal nitride coatings

Dr. Zaoli Zhang[1], Dr. Zhuo Chen[1], Mr. Yong Huang[1]
[1]Erich Schmid Institute, Austrian Academy of Sciences, Leoben, Austria

PS-01 (3), Lecture Theater 3, august 30, 2024, 14:00 - 16:00

Introduction
The industrial applications of transition metal nitrides require an in-depth understanding of the structures and their correlations to properties. This has led to numerous experimental and theoretical research [1-5]. Utilizing modern electron microscopy and spectroscopy, our understanding of nitride structure and property relations and its deformation has been significantly advanced. This presentation will briefly summarize our recent atomic-resolution studies on transition metal nitride coatings using spherical aberration-corrected transmission electron microscopy (TEM).
Methods
The film used in this study was prepared by direct current magnetron sputtering using a custom-made lab-scale magnetron sputter deposition system. The film was grown on MgO(001) or Si substrate at 700 ℃, and the potential was kept floating during the deposition. Specific deposition conditions for different films are slightly different. Nanoindentation tests were conducted on a KLA Nanoindenter G200 equipped with a diamond cube-corner indenter tip to obtain H and E by the conventional analysis first proposed by Oliver and Pharr. The tests applied the continuous stiffness measurement method with a constant indentation strain rate □ of 0.05 s−1. The cross-sectional TEM lamella of the as-deposited and indented films was machined by focused ion beam (FIB) using an FEI Helios NanoLab 660 workstation. The lamella was cut along the <110> direction of the substrate and then transferred to a Cu TEM grid. The lamella was polished using accelerating voltages from 30 to 2 kV and ion currents ranging from 20 nA to 7 pA. Some TEM specimens were also prepared using a standard approach, i.e., grinding, polishing, dimpling, and Ar ion-milling.
For high-resolution TEM (HRTEM) characterization, a JEOL 2100F and FEI Titan Themis 60-300 cubed TEM, both equipped with an image-side Cs-corrector, were adopted. The scanning TEM (STEM) images and energy-dispersive X-ray spectroscopy (EDXS) were acquired by a 300 kV field emission TEM (JEOL ARM300F) equipped with double Cs-correctors. The microscope has two windowless detectors, each with an active area of 100 mm2.
Results
The extensive high-resolution transmission electron microscopy (HRTEM) observations on TaN/TiN multilayer reveal that the dissociation of full dislocations results in the network of stacking faults (SFs) and the formation of Lomer-Cottrell lock arrays inside the TaN layer. Consequently, the high density of stacking faults dramatically strengthens the TaN/TiN multilayer [1]. Using valence electrons and inner shell electron spectroscopy, a combined experimental analysis on a multilayered structure of CrN/AlN allowed mapping of the multilayer's mechanical properties (bulk modulus) at the nanometer scale [2]. Moreover, we found that the presence of oxygen impurities causes a remarkable reduction of the bulk modulus of rs-CrN while having no significant effect on the bulk modulus of the stable wurtzite structure wz-AlN layers. The findings have been validated by theoretical calculations [2].
We observed an atomic-scale intermixing phenomenon in the nanoscale TiN/AlN multilayer by coupling the cross-sectional FIB cutting with detailed atomic resolution electron microscopy analyses. A new solid solution phase was created during nanoindentation, which could be unambiguously

shown by mapping the electronic structure differences (i.e., using Ti-L2,3 edge). This also raises some concerns about understanding experimentally measured hardness values in multilayers using the nanoindentation method. By using atomic-resolution energy dispersive x-ray spectroscopy, we further corroborated that such a homogenous solid solution zone formed upon loads [3]. We recently found a new deformation mechanism of a high vacancy-mediated WNx/TiN multilayer through quantitative electron microscopy analysis, theoretical calculations enabled by ab initio molecular dynamics, and combined with mechanical testing [5].

Conclusions

Advanced electron microscopy methods reveal the atomic and electronic structures of transition metal nitride coatings, which allows correlating the structure with properties at the atomic scale and leads to new findings. These exciting findings shed light on the design of novel multilayer coatings for applications.

Cross-sectioning of adherent cells on thin plastic substrate for serial block-face imaging

Anne Kauter[1], Silvio Bürge[1], Christian Klotz[2], Michael Laue[1]
[1]Advanced Light and Electron Microscopy (ZBS 4), Centre for Biological Threats and Special Pathogens, Robert Koch Institute, Berlin, Germany, [2]Mycotic and Parasitic Agents and Mycobacteria (FG16), Department of Infectious Diseases, Robert Koch Institute, Berlin, Germany

Poster Group 1

Background

The single-celled enteric parasite Giardia lambia (Figure 1A) uses a ventral disc [1], consisting of a spiral-formed microtubule apparatus, for adhesion to their host duodenal epithelium. For analyzing the phenotype of various mutations of the ventral disc proteins, we started with conventional thin sectioning of the parasites cultivated on thin plastic bottom of plastic culture dishes (Figure 1B). The complexity of the observed phenotypes prompted us to consider volume imaging for a more comprehensive analysis of the ventral disc morphology. Instead of performing an additional cultivation and processing for volume imaging, we tested, if the already available sample blocks, prepared with our standard protocol for thin sectioning (osmium tetroxide, tannic acid, uranyl acetate/UA-Zero, Epon) [2], were suitable for serial block-face (SBF) scanning electron microscopy (SEM) at sufficient resolution. To our surprise, the resulting data sets were of sufficient quality (Fig. 1C) to reconstruct the entire ventral disc microtubule apparatus of the parasite in 3D (Figure 1D), but limited in resolution. SBF SEM usually requires a high-contrast en bloc staining of the sample with various heavy metals and reduction of the charging by improving the electrical conductivity (e.g. conductive filler) or by charge compensation (e.g. gas injection). As a consequence, the time of sample preparation usually is much longer for SBF imaging than for standard thin section imaging. Moreover, the introduction of more heavy metals changes the ultrastructural appearance of the sample. With our study, we wanted to find a generic sample preparation workflow for adherent cells which provides sufficient contrast and image quality in SBF SEM.

Methods

For the experiments we used adherent HeLa cell cultures grown in plastic dishes which were equipped with small silicone inserts on their plastic bottom (ibid µ-dishes, with microinserts). To stepwise improve the image contrast and quality, we introduced various simple modifications to our standard embedding protocol: minimal resin embedding, addition of silver colloids, higher processing temperature during heavy metal treatment, higher concentration of osmium tetroxide, additional heavy metal incubation steps (osmium tetroxide, lead aspartate). Cells were embedded in situ on their substrate in Epon, extracted with a hot scalpel and mounted on an aluminum stub using conductive epoxy glue. After trimming to a size of 1x0.25x0.25 mm, SBF SEM was performed with a Teneo Volumescope at high and low vacuum conditions.

Results

The addition of further incubation steps with heavy metals to our standard sample preparation protocol resulted in improved resolution and image quality in block-face imaging. The contrast of the

samples which were prepared with a single osmium tetroxide incubation and an additional en bloc treatment with lead aspartate (Figure 1E) allowed a proper discrimination of the main organelles and cytoplasmic structures already at low magnification and was very similar to the appearance of cells in thin sections taken from samples prepared by our standard protocol after on-section staining. The increased heavy metal load introduced by an additional osmium tetroxide incubation provided slightly higher lateral resolution at the cost of a rather unusual contrast. SBF imaging of adherent cells at low vacuum resulted in more stable image series at higher resolution in all directions than at high vacuum, regardless of the heavy metal load. The addition of silver colloid improved only the imaging at high vacuum with less significance at highest heavy metal load tested.

Conclusion

Our cross-sectioning workflow for SBF SEM of adherent cells on plastic substrate offers the possibility of direct investigation of cell-substrate interactions. The upright mounting of the sample allows us to collect complete volumes of many cells and large total sample volume. Finally, we could find a protocol which provides comparable ultrastructural appearance than in conventional thin section EM and with only limited additional effort compared to our standard embedding protocol.

Direct visualization of chemical transport in solid-state chemical reactions by time-of-flight secondary ion mass spectrometry

Sang Pham[1], Sean Collins[1,2]
[1]Bragg Centre for Materials Research & School of Chemical and Process Engineering, University of Leeds, Leeds, United Kingdom, [2]School of Chemistry, University of Leeds, Leeds, United Kingdom

IM-05 (3), Lecture Theater 3, august 27, 2024, 10:30 - 12:30

Background incl. aims
Systematic control and design of solid-state chemical reactions are essential for modifying material properties and pioneering novel synthesis techniques. Enhanced chemical transport and accelerated kinetics of active elements and compounds across interfaces are known to drive solid-state chemical reactions [1]. Monitoring temperature-dependent chemical dynamics at micro- to nanometer length scales in real-time is crucial for providing valuable feedback to tailor the properties, performance, and stability of multi-material structures. Conventional methods for studying solid-state reactions, such as in-situ TEM heating, can identify formed phases and their relative weights but may overlook transient and minor phases [2, 3]. Time-of-flight secondary ion mass spectrometry (TOF-SIMS) at nanometer resolution offers a solution to these challenges. This technique provides information about element distribution and bonding encoded in multiatom ions from the near-surface region of solids [4], making it ideal for studying complex chemical processes in energy storage and hot corrosion. In this study, we combine focused ion beam–scanning electron microscopy (FIB-SEM) and TOF-SIMS to track the migration of active chemical elements from a glass coating to the oxide scale during in-situ hot corrosion experiments. Our findings demonstrate the distinct potential of TOF-SIMS in exploring nano-scale chemical dynamics of materials in response to temperature, optical, or electromagnetic stimulations.

Methods
TOF-SIMS analysis was performed using a Ga primary ion beam at an accelerating voltage of 30 kV and a current of 0.23 nA, scanned continuously across the sample surface throughout in-situ heating using MEMS heating chip. The lateral resolution of the resulting images was estimated as better than 290 nm at an abrupt step in the 23Na+ signal (20%–80% of the maximum intensity). Isochronal heating was applied from 50 to 850 °C (1 °C/s), producing a Z-direction (direction of successive two-dimensional scans) that directly tracks the temperature. Each frame's acquisition time was 1.4 s, allowing for real-time observation of chemical dynamics. The examined sample comprises a sodium borate coating as the uppermost layer, followed by the intermediate oxide layers with the dendritic iron oxide grown above the continuous iron–chromium oxide layer. The sample was cross-sectioned using FIB, and the cross-sectioned specimen was lifted out and deposited on a MEMS heating chip (flat on the chip, perpendicular to the ion beam).

Results
This advance in nanoscale chemical analysis with TOF-SIMS reveals corrosion induced by sodium diffusion below the coating's glass transition. These findings unveil sodium diffusion decoupled from boron at much lower temperatures than previously known. Moreover, selective dissolution of iron oxides in solid-state corrosion was observed, with iron moving into the borate coating while chromium remains in the steel oxide, elucidating a part of the nanoscale electrochemical mechanism. Additionally, this technique enables the detection of transient phases and impurities during hot

corrosion reactions between sodium ion and oxide layers, allowing us to track the formation of early-stage corrosion reaction products and lithium impurities in the oxide layers. Ultimately, we can employ image-based determination of the sodium diffusion coefficient by combining our established Fickian diffusion model with microscopic measurements of the moving sodium front, extracting the activation energy for diffusion and the temperature-dependent diffusion coefficient through FIB-based TOF-SIMS analysis.

Conclusion
In summary, the developed in-situ TOF-SIMS experiments provide valuable inputs for the study of chemical dynamics occurring in the hot corrosion processes of inorganic glasses with complex compositions, offering insights for mitigating corrosion reactivity at high temperatures. More widely, the developed TOF-SIMS techniques open the exploration of chemical dynamics at high temperatures in applications from metal-forming and engine lubricants to nuclear reactor components to advance the understanding of performance degradation through to new materials synthesis routes.

Poster Group 2

Background incl. aims
MAB (M = transition metal, A = A group element, B = Boron) phases possess a nanolaminated structure, which gives rise to desirable properties from both metals and ceramics due to the combination of metallic and covalent bonding. The metallically bound A elements can be selectively removed leading to the formation of 2D graphene-like MBenes. The most studied MAB phase system, MoAlB, exhibits an oxidation resistance in line with other alumina formers. Upon addition of Cr, the quaternary (Mo1-xCrx)AlB phase is reported to form for high Mo contents, while the experimental data reported for high Cr contents are limited. To gain a deeper understanding of the system including phase formation and transition, a high-resolution transmission electron microscopy (TEM) study was conducted, whereby the data were correlated with in-situ as well as macroscopic results.

Methods
MAB thin films were synthesized by magnetron sputtering at temperatures up to 600 °C. In order to gain an understanding on the phase formation in the MAB samples, HRSTEM analysis was employed in combination with energy dispersive X-ray (EDX) analysis, used for chemical analysis. To confirm the TEM results, multiple analysis techniques were used. Structural data were acquired by X-ray diffraction, while time-of-flight elastic recoil detection analysis (ToF-ERDA) was used for the macroscopic chemical composition. Additionally, electrical resistance measurements and differential scanning calorimetry (DSC) was performed. To further analyze the mechanisms of phase formation and transition, MAB thin films were deposited on SiN heating chips (Wildfire nano-chips, DENS solutions) and investigated in situ with STEM imaging as well as in situ selected area electron diffraction (SAED). Gibbs energy of formation calculations obtained by DFT revealed the energetically favorable phase formations.

Results
HRSTEM and STEM-EDX analysis revealed the formation of the quaternary $(Mo,Cr)_2AlB_2$ phase in a Cr-rich (Mo0.24Cr0.76)0.40Al0.32B0.28 thin film, which had not been reported beforehand. These results were confirmed on a macroscopic scale by XRD, ERDA and EDX. This in agreement with the Gibbs energy of formation calculations obtained by DFT, which show, that the energetic barriers for phase formation of the quaternary phase can be overcome in the employed synthesis scenario. Additionally, the formation of the Cr_3AlB_4 phase as it is energetically favorable in comparison to the corresponding quaternary phase, as well as the formation of CrB_4 and Mo were observed. The Cr_3AlB_4 and the Cr_2AlB_2 phase could furthermore be found in thin films of the Cr-Al-B system, which

was confirmed by means of HRSTEM, SAED and EDX. Thereby, inclusions of an Al-rich phase within the MAB phase consisting of up to 15 Al layers were revealed.

Conclusions
The phase formations and transformations of MAB systems were identified by in situ and ex situ TEM analysis. In addition to the unreported $(Mo,Cr)_2AlB_2$ phase, further formation of Cr_2AlB_2 and Cr_3AlB_4 MAB phases was reported. The results were confirmed by DSC, ERDA, XRD and resistance measurements. The experimental description of the shown phase formations in the quaternary (Mo,Cr)AlB and ternary CrAlB system allow for a deeper understanding and contribute to a more sustainable usage of the material.

Mechanics of morphogenesis – The re-invention of cell sheet folding

Dr. Pierre Haas[1,2,3], Dr Steph Höhn[4]
[1]Max Planck Institute for the Physics of Complex Systems, Dresden, Germany, [2]Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, [3]Center for Systems Biology Dresden, Dresden, Germany, [4]Department of Applied Mathematics and Theoretical Physics, Cambridge, United Kingdom

LS-02 (1), Lecture Theater 4, august 26, 2024, 10:30 - 12:30

Mechanical constraints impact the way that organs and tissues develop. Yet, we are only beginning to understand the physical principles that shape tissues. The folding of cellular monolayers, as seen in gastrulation, neurulation and organogenesis, serves as a model for understanding the shaping of three-dimensional tissues. Within the algal family Volvocaceae a range of complexity in cell sheet folding has evolved only 200MYA, providing an excellent model system to study the underlying mechanics. Volvox globator embryos consist of a spherical cellular monolayer which turns itself inside-out in a gastrulation-like process called inversion.
We have been using a combination of advanced light sheet and 2-photon time lapse imaging, biophysical perturbations, and mathematical modelling to understand the forces underlying inversion. We found that different ways to turn a sphere inside out have evolved in different volvocacean species, corresponding to deviations in geometrical constraints [1-4]. We have developed a framework to predict out-of-plane forces in dynamic three-dimensional cell sheets. Model-based analyses of orthogonal laser ablations allow us to infer out-of-plane forces and stresses (Fig. 1). [5]. We found that inversion is driven by spatio-temporally concerted changes in cell shapes, cell connections, and tissue properties. Our findings suggest that these green algae have likely evolved mechano-chemical signalling mechanisms, equivalent to those found in the animal kingdom.

Poster Group 1

Background incl. aims
Photoelectrochemical water splitting is a clean and renewable method to directly convert green energy carrier from solar light into hydrogen. Ta3N5 is a promising photocatalytic material for use as a photoanode, with suitable bandgap (2.2 eV), and with the conduction band (CB) and valence band (VB) energy levels appropriately straddling the water redox potentials [1]. By applying only 1.23 V of overpotential, the photocurrent density under 1 Sun illumination reaches the theoretical limit of approx. 13 mA.cm2 [2, 3]. However, during operation when the photoelectrode is exposed to water, sunlight, and biasing conditions, photocorrosion has shown to occur. This reduces the stability of the device significantly and degrades the material by oxidizing the surface. In order to utilize this material as a stable and efficient photoanode, it is important to understand and prevent the solar degradation process. We have previously investigated the stability of the electronic band structure of Ta3N5 using operando ambient pressure X-ray photoelectron spectroscopy (AP-XPS) at the HIPPIE beamline at the MAX IV synchrotron in Lund using the “dip and pull” setup for pure Ta3N5 as well as NiOx coated materials and found Fermi-level pinning to occur, and a significant improvement was made by stabilizing the surface. We then wanted to investigate the dynamic structural changes that occur to Ta3N5 during the degradation process when Ta3N5 is exposed to water vapor, biasing conditions, and light.

Methods
Ta3N5 thin films on glass substrates were made with pulsed vapor deposition of metal Ta, following a nitridation process. Some samples were also made with a protective NiOx coating. The ex-situ characterization work was done using a FEI Titan G2 transmission electron microscope (TEM), DCOR Cs probe corrector, Super-X EDS detector, and Gatan GIF Quantum 965 electron energy loss (EELS) Spectrometer at SINTEF in Oslo. While the in-situ TEM characterization was carried out using an environmental transmission electron microscope a Titan E-Cell 80-300ST TEM at DTU. The TEM sample was made with a focused ion beam and connected to a heating and biasing chip with a diode placed on top of the extra contacts.

Results
During the degradation process, an amorphous layer is formed at the surface. The surface layer formation is highest when combining water, light, and biasing of the sample. The process seems to first make small nanocrystals of Ta3N5. After some time, they are amorphized, and new nanocrystals are formed. This process continues till we have a stable uniform surface layer.

Conclusion

The surface degradation process creates an amorphous layer, and is most pronounced when combining water, light, and bias. The degradation first makes small nanocrystals of Ta3N5, for then to amorphized them separately.

Background incl. aims
Power electronics (PE) are integral to the acquisition, distribution, and storage of energy, serving as a pivotal facilitator for enhancing energy efficiency, leveraging renewable resources, and advancing smart grid technologies. While silicon-based PE components have reached a peak in optimization, further enhancements are constrained by intrinsic material properties. This limitation underscores the appeal of wide bandgap semiconductors in PE applications, offering the potential for superior speed, compactness, and energy efficiency compared to their silicon counterparts [1]. One promising avenue lies in the development of High-Electron-Mobility Transistors (HEMTs) based on novel (MxGa1-x)2O3 thin film heterostructures (where M represents Al or In), which exhibit the promise of heightened operational speeds, reduced footprint, and increased power capabilities owing to their ultra-high breakdown field [2]. Ga2O3, capable of existing in various polymorphs such as α, β, γ, δ, and ε phases, boasts a bandgap ranging from 4.5 to 4.9 eV depending on crystallographic orientation [3]. κ-Ga2O3, notably, demonstrates a substantial polarization effect (23 µC/cm2), indicative of its potential to harbor an interface-localized two-dimensional electron gas (2DEG), making it a viable candidate for HEMTs [4, 5]. Through controlled alloying with group III metals, (MxGa1-x)2O3 presents a tunable framework for adjusting critical properties like bandgap and carrier concentrations, thereby tailoring its suitability for specific applications. The band gap range obtained by using Al and In is spanned out by In2O3 (Eg= 2.9 eV) [6] and Al2O3 (Eg= 8.8 eV) [3], and the values can be calculated by eq1: Eg = 4.91 + 2.10x for κ-(AlxGa1-x)2O3 and eq2: Eg = 4.90 – 1.95y for κ-(InyGa1-y)2O3.

Methods
In this work we have investigated (MxGa1-x)2O3 thin film heterostructures (M = Al, In) with various doping concentrations, thickness of layers, and substrate deposition, made using pulsed laser deposition (PLD) and vertical (quasi-) continuous composition spread (VCCS) PLD. The morphology, crystal structure, element composition and band gaps have been measured by transmission electron microscopy (TEM) for three types of samples. For the analysis, we have used a FEI Titan G2 operated at 60 kV with a monochromator, DCOR Cs probe corrector, Super-X EDS detector, and Gatan GIF Quantum 965 electron energy loss (EELS) Spectrometer. The analysis of the EELS spectrum images (SI) and individual spectra (such as the band gap fitting) are performed by our own python-based EELS fitting program combined with Gatan Digital Micrograph and Hyperspy.

Results
Scanning TEM (STEM) image of one type of sample is shown in Figure 1A. Where the top layer is (Al0.3Ga0.7)2O3, second layer is (In1.8Ga0.82)2O3, and the third layer Ga2O3, where the substrate is indium tin oxide (ITO). The band gap has been fitted for each spectrum in the spectrum image (SI) in Figure 1B. The average band gap for each row with the variations (in gray) is plotted in Figure 1C. The band gaps have been fitted to be 5.1 eV, 4.3 eV, and 4.8 eV, for (Al0.3Ga0.7)2O3, (In1.8Ga0.82)2O3, and Ga2O3 respectively. The band gap value for (Al0.3Ga0.7)2O3 and (In1.8Ga0.82)2O3is lower than what can be estimated theoretically, which is 5.54 eV and 4.45 eV respectively. We also observe a

decreasing band gap across the interfaces. Is this due to a decrease in band gap or because of the delocalization of the electron beam? The data has then been analyzed in detail and compared to the structural properties across the interface and compared with two other samples of (MxGa1-x)2O3 deposited on ZnO substrates with different compositions and thinner layer thicknesses.

Conclusion
The results have shown that the reduced band gap values are most likely due to strain in the layers and was not found in layers with high amounts of defects. The decrease in band gap across the interface is a real decrease in value, probably due to lattice mismatch-strain.

The fatigue response of the IN939 superalloy prepared by additive manufacturing

Ivo Kuběna[1], Markéta Gálíková[1], Ivo Šulák[1]
[1]Institute of Physics of Materials, Czech Academy of Sciences, Brno, Czech Republic

Poster Group 2

Background incl. aims
Ni-based superalloys have become a time-honored high-temperature material. The first steps in their development were directed towards optimizing the manufacturing processes, chemical composition, and microstructure. The additive manufacturing (AM) technologies, also commonly called 3D printing, emerged and changed some classical approach. AM offers several advantages such as design freedom, very good efficiency of material usage, possibility to create hierarchical structures, crystallographic texture etc. Recently, the parameters of Laser Powder Bed Fusion (L-PBF) were optimized for the nickel based superalloy IN939. The main aim of the contribution is to address fatigue and thermomechanical fatigue (TMF) properties to the specific microstructure of the IN939 prepared by the L-PBF.

Methods
Microstructural analysis was performed by the mean of scanning and transmission electron microscopy. The Tescan Lyra 3 FEG/FIB scanning electron microscope equipped by the energy dispersive spectroscopy and backscattered electron diffraction detector (EBSD) was used the microstructural analysis, texture measurement and grain size evaluation. The Talos 200i transmission electron microscope equipped by the energy dispersive spectroscopy was adopted for the analysis of typical cell structure and strengthening particles.
The material was prepared by AM method. To achieve ideal microstructure, the IN939 was exposed to three-step heat treatment: solution annealing at 1175°C for 45 minutes followed by two step precipitation hardening 1000°C/6h + 800°C/4h.
The isothermal fatigue at 800 °C with symmetrical push-pull cycle was measure. The two modes of TMF, in-phase and out-of-phase loading were used for testing. During in-phase loading, the maximum mechanical loading corresponds to the maximum temperature, while in the out-of-phase mode, the maximum temperature corresponds to the minimum loading.

Results
Microstructural analysis revealed elongated grains with a preferential orientation <001> parallel to building. IN939 incorporates a considerable amount of a reinforced gamma prime phase that is embedded coherently within the matrix.
The fatigue properties at 800 °C and response to the TMF loading were measured. Obviously, the TMF is more detrimental than pure fatigue in very low cycle region, especially the in-phase TMF loading. The differences between particular loading modes decreases with decreasing strain amplitude. The EBSD measurement revealed no grain coarsening or changes in crystallographic texture. The fatigue cracks propagated predominantly along grain boundaries.

Conclusion
Following conclusion based on obtained results can be drawn :

- The typical AM microstructure consist of dislocation cells with crystalographic texture was revealed.
- The In-phase TMF mode seems to be most damaging in very high strain amplitude region, while the diffences in fatigue life in low strain amplitude region are almost negligible.
- The crack propagation path along grain boundaries was documented.

Revealing the vacancy ordering in Prussian blue analogues through serial electron diffraction

Mr Shihui Feng[1], Dr Hanna Boström[1], Dr Cheuk-Wai Tai[1]
[1]Department of Materials and Environmental Chemistry, Stockholm University, Stockholm, Sweden

Poster Group 2

The irregular arrangements of the vacancies, interstitials or impurities on the lattice sites in a crystal structure can cause diffuse scattering in diffraction patterns, causing deviation from Bragg diffraction spots. Such diffuse scattering features can be utilized and back-calculated to explore the arrangements of defects within the structure. The Prussian blue analogues (PBAs) are composed of two transition metals coordinated with cyanide ligands, resulting in a specific porous structure with diverse applications such as electrochemical catalysis, ion transportation, and gas absorption. Some researcher elucidated the vacancy networks in series of PBAs using single-crystal synchrotron diffraction. However, above mentioned techniques require large single-crystals (>500 um), which is not suitable for some groups of PBAs.
Here, contributed by high spatial-resolution, transmission electron microscope was applied. We focus on the vacancies ordering in Cu[Co(CN)6] PBAs nanoparticles, which is hard to collecting single crystal x-ray or synchrotron data. Additionally, the presence of cyanide ligands and zeolitic water inside structure makes PBAs can be easily damaged by electron beam within seconds, which hindering structural study using 3D electron diffraction. To address these challenges, the serial electron diffraction (serialED) was introduced to capture single-frame exposure electron diffraction for thousands of nanocrystals. Following by clustering and indexing, the diffuse scattering patterns were analysed from serval main zone-axis diffraction patterns. The diffuse scattering features from HK0 slice closely resembled those reported in the literature obtained by synchrotron methods, confirming the consistency and reliability of our method. The delta pair-distribution function also provides insights into the structural ordering in PBAs.

Poster Group 2

Wide-bandgap (WBG) materials such as gallium nitride (GaN) are better candidates for fabricating power switches and high-frequency transistors than conventional Silicon-based technology. At the interfaces of a high mobility transistor heterojunction (HEMTs) such as that between AlGaN/GaN, in addition to the formation of a strained zone which increases the electronic mobility of the charges located there, a strong polarization effect is created as well. Such polarization causes band bending, including the Fermi level, at the AlGaN/GaN interface resulting in the accumulation of electric charges and the formation of a very electron-rich two-dimensional gas (2DEG). 2DEG contributes to the outstanding performance of AlGaN/GaN based HEMTs and can achieve a sheet carrier concentration close to the interface, well in excess of those observed in other III – V material systems.[1]. The ability to reveal the 2DEG in real space by TEM's conventional techniques would be desirable, but up to now has been very challenging to accomplish due to an unavoidable strong diffraction contrast formation at the heterointerfaces. [2]. Recently a new microscopy technique called 4D scanning transmission electron microscopy (4D-STEM) is gaining momentum for probing materials at sub-Angstrom resolution with the full electron−atom scattering interactions recorded in a convergent beam electron diffraction pattern (CBED) [3]. The 4DSTEM has been demonstrated that sub-Å measurements of electric fields and electrostatic potentials in materials is feasible [4].

In this work we studied a AlGaN/GaN based device where the 2DEG has been kept on and off in two different regions of the device, the latter obtained by means a p-GaN structure. In our opinion, this is the best system to test this technique to directly visualize the 2DEG in real space. The acquisition of a full set of CBED on the entire field of view could be very time and data consuming. For this reason, in this study, we acquired a sub-sampled 4DSTEM dataset by sampling only the 10% of the entire field of views [5]. As for the detector we used a QD MerlinEM Direct Electron Detector (DED) 256x256 and with 2x12bit count depth able to work as fast as 2000fps. The experiments have been carried out on a probe corrected ARM200F operated at 200keV. Data analysis was performed by center of mass (CoM) field shift data analysis method.

The 2DEG has been revealed in the regions in the proximity of the interface between GaN/AlGaN and in both regions. We discovered that where we expect 2DEG to be off it appears still visible instead but shifted far away by the interface due probably to the counter field of the p-GaN located at the opposite interface.

In this work we have shown that 4DSTEM through its analysis methods, such as CoM, can show the exact location of 2DEG as a function of interface electric fields.

The localization of 2DEG in the real space is essential for understanding its properties and to improve device designs aimed at optimizing both properties and miniaturization.

IM-06 (1), Lecture Theater 1, august 29, 2024, 14:00 - 16:00

Identifying the orientation of crystalline phases at the nanometer scale is relevant for understanding materials properties. Here we will demonstrate that collecting and processing scanning precession electron diffraction (SPED) datasets collected at a few different specimen tilts can improve the accuracy of template-based orientation mapping [1,2]. In addition, the tilt series allows complete determination of the relation between the specimen crystallographic setting and the goniometer axes. This insight, combined with the orientation map, can be used in a convenient semi-automatic approach to predict the tilts required to reach a target specimen orientation for further structure analysis.
SPED of different polycrystalline systems (Si, Ag, and oxides) were recorded in a JEOL JEM2100F with a NanoMegas DigiStar precession system and a Quantum Detectors MerlinEM direct electron detector. Scans were taken over areas up to 15 x 15 µm containing 10's of grains using a nominal precession angle of 1˚. Tilts series using one or two axes contained 3-5 tilts in the range 0 - 20˚ from the initial flat specimen position. For data analysis and visualization, we used primarily the open-source python library pyxem [3].
The indexed frames, taken at different tilts, were compared, after manually aligning the frames, using the set tilt as expected misorientation. Together with considering as well the best 5 to 25 normalized cross correlations between the experimental patterns and the simulated pattern bank, orientation-dependent misindexations can be identified and the orientation estimate refined. Compared to the standard approach of collecting SPED using only a single specimen tilt and the best correlation scores for each pattern, the tilt series approach reduces indexation variations within grains. This gives a more uniform representation of the grains in the final orientation maps.
The accuracy of the refined orientation analysis can be determined with a known orientation relation, here for example Σ3 twins in face-centered cubic and diamond crystal systems. The misorientation deviation between the measured and expected misorientation between twin domains is used as the metric [4]. The found accuracy is below the used precession angle.
The refined orientation mapping based on a small tilt series has a further practical use. From a single axis tilt series, the position of the two perpendicular tilt axes can be determined. As the tilt series is small and over a limited angular range, sufficient probe positions must be used to accurately determine the tilt axis position. Misaligned between frames and areas with overlap, such as grain boundary areas, were excluded through thresholding. A second tilt axis series or grains correctly indexed in different frames can be used to verify the found axes positions. Using the determined orientation of a grain together with the deduced axes positions, the tilts to reach a target zone for a grain can be predicted. Based on tests on different TEMs and holders, the target zone was within 2˚. In the tests the specimen was placed at approximately the same rotation relative to the holder axes. However, should the specimen be differently placed compared to where the orientation was mapped

out, an additional transformation matrix can be included in the navigation tool to recalculate the target tilts for the given specimen placing. This correction is based on a manual estimation of misorientation from the tilts to the actual target zone, diffraction (using the Laue circle), or imaging (assuming in-plane rotation).
To conclude, template matching based on multiple SPED scans at a few varying specimen tilts improves the accuracy and the final orientation visualization. In addition, the approach is used to make a practical navigator tool that widens to use of template matching results for subsequent lattice imaging and further crystallographic analysis. With the advancements in automatic scan controls, faster detectors and optimized transparent open-source routines, the benefits gained will more than compensate for the drawbacks of acquiring and processing multiple scans.

Deep Learning assisted X-ray Microscopy Characterization of Nickel based Metal Matrix composite reinforced with TiC

Dr. Kaushik Yanamandra[1], Dr. Hrishikesh Bale[1], Dr. Rajarshi Banerjee[2], Ria Mitchell[1]
[1]Carl Zeiss Research Microscopy Solutions, Dublin, United States of America, [2]Materials Science and Engineering, University of North Texas, Denton, United States of America

Poster Group 1

Background
Metal Matrix Composite (MMC) are a class of materials with remarkable mechanical, thermal, and electrical properties. These composites consist of a metallic matrix reinforced with ceramic or other non-metallic phases. Reinforced MMC are of interest in many applications due to their multifunctionality, which yields combinations of properties such as high specific strength, stiffness and toughness, and a low coefficient of thermal expansion [1]. Ni-Ti-C based metal matrix composites explored in this paper is produced using the laser engineered net shaping (LENS) process presenting a unique hierarchical microstructure consisting of an in situ formed and homogeneously distributed titanium carbide (TiC) phase reinforcing the nickel matrix [2]. Additionally, by tailoring the Ti/C ratio in these composites, an additional graphitic phase can also be engineered into the microstructure. The resulting three-phase Ni-TiC-C composites were comprehensively characterized using Deep learning assisted X-ray Microscopy (XRM). By analyzing the microstructure at the sub-micron level, XRM enables the understanding of the spatial distribution and alignment of reinforcing phases within the metal matrix.
Method
Ni-Ti-C-based MMCs were fabricated using the laser engineered net shaping (LENS) process. The LENS process involves the deposition of metal powder layers using a laser beam, allowing precise control over the composition and microstructure. XRM, with its high-resolution and non-destructive capabilities, provides valuable insights into MMCs. Notably, certain phases within the titanium carbide (TiC) domains push the limits of X-ray microscopy detection, relying on X-ray-to-visible-light conversion via scintillators coupled with optical magnification objectives. To overcome previous limitations, a unique combination of specially designed high-resolution objectives and deep-learning-based 3D reconstruction was utilized. The combination of new generation scintillator technology and integrated deep-learning reconstruction known as DeepRecon [3] enable sub-micron resolutions in dense and large MMC sample.
Results
Ni-Ti-C based MMC exhibits intricate microstructures that span a wide range of length scales, with various phases playing a critical role in determining its exceptional properties. Leveraging the high-resolution and non-destructive capabilities of X-ray microscopy the microstructure of the MMC is studied and analyzed in 3D at different length scales. The X-ray microscopy images reveal the spatial arrangement of TiC phases within the metal matrix. Features of <.0.1µm were previously undetectable in large and dense samples due to their small size and due to the noise produced in a tomography scan from these samples were observed using the DeepRecon – Deep Learning based reconstruction algorithm. The findings from XRM data significantly enhance the understanding of MMCs.
Conclusion
These composites hold promise for various engineering applications, including aerospace, automotive, and structural components. The study of Ni-Ti-C-based MMCs not only provides insights

into the relationship between microstructure and properties but also set forth a vital tool and technology needed to understand these intricate structures. X-ray microscopy emerges as a powerful tool for MMC analysis, offering high resolution and non-destructive capabilities. Its application enhances the comprehension of MMC performance, thus opening new avenues for their optimized design and engineering.

Cryo-FIB as a preparation tool for soft X-Ray Tomography: Analysis beyond EM

Dr Chris Parmenter[1], Dr Kenneth Fahy[2]
[1]Nanoscale and Microscale Research Centre, University of Nottingham, Nottingham, UK, [2]SiriusXT, Dublin, Ireland

Poster Group 1

Background incl. aims
Focused Ion Beam Scanning Electron Microscopes (FIB-SEM) used at Cryogenic (cryo) conditions have been used as a preparation tool for soft-matter samples since 2006 with a recent rapid expansion of their use in the case of the 'on-grid' thinning approach for cryo-electron tomography (cryo-ET). Less well developed is the site-specific cryo-FIB preparation of samples that cannot be grown (or deposited) and thinned on a TEM grid, such as tissue or other soft matter samples e.g. battery materials. Site-specific FIB preparation followed by extraction (lift-out) is a route to achieving the thickness requirements of the TEM prior to transfer. By adapting this approach to meet the dimensions and requirements of other analytical equipment it is possible to expand beyond the limit of electron microscopy.
Methods
This work utilised a Crossbeam 550 FIB-SEM (Carl Zeiss) equipped with a Quorum 3010 (Quorum Technologies) cryo-system. The micromanipulator was an Omniprobe 200-cryo (Oxford Instruments). Samples were frozen by slushy nitrogen, metal mirror (MM) freezing or high pressure freezing (HPF) before transfer to the cryo-system. Prior to FIB-SEM the samples were platinum sputter coated in the preparation chamber and subsequently by the platinum organometallic precursor of the gas injection system (GIS) of the FIB. Gallium FIB preparation was performed at 30kV accelerating voltage currents of between 15nA (initial larger volume milling) and 50 pA (final polishing of samples). SEM of the samples was performed at 2-5 kV. Cryo-redeposition milling was used to attach samples to the micromanipulator and support substrates.
Results
Building on pre-existing protocols for the preparation of TEM compliant samples (lamellae) we increased the dimensions of the volumes prepared to meet the requirements of a soft-x-ray tomography (sRT) microscope which to approx. 45µm and a thickness of 5µm which we term 'slabs' (fig 1a). The sXT can penetrate a sample up to 10 µm thick however, we accounted for the sample needing to be tilted in the X-Ray beam (+/- 55°). These slabs were transferred to specially modified copper support structures (fig 1 b-d).

Fig 1. (A) Schematic showing the relative dimensions of the lamella and slab, the tip of a micromanipulator is included for scale. (B) FIB image showing the micromanipulator with attached slab during slab extraction. (C&D) Micrographs of the slabs following deposition onto the support structure and subsequent polishing using the FIB. Scale bars 10 µm (B&C) 4 µm (D).

Conclusion
Cryogenic FIB preparation combined with lift-out using a cryogenically cooled in situ micromanipulator is demonstrated as a viable preparation tool for the preparation of soft-matter sample (~45x5 µm) slabs for sXT. We have presented recent efforts to use Cryogenic Focused Ion Beam Scanning Electron Microscopes (cryo-FIB-SEM) as a preparation tool for cryogenic analysis

beyond the FIB itself, embracing emerging themes in multi-length-scale analysis and correlative microscopy.

Poster Group 1

Background
A single protein can be chemically labeled with different fluorescent dyes in order to get insights about its cellular localization and molecular mechanism of action [1]. Overall, an ideal fluorescent dye should be specific and stable, and should not interfere with the physicochemical and conformational properties of the protein. For internalization assays in living cells, organic fluorophores such as fluorescein (FITC) and rhodamine (TRITC) are the dyes of choice since they have a short lifetime (<5 ns), and they are brighter and more photostable than other fluorescent labels [2]. They also have a small size, thus interfering less with the biological system (i.e. protein). The main disadvantages of these compounds are their low specificity and unknown binding stoichiometry. In this work, we have tailored a minimal labeling protocol, originally developed for proteomic applications, in order to tag single proteins for being used in live cell internalization assays.

Methods
The original 2D-DIGE minimal labeling protocol ensures that only 1–2% of the available Lys is labeled. Thus, this protocol facilitates successful labeling of an individual protein at a specific location (ε amino group of Lys) and with a well-defined stoichiometry (1:1). Moreover, this modification only adds just about 500 Da to the protein total molecular weight, thus minimizing perturbations of the physicochemical and conformational properties of the protein. Overall, the full standard protocol is accomplished in 4-5 hours and comprises three different steps (Figure 1). Firstly, the protein of interest is resuspended in the reconstitution buffer and labeled with the CyDye fluorophore of choice. After incubation, labeling is stopped by adding an excess of L-lysine (Lys) to the reaction mixture. Secondly, the excess of free Lys-bound CyDye is removed to minimize background in the internalization experiments. At this point, the Cy-labeled protein can be concentrated if necessary, by filtration through a size exclusion membrane of suitable cutoff. Finally, in the last step, the quality of the labeling reaction is tested by SDS-PAGE.

Results
To validate experimentally our protocol, we carried out the fluorescent labeling of IBB1, a major soybean protease isoinhibitor of the Bowman-Birk family that is currently being investigated as colorectal chemopreventive agent [3], with two different CyDye fluors. A single protein band of about 12 kDa was visible after scanning the polyacrylamide gel at 488 nm (IBB1-Cy2) or 635 nm (IBB1-Cy5), respectively, proving the success of the minimal labeling reaction. Then, we monitored the in vivo internalization dynamics of the labeled IBB1 protein in human colorectal adenocarcinoma HT29 cells. We observed that the CyDye-labeled IBB1 proteins crossed the plasma membrane of HT29 cells after a few minutes and was gradually accumulated, forming fluorescent patches randomly distributed across the cytoplasm. We also tested the suitability of this method for carrying out multiplex

experiments. Thus, two different combinations of labels were tested. Firstly, IBB1-Cy2 internalization was combined with nuclei staining using Hoechst 33342 dye. The fluorescent signal of IBB1 did not overlap with Hoechst-specific labeling, indicating that the protein did not internalize into the cell nucleus. Secondly, IBB1-Cy2 internalization was combined with the fluorescent probe FM 4-64, an endocytic tracer [4]. We observed that the fluorescent signal from the endosome marker colocalized with the Cy2-labeled IBB1 protein in the cytoplasm of HT29 cells, suggesting that IBB1 is internalized through one of the existing endocytosis pathways.

Conclusions
In this work, we have adapted a protocol that was originally developed for two-dimensional fluorescence difference gel electrophoresis (2D-DIGE) applications, to label proteins with CyDye fluors for single-molecule internalization assays in living cells. This protocol is suitable for both proteins purified from their natural sources and recombinant proteins expressed in heterologous systems (e.g. E. coli, P. pastoris, etc.). This “minimal labeling” method offers a number of advantages including specificity and known stoichiometry, simplicity, high reproducibility, and sensitivity and allows multiplexing while minimizing perturbations of the biological system. Moreover, the minimal labeling protocol is suitable for multiplex experiments, either combining up to three different proteins labeled with Cy2, Cy3, and Cy5, respectively, or using CyDye fluors together with other fluorescent labels. Finally, since only a single lysine (Lys) residue per protein molecule is labeled, this method is also quantitative.

Poster Group 1

Background
Pollen, the male gametophyte, plays a pivotal role in plant reproduction, being essential for successful fertilization and seed production in Angiosperms. Thus, understanding its biology is crucial for ensuring optimal crop yields. Carbonylation is an irreversible post-translational modification (PTM) characterized by the non-enzymatic addition of carbonyl groups to amino acid residues, leading to protein malfunction and cell death. Carbonylation leads to disruption of protein structure and function. On the other hand, S-acylation or palmitoylation is another PTM that involves the reversible attachment of palmitic acid to specific Cys residues of proteins by the action of protein S-acyltransferases (PATs). This PTM plays crucial roles response to biotic and abiotic stresses, hormonal signaling, cell polarization and expansion, and cytoskeleton organization [1].
Protein labeling techniques for in vivo studies have garnered considerable attention, with cycloaddition reactions emerging as promising methods due to their compatibility with diverse conditions. However, the cytotoxic effects of copper catalysts have limited their widespread application [2]. This study aimed to develop innovative protein labeling methods for assessing protein carbonylation and S-acylation in plant tissues.

Methods
For S-acylation studies, we developed a new method for incorporating fluorescence-labeled palmitic acid into proteins using an azide-alkyne cycloaddition reaction. This method was experimentally validated using an in vitro culture system for pollen. In a first approach, the synthetic lipid containing the azide functional group was added to the culture medium, either in the presence or not of a chemical PAT inhibitor [3], being incorporated to proteins by the enzymatic machinery of germinating pollen grains. Then, pollen was fixed and the fluorescent labeling reaction was performed and visualized by fluorescence microscopy. Alternatively, the fluorescent labeling was carried out exogenously. Then, copper was removed using size exclusion techniques, thus eliminating its cytotoxic effect. Finally, pollen was germinated in the presence of the palmitol-fluorochrome conjugate and the dynamics of the S-acylome was monitored by using time-lapse fluorescence microscopy.
For detecting carbonylated proteins, we developed two different methods. First, we carried out derivatization of carbonyl groups by DNPH (2,4-dinitrophenylhydrazine) [4] to hydrazone groups, which were further detected using an Alexa Fluor 488-conjugated antibody. Alternatively, we used the fluorescent probe BzCH (7-hydrazinyl-4-methyl-2H-1-benzopyran-2-one,), which is capable of binding specifically to carbonyl groups [5]. These two methods were further experimentally validated as above in the presence or absence of the ROS inducer Paraquat in the culture medium. Moreover, this method also allowed to quantify protein carbonylation by conducting derivatization assays followed by image processing and fluorescence quantification.

Results
Both fluorescent labeling approaches revealed the dynamics of S-acylated proteins in growing pollen tubes, showing a similar distribution pattern of S-acylated proteins. Thus, a high fluorescent signal was observed in the cytoplasm of the vegetative cell and, to a lesser extent, in the cytoplasm of the pollen tube. Fluorescence significantly decreased in the presence of the PAT inhibitor, suggesting that was mostly due to the activity of PAT enzymes. Moreover, the exogenous labeling of the synthetic lipid allowed the real-time monitoring of the S-acylome in a single growing pollen tube by using time-lapse microscopy.
On the other hand, carbonylated proteins were found to accumulate in the cytoplasm of the vegetative cell of non-germinated pollen grains, suggesting that this PTM may be a marker of loss of pollen viability. In addition, we observed a consistent accumulation pattern of carbonylated proteins at the apical region of the pollen tube. Interestingly, protein carbonylation levels significantly increased in the presence of Paraquat in the germination medium, suggesting that ROS-mediated oxidative stress may triggers carbonylation, leading to pollen tube growth arrest.

Conclusions
In this work we have developed a novel and reliable fluorescent labeling method to study S-acylation of plant proteins, overcoming limitations associated with cytotoxic catalysts during cycloaddition reactions. Moreover, we have set up two methods to localize carbonylated proteins in plant tissues by using fluorescent probes.

This research was funded by projects PID2020-113324GB-100 and TED2021-130015B-C22 from MICIIN/AEI, both of them cofinanced by the ERDF program of the European Union. Salvador Priego and Andrea Román were granted with a PhD fellowship from Junta de Andalucía and MICINN, respectively.

Supersilent AlCoFeNiCux (x = 0.6 – 3.0) high-entropy alloys

Dr. Andreja Jelen[1]
[1]J. Stefan Institute, Ljubljana, Slovenia

PS-02 (3), Lecture Theater 4, august 30, 2024, 14:00 - 16:00

BACKGROUND INCL. AIMS
In the search for the materials that possess a combination of excellent magnetic softness and vanishing magnetostriction, the ferromagnetic high-entropy alloy (HEA) system AlCoFeNiCux (x = 0.6–3.0) was investigated.

HEAs are expected to find applications as supersilent (inaudible to a human ear) materials for transformers, magnetocaloric coolers, and other “humming” electromagnetic machinery.

METHODS
The AlCoFeNiCux HEAs with the Cu content x = 0.6–3.0 were prepared from high purity elements (>99.99 wt.%) by arc melting under an argon atmosphere. Altogether, there were seven samples fabricated.

An evolution of the crystal structure and chemical composition was observed with increasing Cu content by XRD and SEM EDS characterization. The phases constitutions and their domain sizes were characterized by correlative SEM and TEM techniques, as HEAs usually have highly complex structures on different spatial scales that contribute to specific physical properties such as magnetic softness and magnetostriction.

The magnetic properties were investigated by a Quantum Design Magnetic Property Measurement System MPMS3 magnetometer. The magnetometer uses a superconducting magnet with variable magnetic field of ± 7 tesla and the temperature range of the measurements is from 1.8 K to 400 K.

Electrical resistivity was measured by a Quantum Design Physical Property Measurement System PPMS 9T by. The apparatus uses a superconducting magnet with a variable magnetic field of ±9 tesla and the temperature range of the measurements is between 1.9 K and 400 K.

RESULTS
XRD revealed the evolution of the samples’ crystal structure. At low Cu contents, x = 0.6 and 0.8, the predominant phase is bcc (≈85 wt.%) with the unit cell parameter a = 2.869 Å, and the second phase is fcc (≈15 wt.%) with a = 3.612 Å. On increasing the Cu content, the fraction of the fcc phase increases, while the bcc phase fraction decreases. Detailed observation of the fcc-phase diffraction peaks reveals that there are actually two fcc-phases with slightly different unit cell sizes, denoted as fcc(L)-large and fcc(S)-small.
For the two highest Cu contents (x = 2.5 and 3.0), the bcc phase is no longer visible in the XRD patterns and the structure is two-phase, composed of the fcc(L) and fcc(S) phases.

The development of the microstructure of all alloys was made visual by SEM BSE imaging. All alloys show inhomogeneous microstructure, where the brighter parts are enriched in the heaviest element Cu.

The TEM analysis of the AlCoFeNiCu2.5 alloy reveals that the three constituent phases are nanostructured on the 10 nm scale due to fine dispersion of the Guinier-Preston (GP) zones that are enriched in Cu. The GP zones were observed in all three phases except at the locations of the highest Cu enrichment. The concentrations of the chemical elements also show nanometer-scale variations. It is straightforward to anticipate this result to the entire series of the investigated AlCoFeNiCux (x = 0.6–3.0) HEAs, so that the alloys can be considered as nanostructured composite materials with a multiphase (up to three phases) microstructure.

Magnetic softness characterization was performed by determining the magnetization versus the magnetic field, M(H), hysteresis loops in the magnetic field sweep $\mu_0 H = \pm 7$ T. Rapid change of the M(H) curves in the close vicinity of $H = 0$ and small coercive fields Hc are evident for all samples, revealing magnetic softness.

Magnetostriction experiments were performed at RT in a static magnetic field range $-0.2\ \text{T} < \mu_0 H < 0.2\ \text{T}$ by measuring the samples' elongation (or contraction) with a strain gage. The magnetostriction curves $\lambda(H)$ at RT show the largest (positive) value $\lambda_s = 21\ \mu\text{m m}^{-1}$ for the lowest Cu content x = 0.6. The positive saturation magnetostriction decreases with increasing x and vanishes ($\lambda_s = 0$) at x = 2.0. For the two alloys with the highest Cu contents, x = 2.5 and 3.0, λ_s remains very close to zero. In practical terms, all AlCoFeNiCux alloys in the Cu content range $2.0 \le x \le 3.0$ can be considered as vanishing-magnetostriction HEAs, so that the precise Cu concentration within this range is unimportant.

Superior parameters were obtained for the composition AlCoFeNiCu2.0, which shows precisely zero magnetostriction, $\lambda_s = 0$, reasonably low coercivity $H_c \approx 650\ \text{A m}^{-1}$ and substantial saturation magnetic polarization of $J_s \approx 0.55$ T, which is about the same as that of the mumetal, a widely used commercial soft magnet.

CONCLUSIONS

Magnetic softness and vanishing magnetostriction originate from the choice of constituent elements (magnetic Co, Fe, and Ni and nonmagnetic Al and Cu) and the multiphase composite microstructure is nanostructured on the 10 nm scale.

Magnetic softness originates from the nanostructured character of the alloys that are random mixtures of the ferromagnetic Al–Co–Fe–Ni domains and nonmagnetic or weakly magnetic Cu-rich domains on the 10 nm scale, which makes the mechanism of exchange-averaging of magnetic anisotropy efficient.

Since vanishing magnetostriction is a prerequisite for the supersilence of the material in audio-frequency AC applications, such HEAs are expected to find application as supersilent magnetically soft materials in transformers, electromotors, generators, magnetocaloric coolers, and other "humming" electromagnetic machinery.

We found that the alloys in the high Cu content range x = 2.0–3.0 indeed possess the targeted combination.

Development and characterization of a laser-driven cold-field emission source

Alexander Schröder[1], Mukai Masaki[2], Kohno Yuji[2], Sascha Schäfer[1,3]
[1]Department of Physics, University of Regensburg, Regensburg , Deutschland, [2]JEOL Ltd., , Japan, [3]Regenburg Center for Ultrafast Nanoscopy (RUN), Regensburg, Germany

IM-08, Lecture Theater 2, august 28, 2024, 10:30 - 12:30

Background
Ultrafast transmission electron microscopy (UTEM) utilizing pulsed electron sources, has emerged as a crucial tool for probing ultrafast dynamics at the nanoscale. Recent breakthroughs in laser-driven Schottky electron emitters have significantly enhanced the spatial and temporal coherence of electron pulses, achieving temporal pulse widths below 200 fs and electron spot sizes as small as 1 nm [1]. The potential for further enhancement in pulse coherence is anticipated through the application of laser-driven cold-field emitters, especially when operated in a linear photoemission regime [2].
Methods
Here, we present the development and characterization of a long-term-stable laser-driven cold-field emitter source, designed for advanced ultrafast transmission electron microscopes and operating at 200 keV electron energy [3]. Based on a JEOL cold-field emitter gun (CFEG), the source utilizes a sharp single-crystalline (310) tungsten tip within a vacuum level of 10^-12 to 10^-11 mbar. For pulsed operation, the source is modified to allow for a direct optical line-of-sight onto the emitter through opposing optical entrance windows.
Results
In the initial implementations, we conducted a comprehensive characterization of the photoemission yield from the tip using a continuous-wave optical illumination at 3.59 and 3.06 eV photon energy focused to a 20 µm scale spot on the emitter apex (Fig. 1c, right inset). Notably, the employed photon energy is below the work function of tungsten so that linear photoemission is only feasible at the apex of the tip which exhibits a Schottky-reduced effective workfunction. Continuous field emission, following a Fowler-Nordheim description, is observed at large electric extraction fields without illumination (blue curve in Fig. 1b). Illumination at 1 mW optical power reveals an additional photoelectron contribution at low extraction field values, for which continuous field emission is absent (yellow and red curves in Fig. 1b). The onset of photocurrents is dependent on the photon energy of the illuminating light field. Above this threshold the current scales linearly with light intensity (Fig. 1c). Notably, under extreme high vacuum (XHV) conditions near the emitter, no significant drop in photoemission yield is observed over a 10-hour period (Fig. 1c, left inset).
In a subsequent step, the emitter is operated as part of the Regensburg JEOL F200 UTEM (Fig. 1a), using ultrashort laser pulses with a duration of 200 fs at a central wavelength of 345 nm. We systematically carried out an extensive pulse characterization, including the pulsed electron energy distribution, pulse duration, and the spatial attributes of electron brightness across varied excitation fields.
When operated at a state in which both, field- and photoemission can occur, the final kinetic energy of electron generate by the two emission processes are needly separated (Fig. 1d). Performing an electron-photon cross correlation we obtain 300 fs-electron pulse duration and energy width of about 300 meV.

Remarkably, our findings reveal that focal sizes of below 0.74 nm and a normalized peak brightness of 10^14 A/m²sr (Fig. 1e) can be achieved, surpassing the brightness of the laser-driven Schottky field emitter constructed in our lab by an order of magnitude. Currently, small electron focal spot sizes are limited to a low current-regime, due to the onset of spherical aberration at larger convergence angles. It should be possible to further improve the transversal beam properties at higher pulse charges utilizing a probe aberration corrector.

Conclusion

In conclusion, we demonstrate the successful development of a stable, laser-driven cold-field emitter source for ultrafast transmission electron microscopy applications. Our findings illustrate the potential to significantly enhance electron beam brightness and reduce energy spread of electron pulses, paving the way for further advancements in probing ultrafast dynamics at the nanoscale.

Microchannel Plate-based Detector with High Pressure Operation up to 1 Pa for Scanning Electron Microscopy

Mr Masahiro Hayashi[1], Mr. Yuya Washiyama[1], Dr. Matthias Sachsenhauser[2]
[1]Hamamatsu Photonics K.K., Hamamatsu , Japan, [2]Hamamatsu Photonics Deutschland GmbH, Herrsching, Germany

Poster Group 1

Background incl. aims
Microchannel Plates (MCP) are electron multipliers with a secondary electron amplifier mechanism. MCP detectors have many advantages such as small size, high temporal resolution, high gain, and very high detection efficiency for electron energies of the order of tens to hundreds of electron volts in scanning electron microscopy (SEM). Recently, almost all commercially available SEMs are operated in low vacuum conditions caused by flowing neutralization gas into the specimen chamber to suppress charging on the sample surface. However, MCPs cannot be utilized in low vacuum conditions because of ion feedback.
Ion feedback, a peculiar phenomenon of secondary electron multipliers, can cause discharges and degradation of signal-to-noise ratio. Ions generated by electron ionization are converted into electrons and multiplied by the secondary multiplier. The generation of ion feedback cannot be suppressed under low vacuum due to the presence of neutralization gas in SEM.
MCPs are powerful to detect secondary and backscattered electrons in SEM, but the challenge is stable operation under low vacuum conditions. Therefore, we have developed a novel detector structure that maintains the advantages of MCPs even under low vacuum conditions. In particular, its specific structure has proven to reduce ion feedback . Instead of using a bi-planar structure, as is the case in conventional MCP detectors, a triode structure is adopted. When a novel electric field configuration is applied to the electrodes, the triode structure can effectively suppress ion feedback even under low vacuum conditions.

Methods
The mechanism of ion feedback was investigated, when residual gas ions are generated by reactions between the residual gas and secondary electrons from the MCP channels. The ions (ionized residual gases) are accelerated by the electric field towards the MCP. If they can gain enough energy to release secondary electrons as they impinge on the channel walls, a second electron avalanche will be initiated. These “false” after-pulses would not only disturb the measurement, but could also ultimately lead to a permanent glow discharge. After-pulses appear several tens of nanoseconds after the "original" output signal, occur repeatedly and sometimes become even larger compared to the original signal. Considering the collision probability of electrons and gas molecules, ion feedback is likely to disturb the output signal, when MCPs are operated at a higher gain, or when increasing the input signal to the MCP.
It is found that residual gas ions causing ion feedback occur between MCP and anode, rather than inside the MCP channels. We concluded that controlling ions is more important than suppressing ion generation. Therefore, a triode-type detector structure was developed, in which a mesh anode was placed between MCPs and a dynode. It is confirmed that the dynode prevents ion feedback by capturing residual gas ions.

Results

First, we examined the effect of the triode structure for operation under low vacuum conditions by using a first prototype detector, which was composed of chevron stack MCPs (dimeter of 14.5 mm), a mesh anode and a metal dynode, in a vacuum chamber. While adjusting the degree of vacuum in the chamber, the detector was operated in two voltage modes: standard potential mode, i.e., MCP-in < MCP-out < anode = dynode, and novel potential mode, i.e., MCP- in < dynode < MCP-out < anode. As a result, when the gain of detector is low, there is no difference between the two potential modes in high pressure operation up to 1 Pa with or without input signals. When the gain becomes higher (105), ion feedback occurs at 10-3 Pa in standard potential mode, even without input signals, but does not occur in novel potential mode up to 1 Pa. Hence, it is confirmed that MCP detectors are capable of high-pressure operation by adapting the triode structure with novel potential mode.
The second prototype detector is under development with a very compact size to optimize it for SEM. The detector can be simplified by setting MCP-in and dynode at the same potential, and it fits into confined space by having an outer diameter of 35 mm, a height of 3 mm and a center hole diameter of 6mm. Our target specification of the detector is to maintain a gain of 5×106 up to 1 Pa without generating ion feedback signal.

Solving the crystallographic phase problem by linearizing dynamical electron diffraction

Prof. Christoph Koch[1], Sam Fairman[1], Grigory Kornilov[1], Dr. Benedikt Haas[1], Dr. Niklas Delby[2]
[1]Humboldt-Universität zu Berlin, Dept. of Physics & Center for the Science of Materials Berlin, Berlin, Germany, [2]Bruker AXS (formerly Nion Co. R&D), Kirkland, USA

IM-06 (1), Lecture Theater 1, august 29, 2024, 14:00 - 16:00

Background and aims
In contrast to kinematical diffraction intensities, which are insensitive to the phases of structure factors, dynamical diffraction intensities, as observed in most electron diffraction patterns, encode sums of phases of structure factor triplets and higher order multiplets, i.e. sets of structure factors for which the sum of the corresponding reciprocal lattice vectors vanishes. The scattering matrix S(kt)n,m = [exp(iTA(kt)]n,m, which is given by the matrix exponential of the product of the wavelength-scaled specimen thickness T and the structure factor matrix A(kt), the diagonal of which depends on the incident beam tilt kt, can be expanded to a sum of monomials in the structure factors, as shown in eqn. (1) [1] with the C-coefficients given by expression (2) and examples by expressions (4). Having diffraction data for multiple angles of incidence for a tilt range of several tens of mrad along kx and ky [2] allows the T- and kt-dependent C-coefficients (eqns. (3) & (4)) to be different enough, so that the individual monomials can be determined. For thicker specimen, the expansion order q would be very high, so a stacking of layers with a limited expansion order is proposed.

Methods
Large-angle rocking-beam electron diffraction (LARBED) [2] is a technique which can be used to acquire 2D rocking curve information from nearly arbitrarily small areas of the specimen for beam tilt angles of up to +/- 100 mrad in both tilt dimensions, and more, if the specimen is tilted as well. The diffracted intensities for every beam tilt are then extracted from these 4D datasets and the corresponding coefficients computed according to expression (2) [3]. In order to limit the number of terms in the linear set of equations, only coefficients of significant amplitude should then be kept. An alternative approach which also works for thicker specimen, is to consider the crystalline sample to consist of many identical layers that are stacked on top of each other, use a very limited expansion order (q = 1 is sufficient – in that case we call the approximation first-order expansion stacked Bloch wave (FOESBW) see eqn. (4)), but consider the structure factors in each layer to be independent from one another. This makes the complex scattering amplitude then a linear function in the structure factors, and a solution may then be found by solving this system of equations under the constraint that the structure factors in all of the layers are as close to each other as possible.

Results
Figure (a) shows a simulated LARBED pattern of GaN (110) (thickness 10 nm, acc. voltage 200 kV, max. g-vector 20 1/nm, as indicated by the white dash-dotted circle) on a logarithmic scale. The green dashed circle indicates the tilt range of the illumination during the LARBED simulation. Fig. (b) shows the central part of the diffraction pattern on a linear scale. The geometry of the representation of the LARBED dataset is illustrated by highlighting that the scale of the LARBED discs is 10 times larger than that of the distance between discs (descan = 0.9 [2]). Fig. (c) shows the structure of GaN in the (110) zone axis (1 x 2 unit cells are being displayed). Fig. (d) shows the original

crystal potential simulated using independent atom scattering factors. Fig. (e) shows the crystal potential resulting from all 194 structure factors that have been reconstructed using the FOESBW approach. Fig. (f) shows a bandwidth-limited potential resulting from a set of structure factors that was refined from the FOESBW-reconstruction using a simplex optimization of the full scattering matrix. The potential has been bandwidth limited to the resolution of the diffraction data (20 1/nm). All three potential maps are displayed using the same color map and -range. While these simulated results have also been presented in [3], we will also demonstrate the application to experimental data of various structures acquired using the Nion HERMES equipped with a Dectris ELA detector [4].

Poster Group 2

Background
Nickel oxide (NiO) is a wide-band gap p-type oxide semiconductor with good optical transparency and high chemical stability [1, 2]. These properties have been exploited for applications in photovoltaics and light-emitting diodes as a hole-transporting layer [1, 2]. Doping NiO with other metal elements, such as Cu, is an effective way to adjust its grain size, crystallinity, transmittance, and ultimately its conductivity for wider use in optoelectronic devices [2-4]. Polycrystalline Cu-doped NiO films have been fabricated with different techniques using mainly glass substrates. However, studies on single-crystal thin films are lacking, even though they are fundamental to understanding the interplay between structure and functionality of doped NiO films. In this work, we have employed electron microscopy methods in conjunction with photon spectroscopies to gain insight into the role of Cu concentration on the structural, optical, and electronic properties of NiO films grown by Molecular Beam Epitaxy (MBE) as a function of doping/alloying concentrations.

Methods
A series of Ni1-xCuxO thin films with five different Cu nominal concentrations (x = 0, 3, 6, 10, 24, and 42 at.%) were grown on (001)-oriented MgO substrates by MBE. The structural, optical, and electronic properties of the grown films were characterised by in-situ reflection high-energy electron diffraction (RHEED), X-ray diffraction (XRD), ultraviolet-visible spectroscopy (UV-Vis), energy dispersive x-ray spectroscopy (EDX), X-ray photoemission spectra (XPS), atomic force microscopy (AFM), scanning transmission electron microscopy (STEM), electron energy loss spectroscopy (EELS), and current-voltage (I-V) and hot probe measurements.

Results
The in-situ RHEED analysis of the grown films shows the presence of diffraction spots along modulated RHEED streaks for undoped and 3 at.% Cu-doped NiO (indicative of layer-by-layer growth) and distinctive transmission spots (indicative of 3D island growth) for higher Cu concentration doping, with segregation of the Cu metallic phase as the Cu content reaches 10 at.%. XRD results and diffractogram patterns from cross-sectional HAADF-STEM images show the structure of the grown films remains a single crystal cubic with [001] as the preferred growth orientation, with polycrystallinity developing as Cu content exceeds 10 at.%, with observation of the Cu metallic phase in 42% Cu:NiO films (Figure 1a–c). An increase in Cu concentration also results in increased surface roughness, as confirmed by AFM and cross-sectional HAADF-STEM images. The STEM-EDX maps show a uniform distribution of the Cu in 3 at.% Cu-doped NiO film, Cu ions are likely to be substituted for Ni ions, and a segregation of Cu grains as Cu concentration increases (Figure 1d-f), which is further confirmation of Cu-phase segregation. The correlation between EELS and XPS indicates the

existence of a mixture of oxidation states of Cu (Cu0, Cu+, and Cu2+) up to 10 at.% of Cu, with Cu0 becoming dominant as its concentration increases. The UV-vis absorption spectra show that an increase in Cu content results in a redshift of the absorption edges, leading to a decrease in the band gap of the grown films as Cu concentrations increase. The band gap measurements by EELS were correlated to UV-VIS measurements and were found to be in good agreement. The electrical measurements show the conductivity of NiO films increases from 2.8×10^-5 (Ω.cm)^-1 for un-doped NiO thin film and reaches the highest value of 4.1×10^-1 (Ω.cm)^-1 for NiO film with 42 at.% Cu.

Conclusion
Undoped NiO and low Cu-doped NiO films are grown as a single crystal film, and as Cu exceeds 10 at.%, it starts segregation and forms secondary phases within the NiO film. The Cu doping increases the surface roughness, as confirmed by RHEED, AFM, and STEM. The band gap of the grown films decreases as a function of Cu concentration. The characterization techniques indicate that at the lowest Cu concentration (3 at.%), Cu ions seem to be substituted for Ni ions, and as Cu concentrations increase, Cu likely starts segregating and forming Cu grains within the films. Cu phase segregation is very likely responsible for the conductivity transition from p-type to n-type properties of NiO film with increasing Cu concentrations. This result could open the door for new applications where Cu-doped NiO can be applied as p-type, n-type, or both layers in the same devices.

From DNA Nanotechnology to biomedical insight: Towards single-molecule spatial omics

Prof. Dr. Ralf Jungmann[1]
[1]Max Planck Institute of Biochemistry, Martinsried, Germany, [2]LMU Munich, Munich, Germany

LS-03 (1), Lecture Theater 4, august 26, 2024, 15:00 - 16:00

Super-resolution fluorescence microscopy is a powerful tool for biophysical and biological research. The transient binding of short fluorescently labeled oligonucleotides (DNA-PAINT) can be leveraged for easy-to-implement multiplexed super-resolution imaging that achieves molecular-scale resolution across large fields of view. This seminar will introduce recent technical advancements in DNA-PAINT including approaches that achieve sub-10-nm spatial resolution and spectrally unlimited multiplexing in whole cells followed by recent developments in novel protein labeling probes such as Slow Off-rate Modified Aptamers (SOMAmers), that have the potential to facilitate DNA-barcoded labeling of much of the proteome within intact cellular environments. Applications of these new approaches will be discussed in cell surface receptor imaging and neuroscience. Visualization and quantification of cell surface receptors at thus far elusive spatial resolutions and levels of multiplexing yield fundamental insights into the molecular architecture of surface receptor interactions thus enabling the future development of more refined “pattern”-based therapeutics. A key approach in implementing these methods has been to leverage standard off-the-shelf fluorescence microscopy hardware as a tool for spatial omics, thus democratizing the ability to visualize most biomolecules and probe their network-wide interactions in single cells, tissues, and beyond with single-molecule-based "Localizomics".

Band gap shifts in Ga-doped ZnO using momentum-resolved EELS

Cana Elgvin[1], Dario A. Leon[2], Phuong D. Nguyen[1], Fredrik S. Hage[1], Kristian Berland[2], Øystein Prytz[1]
[1]Department of Physics, University of Oslo, Oslo, Norway, [2]Norwegian University of Life Sciences (NMBU), Ås, Norway

Poster Group 2

Band gap tuning is central to semiconductor research, and is typically done by doping, which in essence alters the material's band structure. Transparent conductive oxides (TCOs) are renowned for their high optical transmittance combined with low electrical resistivity, usually achieved via high doping (~10^{20} /cm^3) to fill the conduction band with charge carriers. This process leads to a widening of the optical band gap: an effect known as the Burstein-Moss (BM) shift (1-3). Conversely, a competing phenomenon known as band gap narrowing (BGN) is also present above a critical carrier density, due to band renormalization (4). While the BM shift and BGN have been studied in the optical limit ($q \rightarrow 0$) , reports on their momentum dependencies are lacking in literature. We use momentum-resolved electron energy loss spectroscopy (q-EELS) to study how the band gap signal in both doped and undoped ZnO evolves with transferred momentum. We show that doping induces a distinct modification of the momentum dependent EEL band gap signal. This result is discussed in terms of the competing effects of the BM shift and BGN.

The experiments were done on a monochromated FEI Titan G2 60-300 kV at 60 kV, equipped with a Gatan 965 GIF. q-EEL spectra were acquired by a nanoprobe with a convergence angle of $\alpha = 0.27$ mrad, with a corresponding diffraction-limited ~ 4 nm probe size. A rectangular spectrometer entrance slit was inserted in the diffraction plane selecting primarily for momentum transfers perpendicular to the energy dispersive direction. Post specimen lens rotation was set to allow for high-symmetry directions of the Brillouin zone to be admitted by the rectangular spectrometer selection slit, here the ΓM direction. Two samples were studied: the first is a thin film of Ga-doped ZnO (GZO) grown on a sapphire substrate using molecular beam epitaxy. This film displays a polycrystalline structure and a charge carrier concentration of $1 \cdot 10^{21}$ /cm^3, determined through Hall-effect measurements. The second sample is a purchased single crystal ZnO substrate with a purity level of at least 99.99%.

q-EEL spectra of the undoped and doped ZnO are shown in Fig. 1a. We track the band gap signal energy by a parabolic fit (5) and as a function of momentum transfer (see Fig. 1b). At the optical limit (within experimental momentum resolution), the band gap signals of ZnO and GZO is determined to be 3.22 eV and 3.74 eV, respectively. The difference in these values is 0.52 eV, clearly showing the effects of BGN and the BM shift. At $q > 0$, the GZO band gap follows a shallow dispersion curve, gradually approaching the curve of the non-doped ZnO, to coincide at $q \geq 0.65$ 1/Å . Hence, our results suggest that the GZO conduction band is unaffected by doping beyond this q-value (at least within experimental uncertainty). If assuming a simplistic model wherein we have an unaltered ZnO band structure with an elevated Fermi level, the conduction bands of GZO and ZnO would be expected to be the same at $k > 0.3$ 1/Å. This approach alone clearly does not agree with our experiments. We suggest that a deviation of the band topology of GZO from that of ZnO contributes significantly to the difference between that predicted by this simplistic approach and our experimental observations. The roles of the BM and BGN effects will be discussed for finite

momentum transfers, as will insights gained with respect to dopant-induced band structure modifications of the ZnO-GZO system.

We demonstrate and discuss how q-EELS can be used for investigating the influence of doping of the finite q response of ZnO. This approach holds promise for probing the electro-optical response of various technologically important materials, with potential applications in solar cells, transistors, light emitters, and beyond.

Figure 1: (a) Electron-energy loss edges of ZnO and GZO at q → 0, after background-subtraction. (b) Band gap signals for ZnO and GZO as a function of q, obtained by q-EELS and extracted by fitting as in (a).

Zorya is a recently identified and widely distributed bacterial immune system, which protects against phage invasion. It consists of a predicted membrane-embedded complex (ZorAB) and soluble components that differ among Zorya subtypes, notably ZorC and ZorD, in type I Zorya systems. Here, we reveal the molecular basis of the Zorya defense system using cryo-electron microscopy, mutagenesis, fluorescence microscopy, proteomics, and functional studies. We demonstrate that ZorAB shares the stoichiometry of other 5:2 inner membrane ion-driven rotary motors. Additionally, ZorA5B2 features a dimeric ZorB peptidoglycan binding domain and a pentameric α-helical coiled-coil tail made of ZorA that projects approximately 700 Å into the cytoplasm. We further characterize the structure and function of the soluble Zorya components, ZorC and ZorD, and find that they harbour DNA binding and nuclease activity, respectively. Comprehensive functional and mutational analyses demonstrates that all Zorya components work in concert to protect bacterial cells against invading phages. We present evidence that ZorAB operates as an ion-driven motor that becomes activated and anchors to the cell wall upon sensing of cell envelope perturbations during phage invasion. Subsequently, ZorAB transfers the phage invasion signal through the ZorA cytoplasmic tail to the soluble effectors, which function to prevent phage propagation. In summary, our study elucidates the foundational mechanisms of Zorya function and reveals a novel triggering signal for the rapid activation of an anti-phage defense system.
